In a subsequent study, Tam and Ghajar (1998) experimentally investigated the behavior of local heat transfer coefficients in the transition region for a tube with a bell-mouth inlet. This type of inlet is used in some heat exchangers mainly to avoid the presence of eddies, which are believed to be one of the causes for erosion in the tube inlet region. For the bell-mouth inlet, the variation of the local heat transfer coefficient with length in the transition and turbulent flow regions is very unusual. For this inlet geometry, the boundary layer along the tube wall is at first laminar and then changes through a transition to the turbulent condition, causing a dip in the  $Nu$  versus  $x/D$  curve. In their experiments with a fixed inside diameter of 15.84 mm, the length of the dip in the transition region was much longer ( $100 < x/D < 175$ ) than in the turbulent region ( $x/D < 25$ ). The presence of the dip in the transition region causes a significant influence in both the local and the average heat transfer coefficients. This is particularly important for heat transfer calculations in short tube heat exchangers with a bell-mouth inlet. Figure 8–39 on the next page shows the variation of local Nusselt number along the tube length in the transition region for the three inlet configurations at comparable Reynolds numbers.

As mentioned earlier finned tubes (Fig. 8–30) enhance convection heat transfer. Single-phase liquid flow in internally enhanced tubes is becoming more important in commercial heating, ventilating, and air conditioning (HVAC) applications. One kind of internally enhanced tube is the spiral micro-fin tube (Fig. 8–40 on the next page). The tube side roughening increases heat transfer surface area, resulting in high-efficiency heat exchangers. The increase in the surface area causes low flow rates in the heat exchanger tubes, resulting in the flow to be at Reynolds numbers that are between laminar and turbulent, that is, in the transition region. Owing to the high efficiency requirements, it is likely that more HVAC units will

**FIGURE 8–38**

Influence of different inlets on the heat transfer transition region at  $x/D = 192$  (filled symbols designate the start and end of the transition region for each inlet) between limits of Dittus–Boelter correlation ( $Nu = 0.023 Re^{0.8} Pr^n$ ) for fully developed turbulent flow (using  $n = 1/3$  for heating) and  $Nu = 4.364$  for fully developed laminar flow with a uniform heat flux boundary condition. Note buoyancy effect on the laminar flow data, giving the much larger mixed convection heat transfer coefficient.

(a) Sectional view of the micro-fin tube; (b) The plain and micro-fin tubes.

Reprinted from "Experimental Investigation of Heat Transfer, Friction Factor, and Optimal Fin Geometries For The Internally Microfin Tubes In The Transition and Turbulent Regions" by : H. K. Tam, L. M. Tam, A. J. Ghajar, S. C. Tam, and T. Zhang in Journal of Enhanced Heat Transfer, Vol. 19, No. 5 (2012), pp. 457-476 with permission from Begell House, Inc.

operate in the transition region where the understanding of the pressure drop and heat transfer is limited. To respond to some of these challenges, Ghajar and coworkers extended their plain tube studies presented earlier to finned tubes. They conducted pressure drop (friction factor) and heat transfer experiments in the transition region in three different micro-fin tubes and a plain tube with square-edged and re-entrant inlets [Tam et al. (2012)]. Table 8-10 shows the specifications of the plain and micro-fin tubes used in the studies of Tam et al. (2012).

Figure 8-41 represents the fully developed friction factor characteristics for the plain and different spiral-angle micro-fin tubes and different inlet configurations under the isothermal boundary condition. The plain tube behavior is similar to what was presented earlier (Fig. 8-37). However, for all the micro-fin tubes a parallel shift from the classical laminar equation ( $C_{f,\text{lam}} = 16/\text{Re}$ ) is observed regardless of the fin geometry and the type of inlet. In the transition region, it can be observed that the transition range of the micro-fin tubes is much wider than the plain tube transition range. The friction factor for all the micro-fin tubes goes through a steep increase followed by a relatively constant  $C_f$  section and then a parallel shift from the classical Blasius turbulent friction factor correlation ( $C_{f,\text{turb}} = 0.0791 \text{ Re}^{-0.25}$ ). For the end of the transition for micro-fin tube, it is defined as the first point where the friction factor data become parallel to the Blasius correlation. Beyond

TABLE 8-10

Specifications of the test tubes

| Tube Type         | Outer dia., $D_o$ (mm) | Inner dia., $D_i$ (mm) | Spiral angle, $\alpha$ | Fin height, $\epsilon$ (mm) | Number of starts, $N_s$ |
|-------------------|------------------------|------------------------|------------------------|-----------------------------|-------------------------|
| Plain tube        | 15.9                   | 14.9                   | —                      | —                           | —                       |
| Micro-fin tube #1 | 15.9                   | 14.9                   | 18°                    | 0.5                         | 25                      |
| Micro-fin tube #2 | 15.9                   | 14.9                   | 25°                    | 0.5                         | 25                      |
| Micro-fin tube #3 | 15.9                   | 14.9                   | 35°                    | 0.5                         | 25                      |

this point, the flow is considered turbulent. With a higher spiral angle in the micro-fin tube, the increase of friction factor can be observed in the transition and turbulent regions. The increase in the friction factor is caused by the stronger drag due to the larger spiral angle on the tube wall. From Fig. 8-41, it can be observed that the start of transition is inlet and spiral angle dependent. For all the micro-fin tubes, the square-edged inlet delays the start of transition. The micro-fin tube #3 with a larger spiral angle has an earlier start of transition. Moreover, it is also observed that a larger spiral angle in the micro-fin tube advances the end of transition for both inlet configurations.

Figure 8-42 shows the heat transfer behavior in the upper transition region for the plain and micro-fin tubes is very different. For the plain tube, the heat transfer initially experienced an abrupt change in the lower transition region; this was followed by a moderate change in the upper transition and finally the transition ended and the heat transfer data followed the Sieder and Tate correlation (1936) at Reynolds number around 8000. The plain tube behavior is similar to what was presented earlier (Fig. 8-38). However, for the micro-fin tube, such characteristic cannot be seen and the abrupt change was observed in the entire transition region. When Reynolds number is around 8000, a parallel shift of heat transfer data from the Sieder and Tate equation was observed. This increase in the Colburn  $j$  factor ( $j_H = St Pr^{0.67}$ ) and the parallel shift from the Sieder and Tate correlation in the turbulent region is due to the swirling motion induced by the micro-fin. The larger spiral angle leads to a higher Colburn  $j$  factor. It is because the larger spiral angle increases the fluid mixing between the bulk fluid and the tube wall and therefore the heat transfer is enhanced. Regarding to the start and end of transition of heat transfer, it can be observed from Fig. 8-42 that the start of transition is defined as the critical point for the sudden change from the laminar region (the line parallel to  $Nu = 4.364$ ) to the transition region. For the end of the transition for micro-fin tube, it is defined as the first point where the heat transfer data landed on a line parallel to the correlation proposed by Sieder and Tate (1936). As seen from Fig. 8-42, for the heat transfer, the transition is inlet dependent and the start and end of transition is spiral angle dependent. The delay of transition is obvious for smaller spiral angles while the early transition occurred when larger spiral angle tubes were used.

### EXAMPLE 8-9 Heat Transfer in the Transition Region

Ethylene glycol-distilled water mixture with a mass fraction of 0.6 and a flow rate of  $2.6 \times 10^{-4} \text{ m}^3/\text{s}$  flows inside a tube with an inside diameter of 0.0158 m subjected to uniform wall heat flux. For this flow, determine the Nusselt number at the location  $x/D = 90$  if the inlet configuration of the tube is: (a) re-entrant, (b) square-edged, and (c) bell-mouth. At this location, the local Grashof number is  $Gr = 51,770$ . The properties of ethylene glycol-distilled water mixture at the location of interest are  $Pr = 29.2$ ,  $\nu = 3.12 \times 10^{-6} \text{ m}^2/\text{s}$  and  $\mu_b/\mu_s = 1.77$ .

**SOLUTION** A liquid mixture flowing in a tube is subjected to uniform wall heat flux. The Nusselt number at a specified location is to be determined for three different tube inlet configurations.

**Assumptions** Steady operating conditions exist.

FIGURE 8-41

Fully developed friction factor characteristics for the plain and micro-fin tubes under isothermal boundary condition.

From Tam et al., 2012.

FIGURE 8-42

Fully developed heat transfer characteristics for the plain and micro-fin tubes under uniform wall heat flux boundary condition.

From Tam et al., 2012.

**Properties** The properties of the ethylene glycol-distilled water mixture are given to be  $\text{Pr} = 29.2$ ,  $\nu = 3.12 \times 10^{-6} \text{ m}^2/\text{s}$ , and  $\mu_b/\mu_s = 1.77$ .

**Analysis** For a tube with a known diameter and volume flow rate, the type of flow regime is determined before making any decision regarding which Nusselt number correlation to use. The Reynolds number at the specified location is

$$\text{Re} = \frac{(\dot{V}/A_c)D}{\nu} = \frac{[(2.6 \times 10^{-4} \text{ m}^3/\text{s})(1.961 \times 10^{-4} \text{ m}^2)](0.0158 \text{ m})}{3.12 \times 10^{-6} \text{ m}^2/\text{s}} = 6714$$

since

$$A_c = \pi D^2/4 = \pi(0.0158 \text{ m})^2/4 = 1.961 \times 10^{-4} \text{ m}^2$$

Therefore, the flow regime is in the transition region for all three inlet configurations (thus use the information given in Table 8–9 with  $x/D = 90$ ), and therefore Eq. 8–87 should be used with the constants  $a$ ,  $b$ ,  $c$  found in Table 8–8. However,  $\text{Nu}_{\text{lam}}$  and  $\text{Nu}_{\text{turb}}$  are the inputs to Eq. 8–87, and they need to be evaluated first from Eqs. 8–88 and 8–89, respectively. It should be mentioned that the correlations for  $\text{Nu}_{\text{lam}}$  and  $\text{Nu}_{\text{turb}}$  have no inlet dependency. From Eq. 8–88:

$$\begin{aligned}\text{Nu}_{\text{lam}} &= 1.24 \left[ \left( \frac{\text{RePr}D}{x} \right) + 0.025(\text{GrPr})^{0.75} \right]^{1/3} \left( \frac{\mu_b}{\mu_s} \right)^{0.14} \\ &= 1.24 \left[ \left( \frac{(6714)(29.2)}{90} \right) + 0.025[(51,770)(29.2)]^{0.75} \right]^{1/3} (1.77)^{0.14} = 19.9\end{aligned}$$

From Eq. 8–89:

$$\begin{aligned}\text{Nu}_{\text{turb}} &= 0.023\text{Re}^{0.8}\text{Pr}^{0.385} \left( \frac{x}{D} \right)^{-0.0054} \left( \frac{\mu_b}{\mu_s} \right)^{0.14} \\ &= 0.023(6714)^{0.8}(29.2)^{0.385}(90)^{-0.0054}(1.77)^{0.14} = 102.7\end{aligned}$$

Then the transition Nusselt number can be determined from Eq. 8–87,

$$\text{Nu}_{\text{trans}} = \text{Nu}_{\text{lam}} + \{ \exp[(a - \text{Re})/b] + \text{Nu}_{\text{turb}}^c \}^c$$

Case 1: For re-entrant inlet:

$$\text{Nu}_{\text{trans}} = 19.9 + \{ \exp[(1766 - 6714)/276] + 102.7^{-0.955} \}^{-0.955} = 88.2$$

Case 2: For square-edged inlet:

$$\text{Nu}_{\text{trans}} = 19.9 + \{ \exp[(2617 - 6714)/207] + 102.7^{-0.950} \}^{-0.950} = 85.3$$

Case 3: For bell-mouth inlet:

$$\text{Nu}_{\text{trans}} = 19.9 + \{ \exp[(6628 - 6714)/237] + 102.7^{-0.980} \}^{-0.980} = 21.3$$

**Discussion** It is worth mentioning that, for the re-entrant and square-edged inlets, the flow behaves normally. For the bell-mouth inlet, the Nusselt number is low in comparison to the other two inlets. This is because of the unusual behavior of the bell-mouth inlet noted earlier (see Fig. 8–39); i.e., the boundary layer along the tube wall is at first laminar and then changes through a transition region to the turbulent condition.

**TABLE 8–11**

Summary of transition Reynolds number ranges for various stainless steel tube sizes  
(From Ghajar et al., 2010.)

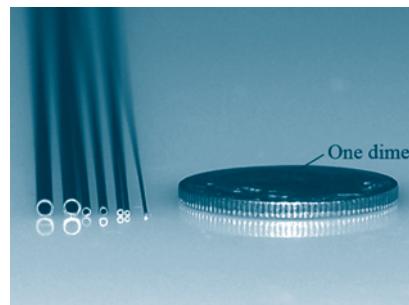

| Tube I.D. [μm] | Transition range   | Tube I.D. [μm] | Transition range   |
|----------------|--------------------|----------------|--------------------|
| 2083           | $1500 < Re < 4000$ | 732            | $2200 < Re < 3000$ |
| 1600           | $1700 < Re < 4000$ | 667            | $2200 < Re < 3000$ |
| 1372           | $1900 < Re < 4000$ | 559            | $1900 < Re < 2500$ |
| 1067           | $2000 < Re < 4000$ | 508            | $1700 < Re < 2100$ |
| 991            | $2000 < Re < 4000$ | 413            | $1500 < Re < 1900$ |
| 838            | $2200 < Re < 4000$ | 337            | $1300 < Re < 1700$ |

## Pressure Drop in the Transition Region in Mini and Micro Tubes

Due to rapid advancement in fabrication techniques, the miniaturization of devices and components is ever increasing in many applications. Whether it is in the application of miniature heat exchangers, fuel cells, pumps, compressors, turbines, sensors, or artificial blood vessels, a sound understanding of fluid flow in micro-scale channels and tubes is required. To better understand the flow behavior in small tubes, Ghajar and coworkers extended their isothermal transitional pressure drop studies in standard size tubes to mini and microtubes. They performed a systematic and careful experimental study of friction factor in the transition region for single-phase water flow in 12 stainless steel tubes with diameters ranging from 2083 μm to 337 μm (Fig. 8–43). The pressure-drop measurements were carefully performed by paying particular attention to the sensitivity of the pressure-sensing diaphragms used in the pressure transducer. Experimental results indicated that the start and end of the transition region were influenced by the tube diameter (Table 8–11). The friction factor profile was not significantly affected for the tube diameters between 2083 μm and 1372 μm (Fig. 8–44). However, the influence of the tube diameter on the friction factor profile became noticeable as the diameter decreased from 838 μm to 337 μm (Fig. 8–45). The Reynolds number range for transition flow became narrower with decreasing tube diameter (Table 8–11). The results show that decrease in tube diameter and increase in relative roughness ( $\epsilon/D$ ), which is approximately within the range of  $0.01 < \epsilon/D < 0.04$ , influence the friction factor, even in the laminar region. In addition, these factors cause the onset of transition from laminar flow to occur at lower Reynolds numbers.

## SUMMARY

*Internal flow* is characterized by the fluid being completely confined by the inner surfaces of the tube. The mean or average velocity and temperature for a circular tube of radius  $R$  are expressed as

$$V_{\text{avg}} = \frac{2}{R^2} \int_0^R u(r) r dr \quad \text{and} \quad T_m = \frac{2}{V_{\text{avg}} R^2} \int_0^R u(r) T(r) r dr$$

The Reynolds number for internal flow and the hydraulic diameter are defined as

$$\text{Re} = \frac{\rho V_{\text{avg}} D}{\mu} = \frac{V_{\text{avg}} D}{\nu} \quad \text{and} \quad D_h = \frac{4A_c}{p}$$

The flow in a tube is laminar for  $\text{Re} < 2300$ , turbulent for about  $\text{Re} > 10,000$ , and transitional in between.

The length of the region from the tube inlet to the point at which the flow becomes fully developed is the *hydrodynamic entry length*  $L_h$ . The region beyond the entrance region in which the velocity profile is fully developed is the *hydrodynamically fully developed region*. The length of the region of flow over

which the thermal boundary layer develops and reaches the tube center is the *thermal entry length*  $L_t$ . The region in which the flow is both hydrodynamically and thermally developed is the *fully developed flow region*. The entry lengths are given by

$$L_{h, \text{laminar}} \approx 0.05 \text{ Re } D$$

$$L_{t, \text{laminar}} \approx 0.05 \text{ Re Pr } D = \text{Pr } L_{h, \text{laminar}}$$

$$L_{h, \text{turbulent}} \approx L_{t, \text{turbulent}} = 10D$$

For  $\dot{q}_s = \text{constant}$ , the rate of heat transfer is expressed as

$$\dot{Q} = \dot{q}_s A_s = \dot{m} c_p (T_e - T_i)$$

For  $T_s = \text{constant}$ , we have

$$\dot{Q} = h A_s \Delta T_{\text{lm}} = \dot{m} c_p (T_e - T_i)$$

$$T_e = T_s - (T_s - T_i) \exp(-h A_s / \dot{m} c_p)$$

$$\Delta T_{\text{lm}} = \frac{T_i - T_e}{\ln[(T_s - T_e)/(T_s - T_i)]} = \frac{\Delta T_e - \Delta T_i}{\ln(\Delta T_e / \Delta T_i)}$$

The irreversible pressure loss due to frictional effects and the required pumping power to overcome this loss for a volume flow rate of  $\dot{V}$  are

$$\Delta P_L = f \frac{L}{D} \frac{\rho V_{\text{avg}}^2}{2} \quad \text{and} \quad \dot{W}_{\text{pump}} = \dot{V} \Delta P_L$$

For *fully developed laminar flow* in a circular pipe, we have:

$$u(r) = 2V_{\text{avg}} \left(1 - \frac{r^2}{R^2}\right) = u_{\max} \left(1 - \frac{r^2}{R^2}\right)$$

$$f = \frac{64\mu}{\rho DV_{\text{avg}}} = \frac{64}{Re}$$

$$\dot{V} = V_{\text{avg}} A_c = \frac{\Delta PR^2}{8\mu L} \pi R^2 = \frac{\pi R^4 \Delta P}{8\mu L} = \frac{\pi R^4 \Delta P}{128\mu L}$$

$$\text{Circular tube, laminar } (\dot{q}_s = \text{constant}): \text{Nu} = \frac{hD}{k} = 4.36$$

$$\text{Circular tube, laminar } (T_s = \text{constant}): \text{Nu} = \frac{hD}{k} = 3.66$$

For *developing laminar flow* in the entrance region with constant surface temperature, we have

$$\text{Circular tube: } \text{Nu} = 3.66 + \frac{0.065(D/L) \text{ Re Pr}}{1 + 0.04[(D/L) \text{ Re Pr}]^{2/3}}$$

$$\text{Circular tube: } \text{Nu} = 1.86 \left(\frac{\text{Re Pr } D}{L}\right)^{1/3} \left(\frac{\mu_b}{\mu_s}\right)^{0.14}$$

$$\text{Parallel plates: } \text{Nu} = 7.54 + \frac{0.03(D_h/L) \text{ Re Pr}}{1 + 0.016[(D_h/L) \text{ Re Pr}]^{2/3}}$$

For *fully developed turbulent flow with smooth surfaces*, we have

$$f = (0.790 \ln \text{Re} - 1.64)^{-2} \quad 10^4 < \text{Re} < 10^6$$

$$\text{Nu} = 0.125f \text{ Re Pr}^{1/3}$$

$$\text{Nu} = 0.023 \text{ Re}^{0.8} \text{ Pr}^{1/3} \begin{cases} (0.7 \leq \text{Pr} \leq 160) \\ (\text{Re} > 10,000) \end{cases}$$

$$\text{Nu} = 0.023 \text{ Re}^{0.8} \text{ Pr}^n \text{ with } n = 0.4 \text{ for heating and } 0.3 \text{ for cooling of fluid}$$

$$\text{Nu} = \frac{(f/8)(\text{Re} - 1000) \text{ Pr}}{1 + 12.7(f/8)^{0.5} (\text{Pr}^{2/3} - 1)} \begin{cases} (0.5 \leq \text{Pr} \leq 2000) \\ (3 \times 10^3 < \text{Re} < 5 \times 10^6) \end{cases}$$

The fluid properties are evaluated at the *bulk mean fluid temperature*  $T_b = (T_i + T_e)/2$ . For liquid metal flow in the range of  $10^4 < \text{Re} < 10^6$  we have:

$$T_s = \text{constant: } \text{Nu} = 4.8 + 0.0156 \text{ Re}^{0.85} \text{ Pr}_s^{0.93}$$

$$\dot{q}_s = \text{constant: } \text{Nu} = 6.3 + 0.0167 \text{ Re}^{0.85} \text{ Pr}_s^{0.93}$$

For *fully developed turbulent flow with rough surfaces*, the friction factor  $f$  is determined from the Moody chart or

$$\frac{1}{\sqrt{f}} = -2.0 \log \left( \frac{\varepsilon/D}{3.7} + \frac{2.51}{\text{Re} \sqrt{f}} \right) \approx -1.8 \log \left[ \frac{6.9}{\text{Re}} + \left( \frac{\varepsilon/D}{3.7} \right)^{1.11} \right]$$

For a *concentric annulus*, the hydraulic diameter is  $D_h = D_o - D_p$  and the Nusselt numbers are expressed as

$$\text{Nu}_i = \frac{h_i D_h}{k} \quad \text{and} \quad \text{Nu}_o = \frac{h_o D_h}{k}$$

where the values for the Nusselt numbers are given in Table 8–4.

## PROBLEMS\*

### General Flow Analysis

**8-1C** Which fluid at room temperature requires a larger pump to move at a specified velocity in a given tube: water or engine oil? Why?

**8-2C** What do the average velocity  $V_{\text{avg}}$  and the mean temperature  $T_m$  represent in flow through circular tubes of constant diameter?

**8-3C** What is the generally accepted value of the Reynolds number above which the flow in smooth pipes is turbulent?

\*Problems designated by a "C" are concept questions, and students are encouraged to answer them all. Problems designated by an "E" are in English units, and the SI users can ignore them. Problems with the icon are solved using EES, and complete solutions together with parametric studies are included on the text website. Problems with the icon are comprehensive in nature, and are intended to be solved with an equation solver such as EES. Problems with the icon are Prevention through Design problems.

**8-4C** What is hydraulic diameter? How is it defined? What is it equal to for a circular tube of diameter  $D$ ?

**8-5C** What fluid property is responsible for the development of the velocity boundary layer? For what kinds of fluids will there be no velocity boundary layer in a pipe?

**8-6C** In the fully developed region of flow in a circular tube, will the velocity profile change in the flow direction? How about the temperature profile?

**8-7C** Consider laminar flow in a circular tube. Will the friction factor be higher near the inlet of the tube or near the exit? Why? What would your response be if the flow were turbulent?

**8-8C** How does the friction factor  $f$  vary along the flow direction in the fully developed region in (a) laminar flow and (b) turbulent flow?

**8-9C** How does surface roughness affect the pressure drop in a tube if the flow is turbulent? What would your response be if the flow were laminar?

**8–10C** How is the hydrodynamic entry length defined for flow in a tube? Is the entry length longer in laminar or turbulent flow?

**8–11C** Consider the flow of oil in a tube. How will the hydrodynamic and thermal entry lengths compare if the flow is laminar? How would they compare if the flow were turbulent?

**8–12C** Consider the flow of mercury (a liquid metal) in a tube. How will the hydrodynamic and thermal entry lengths compare if the flow is laminar? How would they compare if the flow were turbulent?

**8–13C** How is the thermal entry length defined for flow in a tube? In what region is the flow in a tube fully developed?

**8–14C** Consider laminar forced convection in a circular tube. Will the heat flux be higher near the inlet of the tube or near the exit? Why?

**8–15C** Consider turbulent forced convection in a circular tube. Will the heat flux be higher near the inlet of the tube or near the exit? Why?

**8–16C** What does the logarithmic mean temperature difference represent for flow in a tube whose surface temperature is constant? Why do we use the logarithmic mean temperature instead of the arithmetic mean temperature?

**8–17C** Consider fluid flow in a tube whose surface temperature remains constant. What is the appropriate temperature difference for use in Newton's law of cooling with an average heat transfer coefficient?

**8–18C** What is the physical significance of the number of transfer units  $NTU = hA_s/mC_p$ ? What do small and large NTU values tell about a heat transfer system?

**8–19** Consider the velocity and temperature profiles for a fluid flow in a tube with diameter of 50 mm can be expressed as

$$u(r) = 0.05[(1 - (r/R)^2)]$$

$$T(r) = 400 + 80(r/R)^2 - 30(r/R)^3$$

with units in m/s and K, respectively. Determine the average velocity and the mean (average) temperature from the given velocity and temperature profiles.

**8–20** Consider the velocity and temperature profiles for air-flow in a tube with diameter of 8 cm can be expressed as

$$u(r) = 0.2[(1 - (r/R)^2)]$$

$$T(r) = 250 + 200(r/R)^3$$

with units in m/s and K, respectively. If the convection heat transfer coefficient is 100 W/m<sup>2</sup>·K, determine the mass flow rate and surface heat flux using the given velocity and temperature profiles. Evaluate the air properties at 20°C and 1 atm.

**8–21** Air enters a 25-cm-diameter 12-m-long underwater duct at 50°C and 1 atm at a mean velocity of 7 m/s, and is cooled by the water outside. If the average heat transfer coefficient is 85 W/m<sup>2</sup>·K and the tube temperature is nearly equal to the water temperature of 10°C, determine the exit temperature of air and the rate of heat transfer. Evaluate air properties at a bulk mean temperature of 30°C. Is this a good assumption?

**8–22** Combustion gases passing through a 3-cm-internal-diameter circular tube are used to vaporize waste water at atmospheric pressure. Hot gases enter the tube at 115 kPa and 250°C at a mean velocity of 5 m/s, and leave at 150°C. If the average heat transfer coefficient is 120 W/m<sup>2</sup>·K and the inner surface temperature of the tube is 110°C, determine (a) the tube length and (b) the rate of evaporation of water.

**8–23** Repeat Prob. 8–22 for a heat transfer coefficient of 40 W/m<sup>2</sup>·K.

**8–24** Cooling water available at 10°C is used to condense steam at 30°C in the condenser of a power plant at a rate of 0.15 kg/s by circulating the cooling water through a bank of 5-m-long 1.2-cm-internal-diameter thin copper tubes. Water enters the tubes at a mean velocity of 4 m/s and leaves at a temperature of 24°C. The tubes are nearly isothermal at 30°C. Determine the average heat transfer coefficient between the water, the tubes, and the number of tubes needed to achieve the indicated heat transfer rate in the condenser.

**8–25** Repeat Prob. 8–24 for steam condensing at a rate of 0.60 kg/s.

**8–26**  Reconsider Prob. 8–24. Using the EES (or other) software, investigate the effect of the cooling water average (mean) velocity on the number of tubes needed to achieve the indicated heat transfer rate in the condenser. By varying the cooling water average velocity from 0.3 to 6 m/s, plot the number of tubes as a function of the water average velocity.

**8–27** Inside a condenser, there is a bank of seven copper tubes with cooling water flowing in them. Steam condenses at a rate of 0.6 kg/s on the outer surfaces of the tubes that are at a constant temperature of 68°C. Each copper tube is 5-m long and has an inner diameter of 25 mm. Cooling water enters each tube at 5°C and exits at 60°C. Determine the average heat transfer coefficient of the cooling water flowing inside each tube and the cooling water mean velocity needed to achieve the indicated heat transfer rate in the condenser.

FIGURE P8–27

**8–28**  Reconsider Prob. 8–27. Using the EES (or other) software, evaluate the effect of the cooling water mean velocity on the rate of steam condensation in the

condenser. By varying the cooling water mean velocity for  $0 < V_{\text{avg}} \leq 2 \text{ m/s}$ , plot the steam condensation rate as a function of the water mean velocity.

**8-29** In a gas-fired boiler, water is being boiled at  $120^\circ\text{C}$  by hot air flowing through a 5-m-long, 5-cm-diameter tube submerged in water. Hot air enters the tube at 1 atm and  $300^\circ\text{C}$  at a mean velocity of 7 m/s, and leaves at  $150^\circ\text{C}$ . If the surface temperature of the tube is  $120^\circ\text{C}$ , determine the average convection heat transfer coefficient of the air and the rate of water evaporation, in kg/h.

FIGURE P8-29

**8-30** Reconsider Prob. 8-29. Using the EES (or other) software, evaluate the effect of the tube length on the average convection heat transfer coefficient of air. By varying the tube length from 3 to 18 m, plot the average convection heat transfer coefficient as a function of the tube length.

#### Laminar and Turbulent Flow in Tubes

**8-31C** Someone claims that the volume flow rate in a circular pipe with laminar flow can be determined by measuring the velocity at the centerline in the fully developed region, multiplying it by the cross-sectional area, and dividing the result by 2. Do you agree? Explain.

**8-32C** Someone claims that the average velocity in a circular pipe in fully developed laminar flow can be determined by simply measuring the velocity at  $R/2$  (midway between the wall surface and the centerline). Do you agree? Explain.

**8-33C** How is the friction factor for flow in a tube related to the pressure drop? How is the pressure drop related to the pumping power requirement for a given mass flow rate?

**8-34C** Someone claims that in fully developed turbulent flow in a tube, the shear stress is a maximum at the tube surface. Do you agree with this claim? Explain.

**8-35C** Consider fully developed flow in a circular pipe with negligible entrance effects. If the length of the pipe is doubled, the pressure drop will (a) double, (b) more than double, (c) less than double, (d) reduce by half, or (e) remain constant.

**8-36C** Consider fully developed laminar flow in a circular pipe. If the diameter of the pipe is reduced by half while the flow rate and the pipe length are held constant, the pressure drop will (a) double, (b) triple, (c) quadruple, (d) increase by a factor of 8, or (e) increase by a factor of 16.

**8-37C** Consider fully developed laminar flow in a circular pipe. If the viscosity of the fluid is reduced by half by heating while the flow rate is held constant, how will the pressure drop change?

**8-38** In fully developed laminar flow in a circular pipe, the velocity at  $R/2$  (midway between the wall surface and the centerline) is measured to be 6 m/s. Determine the velocity at the center of the pipe. *Answer: 8 m/s*

**8-39** The velocity profile in fully developed laminar flow in a circular pipe of inner radius  $R = 10 \text{ cm}$ , in m/s, is given by  $u(r) = 4(1 - r^2/R^2)$ . Determine the mean and maximum velocities in the pipe, and the volume flow rate.

FIGURE P8-39

**8-40** In fully developed laminar flow inside a circular pipe, the velocities at  $r = 0.5R$  (midway between the wall surface and the centerline) are measured to be 3, 6, and 9 m/s. (a) Determine the maximum velocity for each of the measured midway velocities. (b) By varying  $r/R$  for  $-1 \leq r/R \leq 1$ , plot the velocity profile for each of the measured midway velocities with  $r/R$  as the y-axis and  $V(r/R)$  as the x-axis.

**8-41** Water is flowing in fully developed conditions through a 3-cm-diameter smooth tube with a mass flow rate of  $0.02 \text{ kg/s}$  at  $15^\circ\text{C}$ . Determine (a) the maximum velocity of the flow in the tube and (b) the pressure gradient for the flow.

**8-42** Water at  $15^\circ\text{C}$  is flowing through a 5-cm-diameter smooth tube with a length of 200 m. Determine the Darcy friction factor and pressure loss associated with the tube for (a) mass flow rate of  $0.02 \text{ kg/s}$  and (b) mass flow rate of  $0.5 \text{ kg/s}$ .

**8-43** Water at  $10^\circ\text{C}$  ( $\rho = 999.7 \text{ kg/m}^3$  and  $\mu = 1.307 \times 10^{-3} \text{ kg/m}\cdot\text{s}$ ) is flowing in a 0.20-cm-diameter 15-m-long pipe steadily at an average velocity of 1.2 m/s. Determine (a) the pressure drop and (b) the pumping power requirement to overcome this pressure drop. Assume flow is fully developed. Is this a good assumption? *Answers: (a) 188 kPa, (b) 0.71 W*

**8-44** Determine the hydrodynamic and thermal entry lengths for water, engine oil, and liquid mercury flowing through a

2.5-cm-diameter smooth tube with mass flow rate of 0.01 kg/s and temperature of 100°C.

**8–45E** Determine the average velocity, hydrodynamic and thermal entry lengths for water, engine oil, and liquid mercury flowing through a standard 2-in Schedule 40 pipe with mass flow rate of 0.1 lbm/s and temperature of 100°F.

**8–46** An engineer is to design an experimental apparatus that consists of a 25-mm-diameter smooth tube, where different fluids at 100°C are to flow through in fully developed laminar flow conditions. For hydrodynamically and thermally fully developed laminar flow of water, engine oil, and liquid mercury, determine (a) the minimum tube length and (b) the required pumping power to overcome the pressure loss in the tube at largest allowable flow rate.

**8–47** Consider a 25-mm-diameter and 15-m-long smooth tube that is used for heating fluids. The wall is heated electrically to provide a constant surface heat flux along the entire tube. Fluids enter the tube at 50°C and exit at 150°C. If the mass flow rate is maintained at 0.01 kg/s, determine the convection heat transfer coefficients at the tube outlet for water, engine oil, and liquid mercury.

**8–48** Consider a 25-mm-diameter and 15-m-long smooth tube that is maintained at a constant surface temperature. Fluids enter the tube at 50°C with a mass flow rate of 0.01 kg/s. Determine the tube surface temperatures necessary to heat water, engine oil, and liquid mercury to the desired outlet temperature of 150°C.

**8–49E** In a chemical process plant, liquid isobutane at 50°F is being transported through a 30-ft-long standard 3/4-in Schedule 40 cast iron pipe with a mass flow rate of 0.4 lbm/s. Accuracy of the results is an important issue in this problem; therefore, use the most appropriate equation to determine (a) the pressure loss and (b) the pumping power required to overcome the pressure loss. Assume flow is fully developed. Is this a good assumption?

**8–50** Water at 15°C is flowing through a 200-m-long standard 1-in Schedule 40 cast iron pipe with a mass flow rate of 0.5 kg/s. If accuracy is an important issue, use the appropriate equation to determine (a) the pressure loss and (b) the pumping power required to overcome the pressure loss. Assume flow is fully developed. Is this a good assumption?

**8–51**  Reconsider Prob. 8–50. Using the EES (or other) software, investigate the effect of the pipe roughness on the pumping power required to overcome the pressure loss. By varying the pipe roughness for  $0.1 \leq \epsilon \leq 0.26$  mm, plot the pumping power as a function of the pipe roughness.

**8–52** Water at 15°C ( $\rho = 999.1 \text{ kg/m}^3$  and  $\mu = 1.138 \times 10^{-3} \text{ kg/m}\cdot\text{s}$ ) is flowing in a 4-cm-diameter and 25-m-long horizontal pipe made of stainless steel steadily at a rate of 7 L/s. Determine (a) the pressure drop and (b) the pumping power requirement to overcome this pressure drop. Assume flow is fully developed. Is this a good assumption?

FIGURE P8–52

**8–53**  Reconsider Prob. 8–52. Using the EES (or other) software, investigate the effect of the pipe diameter on the pumping power requirement to overcome the pressure loss. By varying the pipe diameter from 2 to 4 cm, plot the pumping power as a function of the pipe diameter.

**8–54** Consider a fluid with mean inlet temperature  $T_i$  flowing through a tube of diameter  $D$  and length  $L$ , at a mass flow rate  $\dot{m}$ . The tube is subjected to a surface heat flux that can be expressed as  $\dot{q}_s(x) = a + b \sin(x\pi/L)$ , where  $a$  and  $b$  are constants. Determine an expression for the mean temperature of the fluid as a function of the  $x$ -coordinate.

**8–55** A fluid is flowing in fully developed laminar conditions in a tube with diameter  $D$  and length  $L$  at a mass flow rate  $\dot{m}$ . The tube is subjected to a surface heat flux that can be expressed as  $\dot{q}_s(x) = a \exp(-bx/2)$ , where  $a$  and  $b$  are constants. Determine an expression for the difference in mean temperature at the tube inlet and outlet.

**8–56** In a thermal system, water enters a 25-mm-diameter and 23-m-long circular tube with a mass flow rate of 0.1 kg/s at 25°C. The heat transfer from the tube surface to the water can be expressed in terms of heat flux as  $\dot{q}_s(x) = ax$ . The coefficient  $a$  is 400 W/m<sup>3</sup>, and the axial distance from the tube inlet is  $x$  measured in meters. Determine (a) an expression for the mean temperature  $T_m(x)$  of the water, (b) the outlet mean temperature of the water, and (c) the value of a uniform heat flux  $\dot{q}_s$  on the tube surface that would result in the same outlet mean temperature calculated in part (b). Evaluate water properties at 35°C.

**8–57** Consider a 10-m-long smooth rectangular tube, with  $a = 50 \text{ mm}$  and  $b = 25 \text{ mm}$ , that is maintained at a constant surface temperature. Liquid water enters the tube at 20°C with a mass flow rate of 0.01 kg/s. Determine the tube surface temperature necessary to heat the water to the desired outlet temperature of 80°C.

FIGURE P8–57

**8–58** A 15-cm × 20-cm printed circuit board whose components are not allowed to come into direct contact with air for reliability

reasons is to be cooled by passing cool air through a 20-cm-long channel of rectangular cross section  $0.2 \text{ cm} \times 14 \text{ cm}$  drilled into the board. The heat generated by the electronic components is conducted across the thin layer of the board to the channel, where it is removed by air that enters the channel at  $15^\circ\text{C}$ . The heat flux at the top surface of the channel can be considered to be uniform, and heat transfer through other surfaces is negligible. If the velocity of the air at the inlet of the channel is not to exceed  $4 \text{ m/s}$  and the surface temperature of the channel is to remain under  $50^\circ\text{C}$ , determine the maximum total power of the electronic components that can safely be mounted on this circuit board. As a first approximation, assume flow is fully developed in the channel. Evaluate properties of air at a bulk mean temperature of  $25^\circ\text{C}$ . Is this a good assumption?

**FIGURE P8–58**

**8–59** Repeat Prob. 8–58 by replacing air with helium, which has six times the thermal conductivity of air. Evaluate properties of helium from EES at a bulk mean temperature of  $25^\circ\text{C}$ . Is this a good assumption?

**8–60** Reconsider Prob. 8–58. Using EES (or other) software, investigate the effects of air velocity at the inlet of the channel and the maximum surface temperature on the maximum total power dissipation of electronic components. Let the air velocity vary from  $1 \text{ m/s}$  to  $20 \text{ m/s}$  and the surface temperature from  $30^\circ\text{C}$  to  $90^\circ\text{C}$ . Plot the power dissipation as functions of air velocity and surface temperature, and discuss the results.

**8–61** A computer cooled by a fan contains eight printed circuit boards (PCBs), each dissipating  $10 \text{ W}$  of power. The height of the PCBs is  $12 \text{ cm}$  and the length is  $18 \text{ cm}$ . The clearance between the tips of the components on the PCB and the back surface of the adjacent PCB is  $0.3 \text{ cm}$ . The cooling air is supplied by a  $10\text{-W}$  fan mounted at the inlet. If the temperature rise of air as it flows through the case of the computer is not to exceed  $10^\circ\text{C}$ , determine (a) the flow rate of the air that the fan needs to deliver, (b) the fraction of the temperature rise of air that is due to the heat generated by the fan and its motor, and (c) the highest allowable inlet air temperature if the surface temperature of the components is not to exceed  $70^\circ\text{C}$  anywhere in the system. As a first approximation, assume flow is fully developed in the channel. Evaluate properties of air at a bulk mean temperature of  $25^\circ\text{C}$ . Is this a good assumption?

**FIGURE P8–61**

**8–62** Liquid water is flowing between two very thin parallel 1-m-wide and 10-m-long plates with a spacing of  $12.5 \text{ mm}$ . The water enters the parallel plates at  $20^\circ\text{C}$  with a mass flow rate of  $0.58 \text{ kg/s}$ . The outer surface of the parallel plates is subjected to hydrogen gas (an ideal gas at  $1 \text{ atm}$ ) flow width-wise in parallel over the upper and lower surfaces of the two plates. The free-stream hydrogen gas has a velocity of  $5 \text{ m/s}$  at a temperature of  $155^\circ\text{C}$ . Determine the outlet mean temperature of the water, the surface temperature of the parallel plates, and the total rate of heat transfer. Evaluate the properties for water at  $30^\circ\text{C}$  and the properties of  $\text{H}_2$  gas at  $100^\circ\text{C}$ . Is this a good assumption?

**FIGURE P8–62**

**8–63** Reconsider Prob. 8–62. Using the EES (or other) software, evaluate the effect of water mass flow rate on the free-stream  $\text{H}_2$  gas velocity and the surface temperature of the parallel plates, and the effect of the free-stream  $\text{H}_2$  gas velocity on the total heat transfer rate. By varying the mass flow rate of water for  $0 < \dot{m} \leq 0.58 \text{ kg/s}$ , plot the free stream  $\text{H}_2$  gas velocity and the surface temperature of the plates as a function of the mass flow rate of water. Also, plot the total heat transfer rate as a function of the free-stream  $\text{H}_2$  gas velocity.

**8–64** Consider the flow of oil at  $10^\circ\text{C}$  in a 40-cm-diameter pipeline at an average velocity of  $0.5 \text{ m/s}$ . A 1500-m-long section of the pipeline passes through icy waters of a lake at  $0^\circ\text{C}$ . Measurements indicate that the surface temperature of the pipe is very nearly  $0^\circ\text{C}$ . Disregarding the thermal resistance of the pipe material, determine (a) the temperature of the oil when the pipe leaves the lake, (b) the rate of heat transfer from the oil, and (c) the pumping power required to overcome the pressure losses and to maintain the flow of oil in the pipe.

**8–65** In a manufacturing plant that produces cosmetic products, glycerin is being heated by flowing through a 25-mm-diameter and 10-m-long tube. With a mass flow rate of 0.5 kg/s, the flow of glycerin enters the tube at 25°C. The tube surface is maintained at a constant surface temperature of 140°C. Determine the outlet mean temperature and the total rate of heat transfer for the tube. Evaluate the properties for glycerin at 30°C.

**8–66** Liquid glycerin is flowing through a 25-mm-diameter and 10-m-long tube. The liquid glycerin enters the tube at 20°C with a mass flow rate of 0.5 kg/s. If the outlet mean temperature is 40°C and the tube surface temperature is constant, determine the surface temperature of the tube.

**8–67** Air at 20°C (1 atm) enters into a 5-mm-diameter and 10-cm-long circular tube at an average velocity of 5 m/s. The tube wall is maintained at a constant surface temperature of 160°C. Determine the convection heat transfer coefficient and the outlet mean temperature. Evaluate the air properties at 50°C.

**8–68** Glycerin is being heated by flowing between two parallel 1-m-wide and 10-m-long plates with 12.5-mm spacing. The glycerin enters the parallel plates with a temperature of 25°C and a mass flow rate of 0.7 kg/s. The plates have a constant surface temperature of 40°C. Determine the outlet mean temperature of the glycerin and the total rate of heat transfer. Evaluate the properties for glycerin at 30°C. Is this a good assumption?

**8–69** Reconsider Prob. 8–68. Using the EES (or other) software, evaluate the effect of glycerin mass flow rate on the surface temperature of the parallel plates and the total rate of heat transfer necessary to keep the outlet mean temperature of the glycerin at 35°C. By varying the mass flow rate from 0.05 to 6 kg/s, plot the surface temperature of the parallel plates and the total rate of heat transfer as a function of the mass flow rate.

**8–70** Glycerin is being heated by flowing between two very thin parallel 1-m-wide and 10-m-long plates with 12.5-mm spacing. The glycerin enters the parallel plates with a temperature 20°C and a mass flow rate of 0.7 kg/s. The outer surface of the parallel plates is subjected to hydrogen gas (an ideal gas at 1 atm) flow width-wise in parallel over the upper and lower surfaces of the two plates. The free-stream hydrogen gas has a velocity of 3 m/s and a temperature of 150°C. Determine the outlet mean temperature of the glycerin, the surface temperature of the parallel plates, and the total rate of heat transfer. Evaluate the properties for glycerin at 30°C and the properties of H<sub>2</sub> gas at 100°C. Are these good assumptions?

FIGURE P8–70

**8–71** Reconsider Prob. 8–70. Using the EES (or other) software, evaluate the effect of glycerin mass flow rate on the free-stream velocity of the hydrogen gas needed to keep the outlet mean temperature of the glycerin at 40°C. By varying the mass flow rate of glycerin from 0.5 to 2.4 kg/s, plot the free stream velocity of the hydrogen gas as a function of the mass flow rate of the glycerin.

**8–72** Determine the convection heat transfer coefficient for the flow of (a) air and (b) water at a velocity of 2 m/s in an 8-cm-diameter and 7-m-long tube when the tube is subjected to uniform heat flux from all surfaces. Use fluid properties at 25°C.

FIGURE P8–72

**8–73** Air at 10°C enters a 12-cm-diameter and 5-m-long pipe at a rate of 0.065 kg/s. The inner surface of the pipe has a roughness of 0.22 mm, and the pipe is nearly isothermal at 50°C. Determine the rate of heat transfer to air using the Nusselt number relation given by (a) Eq. 8–66 and (b) Eq. 8–71. Evaluate air properties at a bulk mean temperature of 20°C. Is this a good assumption?

**8–74** A 10-m-long and 10-mm-inner-diameter pipe made of commercial steel is used to heat a liquid in an industrial process. The liquid enters the pipe with  $T_i = 25^\circ\text{C}$ ,  $V = 0.8 \text{ m/s}$ . A uniform heat flux is maintained by an electric resistance heater wrapped around the outer surface of the pipe, so that the fluid exits at 75°C. Assuming fully developed flow and taking the average fluid properties to be  $\rho = 1000 \text{ kg/m}^3$ ,  $c_p = 4000 \text{ J/kg}\cdot\text{K}$ ,  $\mu = 2 \times 10^{-3} \text{ kg/m}\cdot\text{s}$ ,  $k = 0.48 \text{ W/m}\cdot\text{K}$ , and  $\text{Pr} = 10$ , determine:

- (a) The required surface heat flux  $q_s$ , produced by the heater
- (b) The surface temperature at the exit,  $T_s$
- (c) The pressure loss through the pipe and the minimum power required to overcome the resistance to flow.

**8–75** Water is to be heated from 10°C to 80°C as it flows through a 2-cm-internal-diameter, 13-m-long tube. The tube is equipped with an electric resistance heater, which provides uniform heating throughout the surface of the tube. The outer surface of the heater is well insulated, so that in steady operation all the heat generated in the heater is transferred to the water in the tube. If the system is to provide hot water at a rate of 5 L/min, determine the power rating of the resistance heater. Also, estimate the inner surface temperature of the pipe at the exit.

**8–76** Consider a fluid with a Prandtl number of 7 flowing through a smooth circular tube. Using the Colburn, Petukhov,

and Gnielinski equations, determine the Nusselt numbers for Reynolds numbers at 3500,  $10^4$ , and  $5 \times 10^5$ . Compare and discuss the results.

**8-77E** The hot water needs of a household are to be met by heating water at 55°F to 200°F by a parabolic solar collector at a rate of 4 lbm/s. Water flows through a 1.25-in-diameter thin aluminum tube whose outer surface is black-anodized in order to maximize its solar absorption ability. The centerline of the tube coincides with the focal line of the collector, and a glass sleeve is placed outside the tube to minimize the heat losses. If solar energy is transferred to water at a net rate of 350 Btu/h per ft length of the tube, determine the required length of the parabolic collector to meet the hot water requirements of this house. Also, determine the surface temperature of the tube at the exit.

FIGURE P8-77E

**8-78E** Water at 60°F is heated by passing it through 0.75-in-internal-diameter thin-walled copper tubes. Heat is supplied to the water by steam that condenses outside the copper tubes at 250°F. If water is to be heated to 140°F at a rate of 0.4 lbm/s, determine (a) the length of the copper tube that needs to be used and (b) the pumping power required to overcome pressure losses. Assume the entire copper tube to be at the steam temperature of 250°F.

**8-79** Air (1 atm) enters into a 5-cm-diameter circular tube at 20°C with an average velocity of 5 m/s. The tube wall is maintained at a constant surface temperature of 160°C, and the outlet mean temperature is 80°C. Estimate the length of the tube.

**8-80** In a food processing plant, hot liquid water is being transported in a pipe ( $k = 15 \text{ W/m}\cdot\text{K}$ ,  $D_i = 2.5 \text{ cm}$ ,  $D_o = 3 \text{ cm}$ , and  $L = 10 \text{ m}$ ). The hot water flowing with a mass flow rate of 0.15 kg/s enters the pipe at 100°C and exits at 60°C. The plant supervisor thinks that since the hot water exits the pipe at 60°C, the pipe's outer surface temperature should be safe from thermal burn hazards. In order to prevent thermal burn upon accidental contact with skin tissue for individuals working in the vicinity of the pipe, the pipe's outer surface temperature should be kept below 45°C. Determine whether or not there is a risk of thermal burn on the pipe's outer surface. Assume the pipe outer surface temperature remains constant.

**8-81** Reconsider Prob. 8-80. The mass flow rate of the hot water can be varied between 0.05 and

0.5 kg/s. Using the EES (or other) software, evaluate the effect of the hot water mass flow rate on the pipe's outer surface temperature. Plot the pipe's outer surface temperature as a function of the hot water mass flow rate for the water exit temperature of (a) 60°C and (b) 70°C. To prevent thermal burn on individuals working in the vicinity of the pipe, determine the condition of the hot water mass flow rate such that the pipe's outer surface temperature is below 45°C.

**8-82** A metal pipe ( $k_{\text{pipe}} = 15 \text{ W/m}\cdot\text{K}$ ,  $D_{i,\text{pipe}} = 5 \text{ cm}$ ,  $D_{o,\text{pipe}} = 6 \text{ cm}$ , and  $L = 10 \text{ m}$ ) situated in an engine room is used for transporting hot saturated water vapor at a flow rate of 0.03 kg/s. The water vapor enters and exits the pipe at 325°C and 290°C, respectively. Oil leakage can occur in the engine room, and when leaked oil comes in contact with hot spots above the oil's autoignition temperature, it can ignite spontaneously. To prevent any fire hazard caused by oil leakage on the hot surface of the pipe, determine the needed insulation ( $k_{\text{ins}} = 0.95 \text{ W/m}\cdot\text{K}$ ) layer thickness over the pipe for keeping the outer surface temperature below 180°C.

**8-83** Reconsider Prob. 8-82. Using the EES (or other) software, evaluate the effect of the saturated water vapor mass flow rate on needed insulation thickness for keeping the outer surface temperature below 180°C to prevent fire hazard if oil leak happens. By varying the mass flow rate from 0.01 to 0.1 kg/s, plot the insulation layer thickness as a function of the mass flow rate. If the flow rate of the saturated water vapor is adjusted between 0.03 and 0.1 kg/s, determine the insulation layer thickness that is suitable for this flow rate range.

**8-84** Exposure to high concentrations of gaseous ammonia can cause lung damage. To prevent gaseous ammonia from leaking out, ammonia is transported in its liquid state through a pipe ( $k = 15 \text{ W/m}\cdot\text{K}$ ,  $D_{i,\text{pipe}} = 5 \text{ cm}$ ,  $D_{o,\text{pipe}} = 6 \text{ cm}$ , and  $L = 10 \text{ m}$ ). The liquid ammonia enters the pipe at -30°C with a flow rate of 0.15 kg/s. Determine the insulation thickness for the pipe using a material with  $k = 0.95 \text{ W/m}\cdot\text{K}$  to keep the liquid ammonia's exit temperature at -20°C, while maintaining the insulated pipe outer surface temperature at 20°C.

**8-85** Reconsider Prob. 8-84. Using the EES (or other) software, evaluate the effect of the liquid ammonia mass flow rate on needed insulation thickness for keeping the outer surface temperature at 20°C and the flow exit temperature at -20°C. By varying the mass flow rate from 0.02 to 0.2 kg/s, plot the insulation layer thickness as a function of the mass flow rate. If the flow rate of the liquid ammonia is adjusted between 0.04 and 0.2 kg/s, calculate the insulation layer thickness that is suitable for this range of flow rate.

**8-86** An 8-m-long, uninsulated square duct of cross section  $0.2 \text{ m} \times 0.2 \text{ m}$  and relative roughness  $10^{-3}$  passes through the attic space of a house. Hot air enters the duct at 1 atm and 80°C at a volume flow rate of  $0.15 \text{ m}^3/\text{s}$ . The duct surface is nearly

isothermal at  $60^\circ\text{C}$ . Determine the rate of heat loss from the duct to the attic space and the pressure difference between the inlet and outlet sections of the duct. Evaluate air properties at a bulk mean temperature of  $80^\circ\text{C}$ . Is this a good assumption?

**8-87** Hot air at atmospheric pressure and  $85^\circ\text{C}$  enters a 10-m-long uninsulated square duct of cross section  $0.15 \text{ m} \times 0.15 \text{ m}$  that passes through the attic of a house at a rate of  $0.1 \text{ m}^3/\text{s}$ . The duct is observed to be nearly isothermal at  $70^\circ\text{C}$ . Determine the exit temperature of the air and the rate of heat loss from the duct to the air space in the attic. Evaluate air properties at a bulk mean temperature of  $75^\circ\text{C}$ . Is this a good assumption?

FIGURE P8-87

**8-88** Reconsider Prob. 8-87. Using EES (or other) software, investigate the effect of the volume flow rate of air on the exit temperature of air and the rate of heat loss. Let the flow rate vary from  $0.05 \text{ m}^3/\text{s}$  to  $0.15 \text{ m}^3/\text{s}$ . Plot the exit temperature and the rate of heat loss as a function of flow rate, and discuss the results.

**8-89** Hot air at  $60^\circ\text{C}$  leaving the furnace of a house enters a 12-m-long section of a sheet metal duct of rectangular cross section  $20 \text{ cm} \times 20 \text{ cm}$  at an average velocity of  $4 \text{ m/s}$ . The thermal resistance of the duct is negligible, and the outer surface of the duct, whose emissivity is  $0.3$ , is exposed to the cold air at  $10^\circ\text{C}$  in the basement, with a convection heat transfer coefficient of  $10 \text{ W/m}^2\cdot\text{K}$ . Taking the walls of the basement to be at  $10^\circ\text{C}$  also, determine (a) the temperature at which the hot air will leave the basement and (b) the rate of heat loss from the hot air in the duct to the basement. Evaluate air properties at a bulk mean temperature of  $50^\circ\text{C}$ . Is this a good assumption?

FIGURE P8-89

**8-90** Reconsider Prob. 8-89. Using EES (or other) software, investigate the effect of air velocity and the surface emissivity on the exit temperature of air and the rate of heat loss. Let the air velocity vary from  $1 \text{ m/s}$  to  $10 \text{ m/s}$  and the emissivity from  $0.1$  to  $1.0$ . Plot the exit temperature and the rate of heat loss functions of the air velocity and emissivity, and discuss the results.

**8-91** The components of an electronic system dissipating  $180 \text{ W}$  are located in a 1-m-long horizontal duct whose cross section is  $16 \text{ cm} \times 16 \text{ cm}$ . The components in the duct are cooled by forced air, which enters at  $27^\circ\text{C}$  at a rate of  $0.65 \text{ m}^3/\text{min}$ . Assuming 85 percent of the heat generated inside is transferred to air flowing through the duct and the remaining 15 percent is lost through the outer surfaces of the duct, determine (a) the exit temperature of air and (b) the highest component surface temperature in the duct. As a first approximation assume flow is fully developed in the channel. Evaluate properties of air at a bulk mean temperature of  $35^\circ\text{C}$ . Is this a good assumption?

**8-92** Repeat Prob. 8-91 for a circular horizontal duct of 15-cm diameter.

**8-93** A concentric annulus tube has inner and outer diameters of  $25 \text{ mm}$  and  $100 \text{ mm}$ , respectively. Liquid water flows at a mass flow rate of  $0.05 \text{ kg/s}$  through the annulus with the inlet and outlet mean temperatures of  $20^\circ\text{C}$  and  $80^\circ\text{C}$ , respectively. The inner tube wall is maintained with a constant surface temperature of  $120^\circ\text{C}$ , while the outer tube surface is insulated. Determine the length of the concentric annulus tube. Assume flow is fully developed.

FIGURE P8-93

**8-94** Liquid water flows at a mass flow rate of  $0.7 \text{ kg/s}$  through a concentric annulus tube with the inlet and outlet mean temperatures of  $20^\circ\text{C}$  and  $80^\circ\text{C}$ , respectively. The concentric annulus tube has inner and outer diameters of  $10 \text{ mm}$  and  $100 \text{ mm}$ , respectively. The inner tube wall is maintained with a constant surface temperature of  $120^\circ\text{C}$ , while the outer tube surface is insulated. Determine the length of the concentric annulus tube.

FIGURE P8-94

### Special Topic: Transitional Flow

**8-95** A tube with a bell-mouth inlet configuration is subjected to uniform wall heat flux of  $3 \text{ kW/m}^2$ . The tube has an inside diameter of  $0.0158 \text{ m}$  (0.622 in) and a flow rate of  $1.43 \times 10^{-4} \text{ m}^3/\text{s}$  (2.27 gpm). The liquid flowing inside the tube is ethylene glycol-distilled water mixture with a mass fraction of 2.27. Determine the fully developed friction coefficient at a location along the tube where the Grashof number is  $\text{Gr} = 16,600$ . The physical properties of the ethylene glycol-distilled water mixture at the location of interest are  $\text{Pr} = 14.85$ ,  $\nu = 1.93 \times 10^{-6} \text{ m}^2/\text{s}$ , and  $\mu_b/\mu_s = 1.07$ .

**8-96** Reconsider Prob. 8-95. Calculate the fully developed friction coefficient if the volume flow rate is increased by 50 percent while the rest of the parameters remain unchanged.

**8-97E** A tube with a square-edged inlet configuration is subjected to uniform wall heat flux of  $8 \text{ kW/m}^2$ . The tube has an inside diameter of 0.622 in and a flow rate of 2.16 gpm. The liquid flowing inside the tube is ethylene glycol-distilled water mixture with a mass fraction of 2.27. Determine the friction coefficient at a location along the tube where the Grashof number is  $\text{Gr} = 35,450$ . The physical properties of the ethylene glycol-distilled water mixture at the location of interest are  $\text{Pr} = 13.8$ ,  $\nu = 18.4 \times 10^{-6} \text{ ft}^2/\text{s}$ , and  $\mu_b/\mu_s = 1.12$ . Then recalculate the fully developed friction coefficient if the volume flow rate is increased by 50 percent while the rest of the parameters remain unchanged.

**8-98** A 4-m-long tube is subjected to uniform wall heat flux. The tube has an inside diameter of  $0.0149 \text{ m}$  and a flow rate of  $7.8 \times 10^{-5} \text{ m}^3/\text{s}$ . The liquid flowing inside the tube is ethylene glycol-distilled water mixture with a mass fraction of 0.5. Determine the apparent (developing) friction factor at the location  $x/D = 20$  if the inlet configuration of the tube is: (a) re-entrant and (b) square-edged. At this location, the local Grashof number is  $\text{Gr} = 28,090$  and the properties of the mixture of distilled water and ethylene glycol are:  $\text{Pr} = 20.9$ ,  $\nu = 2.33 \times 10^{-6} \text{ m}^2/\text{s}$ , and  $\mu_b/\mu_s = 1.25$ .

**8-99** Ethylene glycol-distilled water mixture with a mass fraction of 0.72 and a flow rate of  $2.05 \times 10^{-4} \text{ m}^3/\text{s}$  flows inside a tube with an inside diameter of  $0.0158 \text{ m}$  and a uniform wall heat flux boundary condition. For this flow, determine the Nusselt number at the location  $x/D = 10$  for the inlet tube configuration of (a) bell-mouth and (b) re-entrant. Compare the results for parts (a) and (b). Assume the Grashof number is  $\text{Gr} = 60,000$ . The physical properties of ethylene glycol-distilled water mixture are  $\text{Pr} = 33.46$ ,  $\nu = 3.45 \times 10^{-6} \text{ m}^2/\text{s}$  and  $\mu_b/\mu_s = 2.0$ .

**8-100** Repeat Prob. 8-99 for the location  $x/D = 90$ .

### Review Problems

**8-101** The velocity profile in fully developed laminar flow in a circular pipe, in  $\text{m/s}$ , is given by  $u(r) = 6(1 - 100r^2)$  where  $r$  is the radial distance from the centerline of the pipe in  $\text{m}$ . Determine (a) the radius of the pipe, (b) the mean velocity through the pipe, and (c) the maximum velocity in the pipe.

**8-102E** The velocity profile in fully developed laminar flow of water at  $40^\circ\text{F}$  in a 140-ft-long horizontal circular pipe, in  $\text{ft/s}$ , is given by  $u(r) = 0.8(1 - 625r^2)$  where  $r$  is the radial distance from the centerline of the pipe in  $\text{ft}$ . Determine (a) the volume flow rate of water through the pipe, (b) the pressure drop across the pipe, and (c) the useful pumping power required to overcome this pressure drop.

**8-103** Consider laminar flow of a fluid through a square channel maintained at a constant temperature. Now the mean velocity of the fluid is doubled. Determine the change in the pressure drop and the change in the rate of heat transfer between the fluid and the walls of the channel. Assume the flow regime remains unchanged. Assume fully developed flow and disregard any changes in  $\Delta T_{lm}$ .

**8-104** Repeat Prob. 8-103 for turbulent flow.

**8-105** A liquid hydrocarbon enters a 2.5-cm-diameter tube that is 5.0 m long. The liquid inlet temperature is  $20^\circ\text{C}$  and the tube wall temperature is  $60^\circ\text{C}$ . Average liquid properties are  $c_p = 2.0 \text{ kJ/kg}\cdot\text{K}$ ,  $\mu = 10 \text{ mPa}\cdot\text{s}$ , and  $\rho = 900 \text{ kg/m}^3$ . At a flow rate of 1200 kg/h, the liquid outlet temperature is measured to be  $30^\circ\text{C}$ . Estimate the liquid outlet temperature when the flow rate is reduced to 400 kg/h. Hint: For heat transfer in tubes,  $\text{Nu} \propto \text{Re}^{1/3}$  in laminar flow and  $\text{Nu} \propto \text{Re}^{4/5}$  in turbulent flow.

**8-106** A silicon chip is cooled by passing water through microchannels etched in the back of the chip, as shown in Fig. P8-106. The channels are covered with a silicon cap. Consider a 10-mm  $\times$  10-mm-square chip in which  $N = 50$  rectangular microchannels, each of width  $W = 50 \mu\text{m}$  and height  $H = 200 \mu\text{m}$  have been etched. Water enters the microchannels at a temperature  $T_i = 290 \text{ K}$ , and a total flow rate of 0.005 kg/s. The chip and cap are maintained at a uniform temperature of  $350 \text{ K}$ . Assuming that the flow in the channels is fully developed, all the heat generated by the circuits on the top surface of the chip is transferred to the water, and using circular tube correlations, determine:

- (a) The water outlet temperature,  $T_e$
- (b) The chip power dissipation,  $\dot{W}_e$

Evaluate liquid water properties at a bulk mean temperature of  $298 \text{ K}$ . Is this a good assumption?

Circuits generating power  $\dot{W}_e$

FIGURE P8-106

**8-107** A fluid ( $\rho = 1000 \text{ kg/m}^3$ ,  $\mu = 1.4 \times 10^{-3} \text{ kg/m}\cdot\text{s}$ ,  $c_p = 4.2 \text{ kJ/kg}\cdot\text{K}$ , and  $k = 0.58 \text{ W/m}\cdot\text{K}$ ) flows with an average velocity of 0.3 m/s through a 14-m long tube with inside diameter of 0.01 m. Heat is uniformly added to the entire tube at the rate of  $1500 \text{ W/m}^2$ . Determine (a) the value of convection heat transfer coefficient at the exit, (b) the value of  $T_s - T_m$ , and (c) the value of  $T_e - T_i$ .

**8-108** Crude oil at  $22^\circ\text{C}$  enters a 20-cm-diameter pipe with an average velocity of 20 cm/s. The average pipe wall temperature is  $2^\circ\text{C}$ . Crude oil properties are as given below. Calculate the rate of heat transfer and pipe length if the crude oil outlet temperature is  $20^\circ\text{C}$ .

| $T$<br>$^\circ\text{C}$ | $\rho$<br>$\text{kg/m}^3$ | $k$<br>$\text{W/m}\cdot\text{K}$ | $\mu$<br>$\text{mPa}\cdot\text{s}$ | $c_p$<br>$\text{kJ/kg}\cdot\text{K}$ |
|-------------------------|---------------------------|----------------------------------|------------------------------------|--------------------------------------|
| 2.0                     | 900                       | 0.145                            | 60.0                               | 1.80                                 |
| 22.0                    | 890                       | 0.145                            | 20.0                               | 1.90                                 |

**8-109** Air (1 atm) entered into a 5-mm-diameter circular tube at an average velocity of 5 m/s. The tube wall is maintained at a constant surface temperature. Determine the convection heat transfer coefficient for (a) a 10-cm-long tube and (b) a 50-cm-long tube. Evaluate the air properties at  $50^\circ\text{C}$ .

**8-110** To cool a storehouse in the summer without using a conventional air-conditioning system, the owner decided to hire an engineer to design an alternative system that would make use of the water in the nearby lake. The engineer decided to flow air through a thin smooth 10-cm-diameter copper tube that is submerged in the nearby lake. The water in the lake is typically maintained at a constant temperature of  $15^\circ\text{C}$  and a convection heat transfer coefficient of  $1000 \text{ W/m}^2\cdot\text{K}$ . If air (1 atm) enters the copper tube at a mean temperature of  $30^\circ\text{C}$  with an average velocity of 2.5 m/s, determine the necessary copper tube length so that the outlet mean temperature of the air is  $20^\circ\text{C}$ .

FIGURE P8-110

**8-111** Liquid mercury is flowing at  $0.6 \text{ kg/s}$  through a 5-cm-diameter tube with inlet and outlet mean temperatures of  $100^\circ\text{C}$  and  $200^\circ\text{C}$ , respectively. The tube surface temperature is maintained constant at  $250^\circ\text{C}$ . Determine the tube length using (a) the appropriate Nusselt number relation for liquid

metals and (b) the Dittus-Boelter equation. (c) Compare the results of (a) and (b).

**8-112** In the effort to find the best way to cool a smooth thin-walled copper tube, an engineer decided to flow air either through the tube or across the outer tube surface. The tube has a diameter of 5 cm, and the surface temperature is maintained constant. Determine (a) the convection heat transfer coefficient when air is flowing through its inside at 25 m/s with bulk mean temperature of  $50^\circ\text{C}$  and (b) the convection heat transfer coefficient when air is flowing across its outer surface at 25 m/s with film temperature of  $50^\circ\text{C}$ .

**8-113** Water is heated at a rate of  $10 \text{ kg/s}$  from a temperature of  $15^\circ\text{C}$  to  $35^\circ\text{C}$  by passing it through five identical tubes, each 5.0 cm in diameter, whose surface temperature is  $60.0^\circ\text{C}$ . Estimate (a) the steady rate of heat transfer and (b) the length of tubes necessary to accomplish this task.

**8-114** Repeat Prob. 8-113 for a flow rate of  $20 \text{ kg/s}$ .

**8-115** Water at  $1500 \text{ kg/h}$  and  $10^\circ\text{C}$  enters a 10-mm-diameter smooth tube whose wall temperature is maintained at  $49^\circ\text{C}$ . Calculate (a) the tube length necessary to heat the water to  $40^\circ\text{C}$ , and (b) the water outlet temperature if the tube length is doubled. Assume average water properties to be the same as in (a).

**8-116E** The exhaust gases of an automotive engine leave the combustion chamber and enter a 8-ft-long and 3.5-in-diameter thin-walled steel exhaust pipe at  $800^\circ\text{F}$  and  $15.5 \text{ psia}$  at a rate of  $0.05 \text{ lbm/s}$ . The surrounding ambient air is at a temperature of  $80^\circ\text{F}$ , and the heat transfer coefficient on the outer surface of the exhaust pipe is  $3 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$ . Assuming the exhaust gases to have the properties of air, determine (a) the velocity of the exhaust gases at the inlet of the exhaust pipe and (b) the temperature at which the exhaust gases will leave the pipe and enter the air.

**8-117E** Air is flowing through a smooth thin-walled 4-in-diameter copper tube that is submerged in water. The water maintains a constant temperature of  $60^\circ\text{F}$  and a convection heat transfer coefficient of  $176 \text{ Btu/h}\cdot\text{ft}^2\cdot\text{R}$ . If air (1 atm) enters the copper tube at a mean temperature of  $90^\circ\text{F}$  with an average velocity of  $8 \text{ ft/s}$ , determine the necessary copper tube length so that the outlet mean temperature of the air is  $70^\circ\text{F}$ .

FIGURE P8-117

**8–118** Hot water at 90°C enters a 15-m section of a cast iron pipe ( $k = 52 \text{ W/m}\cdot\text{K}$ ) whose inner and outer diameters are 4 and 4.6 cm, respectively, at an average velocity of 1.2 m/s. The outer surface of the pipe, whose emissivity is 0.7, is exposed to the cold air at 10°C in a basement, with a convection heat transfer coefficient of 12 W/m<sup>2</sup>·K. Taking the walls of the basement to be at 10°C also, determine (a) the rate of heat loss from the water and (b) the temperature at which the water leaves the basement.

FIGURE P8–118

**8–119** Repeat Prob. 8–118 for a pipe made of copper ( $k = 386 \text{ W/m}\cdot\text{K}$ ) instead of cast iron.

**8–120** Hot exhaust gases leaving a stationary diesel engine at 450°C enter a 15-cm-diameter pipe at an average velocity of 4.5 m/s. The surface temperature of the pipe is 180°C. Determine the pipe length if the exhaust gases are to leave the pipe at 250°C after transferring heat to water in a heat recovery unit. Use properties of air for exhaust gases.

**8–121** Geothermal steam at 165°C condenses in the shell side of a heat exchanger over the tubes through which water flows. Water enters the 4-cm-diameter, 14-m-long tubes at 20°C at a rate of 0.8 kg/s. Determine the exit temperature of water and the rate of condensation of geothermal steam.

**8–122** Cold air at 5°C enters a 12-cm-diameter, 20-m-long isothermal pipe at a velocity of 2.5 m/s and leaves at 19°C. Estimate the surface temperature of the pipe.

**8–123** 100 kg/s of a crude oil is heated from 20°C to 40°C through the tube side of a multitube heat exchanger. The crude oil flow is divided evenly among all 100 tubes in the tube bundle. The ID of each tube is 10 mm, and the inside tube-wall temperature is maintained at 100°C. Average properties of the crude oil are  $\rho = 950 \text{ kg/m}^3$ ,  $c_p = 1.9 \text{ kJ/kg}\cdot\text{K}$ ,  $k = 0.25 \text{ W/m}\cdot\text{K}$ ,  $\mu = 12 \text{ mPa}\cdot\text{s}$ , and  $\mu_w = 4 \text{ mPa}\cdot\text{s}$ . Estimate the rate of heat transfer and the tube length.

**8–124** Liquid water enters a 10-m-long smooth rectangular tube with  $a = 50 \text{ mm}$  and  $b = 25 \text{ mm}$ . The surface temperature is maintained constant, and water enters the tube at 20°C with a mass flow rate of 0.25 kg/s. Determine the tube surface temperature necessary to heat the water to the desired outlet temperature of 80°C.

FIGURE P8–124

**8–125** A geothermal district heating system involves the transport of geothermal water at 110°C from a geothermal well to a city at about the same elevation for a distance of 12 km at a rate of 1.5 m<sup>3</sup>/s in 60-cm-diameter stainless steel pipes. The fluid pressures at the wellhead and the arrival point in the city are to be the same. The minor losses are negligible because of the large length-to-diameter ratio and the relatively small number of components that cause minor losses. (a) Assuming the pump-motor efficiency to be 65 percent, determine the electric power consumption of the system for pumping. (b) Determine the daily cost of power consumption of the system if the unit cost of electricity is \$0.06/kWh. (c) The temperature of geothermal water is estimated to drop 0.5°C during this long flow. Determine if the frictional heating during flow can make up for this drop in temperature.

**8–126** Repeat Prob. 8–125 for cast iron pipes of the same diameter.

**8–127** A house built on a riverside is to be cooled in summer by utilizing the cool water of the river, which flows at an average temperature of 15°C. A 15-m-long section of a circular duct of 20-cm diameter passes through the water. Air enters the underwater section of the duct at 25°C at a velocity of 3 m/s. Assuming the surface of the duct to be at the temperature of the water, determine the outlet temperature of air as it leaves the underwater portion of the duct. Also, for an overall fan efficiency of 55 percent, determine the fan power input needed to overcome the flow resistance in this section of the duct.

FIGURE P8–127

**8–128** Repeat Prob. 8–127 assuming that a 0.25-mm-thick layer of mineral deposit ( $k = 3 \text{ W/m}\cdot\text{K}$ ) formed on the inner surface of the pipe.

**8–129** Oil at 15°C is to be heated by saturated steam at 1 atm in a double-pipe heat exchanger to a temperature of 25°C.

The inner and outer diameters of the annular space are 3 cm and 5 cm, respectively, and oil enters with a mean velocity of 0.8 m/s. The inner tube may be assumed to be isothermal at 100°C, and the outer tube is well insulated. Assuming fully developed flow for oil, determine the tube length required to heat the oil to the indicated temperature. In reality, will you need a shorter or longer tube? Explain.

**8-130E** A concentric annulus tube has inner and outer diameters of 1 in. and 4 in., respectively. Liquid water flows at a mass flow rate of 396 lbm/h through the annulus with the inlet and outlet mean temperatures of 68°F and 172°F, respectively. The inner tube wall is maintained with a constant surface temperature of 250°F, while the outer tube surface is insulated. Determine the length of the concentric annulus tube. Assume flow is fully developed.

FIGURE P8-130E

### Fundamentals of Engineering (FE) Exam Problems

**8-131** Internal force flows are said to be fully developed once the \_\_\_\_ at a cross section no longer changes in the direction of flow.

- (a) temperature distribution
- (b) entropy distribution
- (c) velocity distribution
- (d) pressure distribution
- (e) none of the above

**8-132** The bulk or mixed temperature of a fluid flowing through a pipe or duct is defined as

- (a)  $T_b = \frac{1}{A_c} \int_{A_c} T dA_c$
- (b)  $T_b = \frac{1}{\dot{m}} \int_{A_c} T \rho V dA_c$
- (c)  $T_b = \frac{1}{\dot{m}} \int_{A_c} h \rho V dA_c$
- (d)  $T_b = \frac{1}{A_c} \int_{A_c} h dA_c$
- (e)  $T_b = \frac{1}{\dot{V}} \int_{A_c} T \rho V dA_c$

**8-133** Water ( $\mu = 9.0 \times 10^{-4}$  kg/m·s,  $\rho = 1000$  kg/m<sup>3</sup>) enters a 2-cm-diameter and 3-m-long tube whose walls are

maintained at 100°C. The water enters this tube with a bulk temperature of 25°C and a volume flow rate of 3 m<sup>3</sup>/h. The Reynolds number for this internal flow is

- (a) 59,000
- (b) 105,000
- (c) 178,000
- (d) 236,000
- (e) 342,000

**8-134** Water enters a circular tube whose walls are maintained at constant temperature at a specified flow rate and temperature. For fully developed turbulent flow, the Nusselt number can be determined from  $Nu = 0.023 Re^{0.8} Pr^{0.4}$ . The correct temperature difference to use in Newton's law of cooling in this case is

- (a) The difference between the inlet and outlet water bulk temperature.
- (b) The difference between the inlet water bulk temperature and the tube wall temperature.
- (c) The log mean temperature difference.
- (d) The difference between the average water bulk temperature and the tube temperature.
- (e) None of the above.

**8-135** Air ( $c_p = 1007$  J/kg·K) enters a 17-cm-diameter and 4-m-long tube at 65°C at a rate of 0.08 kg/s and leaves at 15°C. The tube is observed to be nearly isothermal at 5°C. The average convection heat transfer coefficient is

- (a) 24.5 W/m<sup>2</sup>·K
- (b) 46.2 W/m<sup>2</sup>·K
- (c) 53.9 W/m<sup>2</sup>·K
- (d) 67.6 W/m<sup>2</sup>·K
- (e) 90.7 W/m<sup>2</sup>·K

**8-136** Water ( $c_p = 4180$  J/kg·K) enters a 12-cm-diameter and 8.5-m-long tube at 75°C at a rate of 0.35 kg/s, and is cooled by a refrigerant evaporating outside at -10°C. If the average heat transfer coefficient on the inner surface is 500 W/m<sup>2</sup>·K, the exit temperature of water is

- (a) 18.4°C
- (b) 25.0°C
- (c) 33.8°C
- (d) 46.5°C
- (e) 60.2°C

**8-137** Air enters a duct at 20°C at a rate of 0.08 m<sup>3</sup>/s, and is heated to 150°C by steam condensing outside at 200°C. The error involved in the rate of heat transfer to the air due to using arithmetic mean temperature difference instead of logarithmic mean temperature difference is

- (a) 0%
- (b) 5.4%
- (c) 8.1%
- (d) 10.6%
- (e) 13.3%

**8-138** Engine oil at 60°C ( $\mu = 0.07399$  kg/m·s,  $\rho = 864$  kg/m<sup>3</sup>) flows in a 5-cm-diameter tube with a velocity of 1.3 m/s. The pressure drop along a fully developed 6-m-long section of the tube is

- (a) 2.9 kPa
- (b) 5.2 kPa
- (c) 7.4 kPa
- (d) 10.5 kPa
- (e) 20.0 kPa

**8-139** Engine oil flows in a 15-cm-diameter horizontal tube with a velocity of 1.3 m/s, experiencing a pressure drop of 12 kPa. The pumping power requirement to overcome this pressure drop is

- (a) 190 W
- (b) 276 W
- (c) 407 W
- (d) 655 W
- (e) 900 W

**8-140** Water enters a 5-mm-diameter and 13-m-long tube at 15°C with a velocity of 0.3 m/s, and leaves at 45°C. The tube is subjected to a uniform heat flux of 2000 W/m<sup>2</sup> on its surface. The temperature of the tube surface at the exit is

- |            |            |            |
|------------|------------|------------|
| (a) 48.7°C | (b) 49.4°C | (c) 51.1°C |
| (d) 53.7°C | (e) 55.2°C |            |

(For water, use  $k = 0.615 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 5.42$ ,  $v = 0.801 \times 10^{-6} \text{ m}^2/\text{s}$ .)

**8-141** Water enters a 5-mm-diameter and 13-m-long tube at 45°C with a velocity of 0.3 m/s. The tube is maintained at a constant temperature of 8°C. The exit temperature of water is

- |            |            |            |
|------------|------------|------------|
| (a) 4.4°C  | (b) 8.9°C  | (c) 10.6°C |
| (d) 12.0°C | (e) 14.1°C |            |

(For water, use  $k = 0.607 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 6.14$ ,  $v = 0.894 \times 10^{-6} \text{ m}^2/\text{s}$ ,  $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ,  $\rho = 997 \text{ kg/m}^3$ .)

**8-142** Water enters a 5-mm-diameter and 13-m-long tube at 45°C with a velocity of 0.3 m/s. The tube is maintained at a constant temperature of 5°C. The required length of the tube in order for the water to exit the tube at 25°C is

- |            |            |            |
|------------|------------|------------|
| (a) 1.55 m | (b) 1.72 m | (c) 1.99 m |
| (d) 2.37 m | (e) 2.96 m |            |

(For water, use  $k = 0.623 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 4.83$ ,  $v = 0.724 \times 10^{-6} \text{ m}^2/\text{s}$ ,  $c_p = 4178 \text{ J/kg}\cdot\text{K}$ ,  $\rho = 994 \text{ kg/m}^3$ .)

**8-143** Air enters a 7-cm-diameter and 4-m-long tube at 65°C and leaves at 15°C. The tube is observed to be nearly isothermal at 5°C. If the average convection heat transfer coefficient is 20 W/m<sup>2</sup>·°C, the rate of heat transfer from the air is

- |           |           |           |
|-----------|-----------|-----------|
| (a) 491 W | (b) 616 W | (c) 810 W |
| (d) 907 W | (e) 975 W |           |

**8-144** Air ( $c_p = 1000 \text{ J/kg}\cdot\text{K}$ ) enters a 20-cm-diameter and 19-m-long underwater duct at 50°C and 1 atm at an average velocity of 7 m/s and is cooled by the water outside. If the average heat transfer coefficient is 35 W/m<sup>2</sup>·K and the tube temperature is nearly equal to the water temperature of 5 °C, the exit temperature of air is

- |          |          |          |
|----------|----------|----------|
| (a) 8°C  | (b) 13°C | (c) 18°C |
| (d) 28°C | (e) 37°C |          |

**8-145** Water enters a 2-cm-diameter and 3-m-long tube whose walls are maintained at 100°C with a bulk temperature of 25°C and volume flow rate of 3 m<sup>3</sup>/h. Neglecting the entrance effects and assuming turbulent flow, the Nusselt number can be determined from  $\text{Nu} = 0.023 \text{ Re}^{0.8} \text{ Pr}^{0.4}$ . The convection heat transfer coefficient in this case is

- |                              |                              |
|------------------------------|------------------------------|
| (a) 4140 W/m <sup>2</sup> ·K | (b) 6160 W/m <sup>2</sup> ·K |
| (c) 8180 W/m <sup>2</sup> ·K | (d) 9410 W/m <sup>2</sup> ·K |
| (e) 2870 W/m <sup>2</sup> ·K |                              |

(For water, use  $k = 0.610 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 6.0$ ,  $\mu = 9.0 \times 10^{-4} \text{ kg/m}\cdot\text{s}$ ,  $\rho = 1000 \text{ kg/m}^3$ )

**8-146** Air at 110°C enters an 18-cm-diameter and 9-m-long duct at a velocity of 3 m/s. The duct is observed to be nearly isothermal at 85°C. The rate of heat loss from the air in the duct is

- |           |           |           |
|-----------|-----------|-----------|
| (a) 375 W | (b) 510 W | (c) 936 W |
| (d) 965 W | (e) 987 W |           |

(For air, use  $k = 0.03095 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 0.7111$ ,  $v = 2.306 \times 10^{-5} \text{ m}^2/\text{s}$ ,  $c_p = 1009 \text{ J/kg}\cdot\text{K}$ .)

**8-147** Air at 10°C enters an 18-m-long rectangular duct of cross section 0.15 m × 0.20 m at a velocity of 4.5 m/s. The duct is subjected to uniform radiation heating throughout the surface at a rate of 400 W/m<sup>2</sup>. The wall temperature at the exit of the duct is

- |            |            |            |
|------------|------------|------------|
| (a) 58.8°C | (b) 61.9°C | (c) 64.6°C |
| (d) 69.1°C | (e) 75.5°C |            |

(For air, use  $k = 0.02551 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 0.7296$ ,  $v = 1.562 \times 10^{-5} \text{ m}^2/\text{s}$ ,  $c_p = 1007 \text{ J/kg}\cdot\text{K}$ ,  $\rho = 1.184 \text{ kg/m}^3$ .)

### Design and Essay Problems

**8-148** Electronic boxes such as computers are commonly cooled by a fan. Write an essay on forced air cooling of electronic boxes and on the selection of the fan for electronic devices.

**8-149** Design a heat exchanger to pasteurize milk by steam in a dairy plant. Milk is to flow through a bank of 1.2-cm-internal-diameter tubes while steam condenses outside the tubes at 1 atm. Milk is to enter the tubes at 4°C, and it is to be heated to 72°C at a rate of 15 L/s. Making reasonable assumptions, you are to specify the tube length and the number of tubes, and the pump for the heat exchanger.

**8-150** A desktop computer is to be cooled by a fan. The electronic components of the computer consume 80 W of power under full-load conditions. The computer is to operate in environments at temperatures up to 50°C and at elevations up to 3000 m where the atmospheric pressure is 70.12 kPa. The exit temperature of air is not to exceed 60°C to meet the reliability requirements. Also, the average velocity of air is not to exceed 120 m/min at the exit of the computer case, where the fan is installed to keep the noise level down. Specify the flow rate of the fan that needs to be installed and the diameter of the casing of the fan.

# NATURAL CONVECTION

In Chapters 7 and 8, we considered heat transfer by *forced convection*, where a fluid was *forced* to move over a surface or in a tube by external means such as a pump or a fan. In this chapter, we consider *natural convection*, alternatively called free convection, where any fluid motion occurs by natural means such as buoyancy. The fluid motion in forced convection is quite *noticeable*, since a fan or a pump can transfer enough momentum to the fluid to move it in a certain direction. The fluid motion in natural convection, however, is often not noticeable because of the low velocities involved.

The convection heat transfer coefficient is a strong function of *velocity*: the higher the velocity, the higher the convection heat transfer coefficient. The fluid velocities associated with natural convection are low, typically less than 1 m/s. Therefore, the heat transfer coefficients encountered in natural convection are usually much lower than those encountered in forced convection. Yet several types of heat transfer equipment are designed to operate under natural convection conditions instead of forced convection, because natural convection does not require the use of a fluid mover.

We start this chapter with a discussion of the physical mechanism of *natural convection* and the *Grashof number*. We then present the correlations to evaluate heat transfer by natural convection for various geometries, including finned surfaces and enclosures. Finally, we discuss simultaneous forced and natural convection.

## OBJECTIVES

When you finish studying this chapter, you should be able to:

- Understand the physical mechanism of natural convection,
- Derive the governing equations of natural convection, and obtain the dimensionless Grashof number by nondimensionalizing them,
- Evaluate the Nusselt number for natural convection associated with vertical, horizontal, and inclined plates as well as cylinders and spheres,
- Examine natural convection from finned surfaces, and determine the optimum fin spacing,
- Analyze natural convection inside enclosures such as double-pane windows, and
- Consider combined natural and forced convection, and assess the relative importance of each mode.

**FIGURE 9–1**

The cooling of a boiled egg in a cooler environment by natural convection.

## 9–1 ▪ PHYSICAL MECHANISM OF NATURAL CONVECTION

Many familiar heat transfer applications involve natural convection as the primary mechanism of heat transfer. Some examples are cooling of electronic equipment such as power transistors, TVs, and DVDs; heat transfer from electric baseboard heaters or steam radiators; heat transfer from the refrigeration coils and power transmission lines; and heat transfer from the bodies of animals and human beings. Natural convection in gases is usually accompanied by radiation of comparable magnitude except for low-emissivity surfaces.

We know that a hot boiled egg (or a hot baked potato) on a plate eventually cools to the surrounding air temperature (Fig. 9–1). The egg is cooled by transferring heat by convection to the air and by radiation to the surrounding surfaces. Disregarding heat transfer by radiation, the physical mechanism of cooling a hot egg (or any hot object) in a cooler environment can be explained as follows:

As soon as the hot egg is exposed to cooler air, the temperature of the outer surface of the egg shell drops somewhat, and the temperature of the air adjacent to the shell rises as a result of heat conduction from the shell to the air. Consequently, the egg is surrounded by a thin layer of warmer air, and heat is then transferred from this warmer layer to the outer layers of air. The cooling process in this case is rather slow since the egg would always be blanketed by warm air, and it has no direct contact with the cooler air farther away. We may not notice any air motion in the vicinity of the egg, but careful measurements would indicate otherwise.

The temperature of the air adjacent to the egg is higher and thus its density is lower, since at constant pressure the density of a gas is inversely proportional to its temperature. Thus, we have a situation in which some low-density or “light” gas is surrounded by a high-density or “heavy” gas, and the natural laws dictate that the *light gas rise*. This is no different than the oil in a vinegar-and-oil salad dressing rising to the top (since  $\rho_{\text{oil}} < \rho_{\text{vinegar}}$ ). This phenomenon is characterized incorrectly by the phrase “heat rises,” which is understood to mean *heated air rises*. The space vacated by the warmer air in the vicinity of the egg is replaced by the cooler air nearby, and the presence of cooler air in the vicinity of the egg speeds up the cooling process. The rise of warmer air and the flow of cooler air into its place continues until the egg is cooled to the temperature of the surrounding air. The motion that results from the continual replacement of the heated air in the vicinity of the egg by the cooler air nearby is called a **natural convection current**, and the heat transfer that is enhanced as a result of this natural convection current is called **natural convection heat transfer**. Note that in the absence of natural convection currents, heat transfer from the egg to the air surrounding it would be by conduction only, and the rate of heat transfer from the egg would be much lower.

Natural convection is just as effective in the heating of cold surfaces in a warmer environment as it is in the cooling of hot surfaces in a cooler environment, as shown in Fig. 9–2. Note that the direction of fluid motion is reversed in this case.

In a gravitational field, there is a net force that pushes upward a light fluid placed in a heavier fluid. The upward force exerted by a fluid on a body completely or partially immersed in it is called the **buoyancy force**. The magnitude of the buoyancy force is equal to the weight of the *fluid displaced* by the body. That is,

$$F_{\text{buoyancy}} = \rho_{\text{fluid}} g V_{\text{body}} \quad (9-1)$$

**FIGURE 9–2**

The warming up of a cold drink in a warmer environment by natural convection.

where  $\rho_{\text{fluid}}$  is the average density of the *fluid* (not the body),  $g$  is the gravitational acceleration, and  $V_{\text{body}}$  is the volume of the portion of the body immersed in the fluid (for bodies completely immersed in the fluid, it is the total volume of the body). In the absence of other forces, the net vertical force acting on a body is the difference between the weight of the body and the buoyancy force. That is,

$$\begin{aligned} F_{\text{net}} &= W - F_{\text{buoyancy}} \\ &= \rho_{\text{body}} g V_{\text{body}} - \rho_{\text{fluid}} g V_{\text{body}} \\ &= (\rho_{\text{body}} - \rho_{\text{fluid}}) g V_{\text{body}} \end{aligned} \quad (9-2)$$

Note that this force is proportional to the difference in the densities of the fluid and the body immersed in it. Thus, a body immersed in a fluid will experience a “weight loss” in an amount equal to the weight of the fluid it displaces. This is known as *Archimedes’ principle*.

To have a better understanding of the buoyancy effect, consider an egg dropped into water. If the average density of the egg is greater than the density of water (a sign of freshness), the egg settles at the bottom of the container. Otherwise, it rises to the top. When the density of the egg equals the density of water, the egg settles somewhere in the water while remaining completely immersed, acting like a “weightless object” in space. This occurs when the upward buoyancy force acting on the egg equals the weight of the egg, which acts downward.

The *buoyancy effect* has far-reaching implications in life. For one thing, without buoyancy, heat transfer between a hot (or cold) surface and the fluid surrounding it would be by *conduction* instead of by *natural convection*. The natural convection currents encountered in the oceans, lakes, and the atmosphere owe their existence to buoyancy. Also, light boats as well as heavy warships made of steel float on water because of buoyancy (Fig. 9-3). Ships are designed on the basis of the principle that the entire weight of a ship and its contents is equal to the weight of the water that the submerged volume of the ship can contain. The “chimney effect” that induces the upward flow of hot combustion gases through a chimney is also due to the buoyancy effect, and the upward force acting on the gases in the chimney is proportional to the difference between the densities of the hot gases in the chimney and the cooler air outside. Note that there is *no noticeable gravity* in space, and thus there can be no natural convection heat transfer in a spacecraft, even if the spacecraft is filled with atmospheric air.

In heat transfer studies, the primary variable is *temperature*, and it is desirable to express the net buoyancy force (Eq. 9-2) in terms of temperature differences. But this requires expressing the density difference in terms of a temperature difference, which requires a knowledge of a property that represents the variation of the density of a fluid with temperature at constant pressure. *The property that provides that information is the volume expansion coefficient  $\beta$* , defined as (Fig. 9-4)

$$\beta = \frac{1}{V} \left( \frac{\partial V}{\partial T} \right)_P = -\frac{1}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_P \quad (1/K) \quad (9-3)$$

In natural convection studies, the condition of the fluid sufficiently far from the hot or cold surface is indicated by the subscript “infinity” to serve as a reminder that this is the value at a distance where the presence of the surface

FIGURE 9-3

It is the buoyancy force that keeps the ships afloat in water ( $W = F_{\text{buoyancy}}$  for floating objects).

(a) A substance with a large  $\beta$ (b) A substance with a small  $\beta$ 

FIGURE 9-4

The coefficient of volume expansion is a measure of the change in volume of a substance with temperature at constant pressure.

is not felt. In such cases, the volume expansion coefficient can be expressed approximately by replacing differential quantities by differences as

$$\beta \approx -\frac{1}{\rho} \frac{\Delta\rho}{\Delta T} = -\frac{1}{\rho} \frac{\rho_\infty - \rho}{T_\infty - T} \quad (\text{at constant } P) \quad (9-4)$$

or

$$\rho_\infty - \rho = \rho\beta(T - T_\infty) \quad (\text{at constant } P) \quad (9-5)$$

where  $\rho_\infty$  is the density and  $T_\infty$  is the temperature of the quiescent fluid away from the surface.

We can show easily that the volume expansion coefficient  $\beta$  of an *ideal gas* ( $P = \rho RT$ ) at a temperature  $T$  is equivalent to the inverse of the temperature:

$$\beta_{\text{ideal gas}} = \frac{1}{T} \quad (1/\text{K}) \quad (9-6)$$

where  $T$  is the *thermodynamic* temperature. Note that a large value of  $\beta$  for a fluid means a large change in density with temperature, and that the product  $\beta\Delta T$  represents the fraction of volume change of a fluid that corresponds to a temperature change  $\Delta T$  at constant pressure. Also note that the buoyancy force is proportional to the *density difference*, which is proportional to the *temperature difference* at constant pressure. Therefore, the larger the temperature difference between the fluid adjacent to a hot (or cold) surface and the fluid away from it, the *larger* the buoyancy force and the *stronger* the natural convection currents, and thus the *higher* the heat transfer rate.

The magnitude of the natural convection heat transfer between a surface and a fluid is directly related to the *flow rate* of the fluid. The higher the flow rate, the higher the heat transfer rate. In fact, it is the very high flow rates that increase the heat transfer coefficient by orders of magnitude when forced convection is used. In natural convection, no blowers are used, and therefore the flow rate cannot be controlled externally. The flow rate in this case is established by the dynamic balance of *buoyancy* and *friction*.

As we have discussed earlier, the buoyancy force is caused by the density difference between the heated (or cooled) fluid adjacent to the surface and the fluid surrounding it, and is proportional to this density difference and the volume occupied by the warmer fluid. It is also well known that whenever two bodies in contact (solid–solid, solid–fluid, or fluid–fluid) move relative to each other, a *friction force* develops at the contact surface in the direction opposite to that of the motion. This opposing force slows down the fluid and thus reduces the flow rate of the fluid. Under steady conditions, the airflow rate driven by buoyancy is established at the point where these two effects *balance* each other. The friction force increases as more and more solid surfaces are introduced, seriously disrupting the fluid flow and heat transfer. For that reason, heat sinks with closely spaced fins are not suitable for natural convection cooling.

Most heat transfer correlations in natural convection are based on experimental measurements. The instrument often used in natural convection experiments is the *Mach-Zehnder interferometer*, which gives a plot of isotherms in the fluid in the vicinity of a surface. The operation principle of interferometers is based on the fact that at low pressure, the lines of constant temperature for a gas correspond to the lines of constant density, and that the index of refraction of a gas is a function of its density. Therefore, the degree of refraction of light

at some point in a gas is a measure of the temperature gradient at that point. An interferometer produces a map of interference fringes, which can be interpreted as lines of *constant temperature* as shown in Fig. 9–5. The smooth and parallel lines in (a) indicate that the flow is *laminar*, whereas the eddies and irregularities in (b) indicate that the flow is *turbulent*. Note that the lines are closest near the surface, indicating a *higher temperature gradient*.

## 9–2 • EQUATION OF MOTION AND THE GRASHOF NUMBER

In this section we derive the equation of motion that governs the natural convection flow in laminar boundary layer. The conservation of mass and energy equations derived in Chapter 6 for forced convection are also applicable for natural convection, but the momentum equation needs to be modified to incorporate buoyancy.

Consider a vertical hot flat plate immersed in a quiescent fluid body. We assume the natural convection flow to be steady, laminar, and two-dimensional, and the fluid to be Newtonian with constant properties, including density, with one exception: the density difference  $\rho - \rho_\infty$  is to be considered since it is this density difference between the inside and the outside of the boundary layer that gives rise to buoyancy force and sustains flow. (This is known as the *Boussinesq approximation*.) We take the upward direction along the plate to be  $x$ , and the direction normal to surface to be  $y$ , as shown in Fig. 9–6. Therefore, gravity acts in the  $-x$ -direction. Noting that the flow is steady and two-dimensional, the  $x$ - and  $y$ -components of velocity within boundary layer are  $u = u(x, y)$  and  $v = v(x, y)$ , respectively.

The velocity and temperature profiles for natural convection over a vertical hot plate are also shown in Fig. 9–6. Note that as in forced convection, the thickness of the boundary layer increases in the flow direction. Unlike forced convection, however, the fluid velocity is zero at the outer edge of the velocity boundary layer as well as at the surface of the plate. This is expected since the fluid beyond the boundary layer is motionless. Thus, the fluid velocity increases with distance from the surface, reaches a maximum, and gradually decreases to zero at a distance sufficiently far from the surface. At the surface, the fluid temperature is equal to the plate temperature, and gradually decreases to the temperature of the surrounding fluid at a distance sufficiently far from the surface, as shown in the figure. In the case of *cold surfaces*, the shape of the velocity and temperature profiles remains the same but their direction is reversed.

Consider a differential volume element of height  $dx$ , length  $dy$ , and unit depth in the  $z$ -direction (normal to the paper) for analysis. The forces acting on this volume element are shown in Fig. 9–7. Newton's second law of motion for this volume element can be expressed as

$$\delta m \cdot a_x = F_x \quad (9-7)$$

where  $\delta m = \rho(dx \cdot dy \cdot 1)$  is the mass of the fluid within the volume element. The acceleration in the  $x$ -direction is obtained by taking the total differential of  $u(x, y)$ , which is  $du = (\partial u / \partial x)dx + (\partial u / \partial y)dy$ , and dividing it by  $dt$ . We get

$$a_x = \frac{du}{dt} = \frac{\partial u}{\partial x} \frac{dx}{dt} + \frac{\partial u}{\partial y} \frac{dy}{dt} = u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \quad (9-8)$$

**FIGURE 9–5**  
Isotherms in natural convection over a hot plate in air.

**FIGURE 9–6**  
Typical velocity and temperature profiles for natural convection flow over a hot vertical plate at temperature  $T_s$  inserted in a fluid at temperature  $T_\infty$ .

**FIGURE 9-7**

Forces acting on a differential volume element in the natural convection boundary layer over a vertical flat plate.

The forces acting on the differential volume element in the vertical direction are the pressure forces acting on the top and bottom surfaces, the shear stresses acting on the side surfaces (the normal stresses acting on the top and bottom surfaces are small and are disregarded), and the force of gravity acting on the entire volume element. Then the net surface force acting in the  $x$ -direction becomes

$$\begin{aligned} F_x &= \left( \frac{\partial \tau}{\partial y} dy \right) (dx \cdot 1) - \left( \frac{\partial P}{\partial x} dx \right) (dy \cdot 1) - \rho g (dx \cdot dy \cdot 1) \\ &= \left( \mu \frac{\partial^2 u}{\partial y^2} - \frac{\partial P}{\partial x} - \rho g \right) (dx \cdot dy \cdot 1) \end{aligned} \quad (9-9)$$

since  $\tau = \mu(\partial u / \partial y)$ . Substituting Eqs. 9-8 and 9-9 into Eq. 9-7 and dividing by  $\rho \cdot dx \cdot dy \cdot 1$  gives the *conservation of momentum* in the  $x$ -direction as

$$\rho \left( u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right) = \mu \frac{\partial^2 u}{\partial y^2} - \frac{\partial P}{\partial x} - \rho g \quad (9-10)$$

The  $x$ -momentum equation in the quiescent fluid outside the boundary layer can be obtained from the relation above as a special case by setting  $u = 0$ . It gives

$$\frac{\partial P_\infty}{\partial x} = -\rho_\infty g \quad (9-11)$$

which is simply the relation for the variation of hydrostatic pressure in a quiescent fluid with height, as expected. Also, noting that  $v \ll u$  in the boundary layer and thus  $\partial v / \partial x \approx \partial v / \partial y \approx 0$ , and that there are no body forces (including gravity) in the  $y$ -direction, the force balance in that direction gives  $\partial P / \partial y = 0$ . That is, the variation of pressure in the direction normal to the surface is negligible, and for a given  $x$  the pressure in the boundary layer is equal to the pressure in the quiescent fluid. Therefore,  $P = P(x) = P_\infty(x)$  and  $\partial P / \partial x = \partial P_\infty / \partial x = -\rho_\infty g$ . Substituting into Eq. 9-10,

$$\rho \left( u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right) = \mu \frac{\partial^2 u}{\partial y^2} + (\rho_\infty - \rho)g \quad (9-12)$$

The last term represents the net upward force per unit volume of the fluid (the difference between the buoyant force and the fluid weight). This is the force that initiates and sustains convection currents.

From Eq. 9-5, we have  $\rho_\infty - \rho = \rho\beta(T - T_\infty)$ . Substituting it into the last equation and dividing both sides by  $\rho$  gives the desired form of the  $x$ -momentum equation,

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \nu \frac{\partial^2 u}{\partial y^2} + g\beta(T - T_\infty) \quad (9-13)$$

This is the equation that governs the fluid motion in the boundary layer due to the effect of buoyancy. Note that the momentum equation involves the temperature, and thus the momentum and energy equations must be solved simultaneously.

The complete set of conservation equations, continuity (Eq. 6-39), momentum (Eq. 9-13), and energy (Eq. 6-41) that govern natural convection flow over vertical isothermal plates are:

Continuity:  $\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0$  (Eq. 6-39)

Momentum:  $u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \nu \frac{\partial^2 u}{\partial y^2} + g\beta(T - T_\infty)$  (Eq. 9-13)

Energy:  $u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y} = \alpha \frac{\partial^2 T}{\partial y^2}$  (Eq. 6-41)

with the following boundary conditions (see Fig. 9-6):

At  $y = 0$ :  $u(x, 0) = 0, v(x, 0) = 0, T(x, 0) = T_s$

At  $y \rightarrow \infty$ :  $u(x, \infty) \rightarrow 0, v(x, \infty) \rightarrow 0, T(x, \infty) \rightarrow T_\infty$

The above set of three partial differential equations can be reduced to a set of two ordinary nonlinear differential equations by the introduction of a similarity variable. But the resulting equations must still be solved along with their transformed boundary conditions numerically [Ostrach (1953)]. Interested readers are referred to advanced books on the topic for detailed discussions [e.g., Kays, Crawford, and Weigand (2005)].

## The Grashof Number

The governing equations of natural convection and the boundary conditions can be nondimensionalized by dividing all dependent and independent variables by suitable constant quantities: all lengths by a characteristic length  $L_c$ , all velocities by an arbitrary reference velocity  $V$  (which, from the definition of Reynolds number, is taken to be  $V = \text{Re}_L \nu/L_c$ ), and temperature by a suitable temperature difference (which is taken to be  $T_s - T_\infty$ ) as

$$x^* = \frac{x}{L_c}, y^* = \frac{y}{L_c}, u^* = \frac{u}{V}, v^* = \frac{v}{V} \text{ and } T^* = \frac{T - T_\infty}{T_s - T_\infty}$$

where asterisks are used to denote nondimensional variables. The nondimensionalized forms of continuity (Eq. 6-64) and energy (Eq. 6-66) equations derived in Chapter 6 are still applicable here. However, the nondimensionalized momentum equation due to buoyancy effects will be different. Nondimensionalizing the momentum equation (Eq. 9-13) with the above parameters and simplifying gives

$$u^* \frac{\partial u^*}{\partial x^*} + v^* \frac{\partial u^*}{\partial y^*} = \left[ \frac{g\beta(T_s - T_\infty)L_c^3}{\nu^2} \right] \frac{T^*}{\text{Re}_L^2} + \frac{1}{\text{Re}_L} \frac{\partial^2 u^*}{\partial y^{*2}} \quad (9-14)$$

The dimensionless parameter in the brackets represents the natural convection effects, and is called the **Grashof number**  $\text{Gr}_L$  (Fig. 9-8),

$$\text{Gr}_L = \frac{g\beta(T_s - T_\infty)L_c^3}{\nu^2} \quad (9-15)$$

**FIGURE 9-8**

**Franz Grashof** (1826–1893), a German engineer, was born at Düsseldorf, Germany. He was one of the founding leaders of the Society of German Engineers VDI (Verein Deutscher Ingenieure) and assumed an enormous load as author, editor, corrector, and dispatcher of publications. By 1863, Grashof's name was so esteemed that the Technical of Karlsruhe appointed him to be a successor Superintendent of the Engineering School. He also served as Professor of Applied Mechanics and Mechanical Engineering where his renowned lectures included "Strength of Materials," "Hydraulics," "Theory of Heat," and "General Engineering." After Grashof's death, the Society of German Engineers honored his memory by instituting the Grashof Commemorative Medal as the highest distinction that the society could bestow for merit in the engineering skills. The dimensionless **Grashof number** representing the ratio of buoyant forces to viscous forces is named after him.

**FIGURE 9–9**

The Grashof number  $Gr$  is a measure of the relative magnitudes of the *buoyancy force* and the opposing *viscous force* acting on the fluid.

where

$$g = \text{gravitational acceleration, m/s}^2$$

$$\beta = \text{coefficient of volume expansion, } 1/K \ (\beta = 1/T \text{ for ideal gases})$$

$$T_s = \text{temperature of the surface, } ^\circ\text{C}$$

$$T_\infty = \text{temperature of the fluid sufficiently far from the surface, } ^\circ\text{C}$$

$$L_c = \text{characteristic length of the geometry, m}$$

$$\nu = \text{kinematic viscosity of the fluid, } \text{m}^2/\text{s}$$

We mentioned in the preceding chapters that the flow regime in forced convection is governed by the dimensionless *Reynolds number*, which represents the ratio of inertial forces to viscous forces acting on the fluid. The flow regime in natural convection is governed by the dimensionless *Grashof number*, which represents the ratio of the *buoyancy force* to the *viscous force* acting on the fluid (Fig. 9–9).

The role played by the Reynolds number in forced convection is played by the Grashof number in natural convection. As such, the Grashof number provides the main criterion in determining whether the fluid flow is laminar or turbulent in natural convection. For vertical plates, for example, the critical Grashof number is observed to be about  $10^9$ . Therefore, the flow regime on a vertical plate becomes *turbulent* at Grashof numbers greater than  $10^9$ .

When a surface is subjected to external flow, the problem involves both natural and forced convection. The relative importance of each mode of heat transfer is determined by the value of the coefficient  $Gr_L/Re_L^2$ , which appears in Eq. 9–14 (Fig. 9–10). If  $Gr_L/Re_L^2 \gg 1$ , inertia forces are negligible and natural convection effects dominate. Conversely, if  $Gr_L/Re_L^2 \ll 1$ , buoyancy forces are negligible and forced convection must be considered. For the case, that  $Gr_L/Re_L^2 \approx 1$ , both inertia and buoyancy forces are equally present and both natural and forced convection effects must be considered. In this case, the flow is referred to as **mixed convection**.

### 9–3 • NATURAL CONVECTION OVER SURFACES

Natural convection heat transfer on a surface depends on the geometry of the surface as well as its orientation. It also depends on the variation of temperature on the surface and the thermophysical properties of the fluid involved.

Although we understand the mechanism of natural convection well, the complexities of fluid motion make it very difficult to obtain simple analytical relations for heat transfer by solving the governing equations of motion and energy. Some analytical solutions exist for natural convection, but such solutions lack generality since they are obtained for simple geometries under some simplifying assumptions. Therefore, with the exception of some simple cases, heat transfer relations in natural convection are based on experimental studies. Of the numerous such correlations of varying complexity and claimed accuracy available in the literature for any given geometry, we present here the ones that are best known and widely used.

(a) Natural convection ( $Gr_L / Re_L^2 \gg 1$ )(b) Forced convection ( $Gr_L / Re_L \ll 1$ )(c) Mixed convection ( $Gr_L / Re_L^2 \approx 1$ )**FIGURE 9–10**

The relative importance of convection heat transfer regimes for flow near a hot sphere.

The simple empirical correlations for the average *Nusselt number* Nu in natural convection are of the form (Fig. 9–11)

$$\text{Nu} = \frac{hL_c}{k} = C(\text{Gr}_L \text{Pr})^n = C \text{Ra}_L^n \quad (9-16)$$

where  $\text{Ra}_L$  is the **Rayleigh number** (Fig. 9–12), which is the product of the Grashof number, which describes the relationship between buoyancy and viscosity within the fluid, and the Prandtl number, which describes the relationship between momentum diffusivity and thermal diffusivity. Hence the Rayleigh number itself may also be viewed as the ratio of buoyancy forces and (the products of) thermal and momentum diffusivities.

$$\text{Ra}_L = \text{Gr}_L \text{Pr} = \frac{g\beta(T_s - T_\infty)L_c^3}{\nu^2} \text{Pr} = \frac{g\beta(T_s - T_\infty)L_c^3}{\nu\alpha} \quad (9-17)$$

The values of the constants  $C$  and  $n$  depend on the *geometry* of the surface and the *flow regime*, which is characterized by the range of the Rayleigh number. The value of  $n$  is usually  $\frac{1}{4}$  for laminar flow and  $\frac{1}{3}$  for turbulent flow. The value of the constant  $C$  is normally less than 1.

Simple relations for the average Nusselt number for various geometries are given in Table 9–1, together with sketches of the geometries. Also given in this table are the characteristic lengths of the geometries and the ranges of Rayleigh number in which the relation is applicable. All fluid properties are to be evaluated at the film temperature  $T_f = \frac{1}{2}(T_s + T_\infty)$ .

When the average Nusselt number and thus the average convection coefficient is known, the rate of heat transfer by natural convection from a solid surface at a uniform temperature  $T_s$  to the surrounding fluid is expressed by Newton's law of cooling as

$$\dot{Q}_{\text{conv}} = hA_s(T_s - T_\infty) \quad (\text{W}) \quad (9-18)$$

where  $A_s$  is the heat transfer surface area and  $h$  is the average heat transfer coefficient on the surface.

## Vertical Plates ( $T_s = \text{constant}$ )

For a vertical flat plate, the characteristic length is the plate height  $L$ . In Table 9–1 we give three relations for the average Nusselt number for an isothermal vertical plate. The first two relations are very simple. Despite its complexity, we suggest using the third one (Eq. 9–21) recommended by Churchill and Chu (1975) since it is applicable over the entire range of Rayleigh number. This relation is most accurate in the range of  $10^{-1} < \text{Ra}_L < 10^9$ .

## Vertical Plates ( $\dot{q}_s = \text{constant}$ )

In the case of constant surface heat flux, the rate of heat transfer is known (it is simply  $\dot{Q} = \dot{q}_s A_s$ ), but the surface temperature  $T_s$  is not. In fact,  $T_s$  increases with height along the plate. It turns out that the Nusselt number relations for the constant surface temperature and constant surface heat flux cases

**FIGURE 9–11**

Natural convection heat transfer correlations are usually expressed in terms of the Rayleigh number raised to a constant  $n$  multiplied by another constant  $C$ , both of which are determined experimentally.

**FIGURE 9–12**

**Lord Rayleigh** (1842–1919), born John William Strutt, an English physicist, was born at Langford Grove, Maldon, Essex.

He, with William Ramsay, discovered the element argon, an achievement for which he received the Nobel Prize for Physics in 1904. Rayleigh also discovered the phenomenon now called Rayleigh scattering, explaining why the sky is blue, and predicted the existence of the surface waves known as Rayleigh waves. The **Rayleigh number** is named after him.

[http://commons.wikimedia.org/wiki/File:John\\_William\\_Strutt.jpg](http://commons.wikimedia.org/wiki/File:John_William_Strutt.jpg); from "Obituary Notices of Fellows Deceased," *Proceeding of the Royal Society of London. Series A, Containing Papers of a Mathematical and Physical Character* Vol. 98, No. 695 (Mar. 24, 1921).

TABLE 9-1

Empirical correlations for the average Nusselt number for natural convection over surfaces

| Geometry  | Characteristic length $L_c$   | Range of Ra | Nu   |  |
|---|---|-------------|--|--|
| Vertical plate  |    | $L$         | $\text{Nu} = 0.59\text{Ra}_L^{1/4}$ (9-19)<br>$\text{Nu} = 0.1\text{Ra}_L^{1/3}$ (9-20)<br>$\text{Nu} = \left\{ 0.825 + \frac{0.387\text{Ra}_L^{1/6}}{[1 + (0.492/\text{Pr})^{9/16}]^{8/27}} \right\}^2$ (9-21)<br>(complex but more accurate) |  |
| Inclined plate  |    | $L$         | Use vertical plate equations for the upper surface of a cold plate and the lower surface of a hot plate<br>Replace $g$ by $g \cos\theta$ for $0 < \theta < 60^\circ$   |  |
| Horizontal plate<br>(Surface area $A$ and perimeter $p$ )<br>(a) Upper surface of a hot plate<br>(or lower surface of a cold plate) |    | $A_s/p$     | $\text{Nu} = 0.59\text{Ra}_L^{1/4}$ (9-22)<br>$\text{Nu} = 0.1\text{Ra}_L^{1/3}$ (9-23)  |  |
| (b) Lower surface of a hot plate<br>(or upper surface of a cold plate)  |  |             | $\text{Nu} = 0.27\text{Ra}_L^{1/4}$ (9-24)   |  |
| Vertical cylinder   |  | $L$         | A vertical cylinder can be treated as a vertical plate when<br>$D \geq \frac{35L}{\text{Gr}_L^{1/4}}$  |  |
| Horizontal cylinder   |  | $D$         | $\text{Ra}_D \leq 10^{12}$   | $\text{Nu} = \left\{ 0.6 + \frac{0.387\text{Ra}_D^{1/6}}{[1 + (0.559/\text{Pr})^{9/16}]^{8/27}} \right\}^2$ (9-25) |
| Sphere  |  | $D$         | $\text{Ra}_D \leq 10^{11}$<br>$(\text{Pr} \geq 0.7)$   | $\text{Nu} = 2 + \frac{0.589\text{Ra}_D^{1/4}}{[1 + (0.469/\text{Pr})^{9/16}]^{4/9}}$ (9-26)                       |

are nearly identical [Churchill and Chu (1975)]. Therefore, the relations for isothermal plates can also be used for plates subjected to constant heat flux, provided that the plate midpoint temperature  $T_{L/2}$  is used for  $T_s$  in the evaluation of the film temperature, Rayleigh number, and the Nusselt number. Noting that  $h = \dot{q}_s/(T_{L/2} - T_\infty)$ , the average Nusselt number in this case can be expressed as

$$\text{Nu} = \frac{hL}{k} = \frac{\dot{q}_s L}{k(T_{L/2} - T_\infty)} \quad (9-27)$$

The midpoint temperature  $T_{L/2}$  is determined by iteration so that the Nusselt numbers determined from Eqs. 9-21 and 9-27 match.

## Vertical Cylinders

An outer surface of a vertical cylinder can be treated as a vertical plate when the diameter of the cylinder is sufficiently large so that the curvature effects are negligible. This condition is satisfied if

$$D \geq \frac{35L}{\text{Gr}_L^{1/4}} \quad (9-28)$$

When this criteria is met, the relations for vertical plates can also be used for vertical cylinders. Nusselt number relations for slender cylinders that do not meet this criteria are available in the literature [e.g., Cebeci (1974)].

## Inclined Plates

Consider an inclined hot plate that makes an angle  $\theta$  from the vertical, as shown in Fig. 9-13, in a cooler environment. The net force  $F = g(\rho_\infty - \rho)$  (the difference between the buoyancy and gravity) acting on a unit volume of the fluid in the boundary layer is always in the vertical direction. In the case of inclined plate, this force can be resolved into two components:  $F_x = F \cos \theta$  parallel to the plate that drives the flow along the plate, and  $F_y = F \sin \theta$  normal to the plate. Noting that the force that drives the motion is reduced, we expect the convection currents to be weaker, and the rate of heat transfer to be lower relative to the vertical plate case.

The experiments confirm what we suspect for the lower surface of a hot plate, but the opposite is observed on the upper surface. The reason for this curious behavior for the upper surface is that the force component  $F_y$  initiates upward motion in addition to the parallel motion along the plate, and thus the boundary layer breaks up and forms plumes, as shown in the figure. As a result, the thickness of the boundary layer and thus the resistance to heat transfer decreases, and the rate of heat transfer increases relative to the vertical orientation.

In the case of a cold plate in a warmer environment, the opposite occurs as expected: The boundary layer on the upper surface remains intact with weaker

**FIGURE 9-13**  
Natural convection flows on the upper and lower surfaces of an inclined hot plate.

**FIGURE 9–14**

Natural convection flows on the upper and lower surfaces of a horizontal hot plate.

boundary layer flow and thus lower rate of heat transfer, and the boundary layer on the lower surface breaks apart (the colder fluid falls down) and thus enhances heat transfer.

When the boundary layer remains intact (the lower surface of a hot plate or the upper surface of a cold plate), the Nusselt number can be determined from the vertical plate relations provided that  $g$  in the Rayleigh number relation is replaced by  $g \cos\theta$  for  $\theta < 60^\circ$ . Nusselt number relations for the other two surfaces (the upper surface of a hot plate or the lower surface of a cold plate) are available in the literature [e.g., Fujii and Imura (1972)].

## Horizontal Plates

The rate of heat transfer to or from a horizontal surface depends on whether the surface is facing upward or downward. For a hot surface in a cooler environment, the net force acts upward, forcing the heated fluid to rise. If the hot surface is facing upward, the heated fluid rises freely, inducing strong natural convection currents and thus effective heat transfer, as shown in Fig. 9–14. But if the hot surface is facing downward, the plate blocks the heated fluid that tends to rise (except near the edges), impeding heat transfer. The opposite is true for a cold plate in a warmer environment since the net force (weight minus buoyancy force) in this case acts downward, and the cooled fluid near the plate tends to descend.

The average Nusselt number for horizontal surfaces can be determined from the simple power-law relations given in Table 9–1. The characteristic length for horizontal surfaces is calculated from

$$L_c = \frac{A_s}{p} \quad (9-29)$$

where  $A_s$  is the surface area and  $p$  is the perimeter. Note that  $L_c = a/4$  for a horizontal square surface of length  $a$ , and  $D/4$  for a horizontal circular surface of diameter  $D$ .

**FIGURE 9–15**

Natural convection flow over a horizontal hot cylinder.

## Horizontal Cylinders and Spheres

The boundary layer over a hot horizontal cylinder starts to develop at the bottom, increasing in thickness along the circumference, and forming a rising plume at the top, as shown in Fig. 9–15. Therefore, the local Nusselt number is highest at the bottom, and lowest at the top of the cylinder when the boundary layer flow remains laminar. The opposite is true in the case of a cold horizontal cylinder in a warmer medium, and the boundary layer in this case starts to develop at the top of the cylinder and ending with a descending plume at the bottom.

The average Nusselt number over the entire surface can be determined from Eq. 9–25 [Churchill and Chu (1975)] for an isothermal horizontal cylinder, and from Eq. 9–26 for an isothermal sphere [Churchill (1983)], both given in Table 9–1.

**EXAMPLE 9–1 Heat Loss from Hot-Water Pipes**

A 6-m-long section of an 8-cm-diameter horizontal hot-water pipe shown in Fig. 9–16 passes through a large room whose temperature is 20°C. If the outer surface temperature of the pipe is 70°C, determine the rate of heat loss from the pipe by natural convection.

**SOLUTION** A horizontal hot-water pipe passes through a large room. The rate of heat loss from the pipe by natural convection is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Air is an ideal gas. 3 The local atmospheric pressure is 1 atm.

**Properties** The properties of air at the film temperature of  $T_f = (T_s + T_\infty)/2 = (70 + 20)/2 = 45^\circ\text{C}$  and 1 atm are (Table A–15)

$$\begin{aligned} k &= 0.02699 \text{ W/m}\cdot\text{K} & \text{Pr} &= 0.7241 \\ \nu &= 1.750 \times 10^{-5} \text{ m}^2/\text{s} & \beta &= \frac{1}{T_f} = \frac{1}{318 \text{ K}} \end{aligned}$$

**Analysis** The characteristic length in this case is the outer diameter of the pipe,  $L_c = D = 0.08 \text{ m}$ . Then the Rayleigh number becomes

$$\begin{aligned} \text{Ra}_D &= \frac{g\beta(T_s - T_\infty)D^3}{\nu^2} \text{Pr} \\ &= \frac{(9.81 \text{ m/s}^2)[1/(318 \text{ K})](70 - 20 \text{ K})(0.08 \text{ m})^3}{(1.750 \times 10^{-5} \text{ m}^2/\text{s})^2} (0.7241) = 1.867 \times 10^6 \end{aligned}$$

The natural convection Nusselt number in this case can be determined from Eq. 9–25 to be

$$\begin{aligned} \text{Nu} &= \left\{ 0.6 + \frac{0.387 \text{Ra}_D^{1/6}}{[1 + (0.559/\text{Pr})^{9/16}]^{8/27}} \right\}^2 = \left\{ 0.6 + \frac{0.387(1.867 \times 10^6)^{1/6}}{[1 + (0.559/0.7241)^{9/16}]^{8/27}} \right\}^2 \\ &= 17.39 \end{aligned}$$

Then,

$$h = \frac{k}{D} \text{Nu} = \frac{0.02699 \text{ W/m}\cdot\text{K}}{0.08 \text{ m}} (17.39) = 5.867 \text{ W/m}\cdot\text{K}$$

$$A_s = \pi D L = \pi(0.08 \text{ m})(6 \text{ m}) = 1.508 \text{ m}^2$$

and

$$\dot{Q} = h A_s (T_s - T_\infty) = (5.867 \text{ W/m}\cdot\text{K})(1.508 \text{ m}^2)(70 - 20)^\circ\text{C} = 442 \text{ W}$$

Therefore, the pipe loses heat to the air in the room at a rate of 442 W by natural convection.

**Discussion** The pipe loses heat to the surroundings by radiation as well as by natural convection. Assuming the outer surface of the pipe to be black (emissivity  $\varepsilon = 1$ ) and the inner surfaces of the walls of the room to be at room temperature, the radiation heat transfer is determined to be (Fig. 9–17)

$$\begin{aligned} \dot{Q}_{\text{rad}} &= \varepsilon A_s \sigma (T_s^4 - T_{\text{surr}}^4) \\ &= (1)(1.508 \text{ m}^2)(5.67 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4)[(70 + 273 \text{ K})^4 - (20 + 273 \text{ K})^4] \\ &= 553 \text{ W} \end{aligned}$$

**FIGURE 9–16**  
Schematic for Example 9–1.

**FIGURE 9–17**  
Radiation heat transfer is usually comparable to natural convection in magnitude and should be considered in heat transfer analysis.

**FIGURE 9-18**

Schematic for Example 9-2.

which is larger than natural convection. The emissivity of a real surface is less than 1, and thus the radiation heat transfer for a real surface will be less. But radiation will still be significant for most systems cooled by natural convection. Therefore, a radiation analysis should normally accompany a natural convection analysis unless the emissivity of the surface is low.

### EXAMPLE 9-2 Cooling of a Plate in Different Orientations

Consider a  $0.6\text{-m} \times 0.6\text{-m}$  thin square plate in a room at  $30^\circ\text{C}$ . One side of the plate is maintained at a temperature of  $90^\circ\text{C}$ , while the other side is insulated, as shown in Fig. 9-18. Determine the rate of heat transfer from the plate by natural convection if the plate is (a) vertical, (b) horizontal with hot surface facing up, and (c) horizontal with hot surface facing down.

**SOLUTION** A hot plate with an insulated back is considered. The rate of heat loss by natural convection is to be determined for different orientations.

**Assumptions** 1 Steady operating conditions exist. 2 Air is an ideal gas. 3 The local atmospheric pressure is 1 atm.

**Properties** The properties of air at the film temperature of  $T_f = (T_s + T_\infty)/2 = (90 + 30)/2 = 60^\circ\text{C}$  and 1 atm are (Table A-15)

$$k = 0.02808 \text{ W/m}\cdot\text{K} \quad \text{Pr} = 0.7202$$

$$\nu = 1.896 \times 10^{-5} \text{ m}^2/\text{s} \quad \beta = \frac{1}{T_f} = \frac{1}{333 \text{ K}}$$

**Analysis** (a) *Vertical*. The characteristic length in this case is the height of the plate, which is  $L = 0.6 \text{ m}$ . The Rayleigh number is

$$\begin{aligned} \text{Ra}_L &= \frac{g\beta(T_s - T_\infty)L^3}{\nu^2} \text{Pr} \\ &= \frac{(9.81 \text{ m/s}^2)[1/(333 \text{ K})](90 - 30 \text{ K})(0.6 \text{ m})^3}{(1.896 \times 10^{-5} \text{ m}^2/\text{s})^2} (0.7202) = 7.649 \times 10^8 \end{aligned}$$

Then the natural convection Nusselt number can be determined from Eq. 9-21 to be

$$\begin{aligned} \text{Nu} &= \left\{ 0.825 + \frac{0.387 \text{Ra}_L^{1/6}}{[1 + (0.492/\text{Pr})^{9/16}]^{8/27}} \right\}^2 \\ &= \left\{ 0.825 + \frac{0.387(7.649 \times 10^8)^{1/6}}{[1 + (0.492/0.7202)^{9/16}]^{8/27}} \right\}^2 = 113.3 \end{aligned}$$

Note that the simpler relation Eq. 9-19 would give  $\text{Nu} = 0.59 \text{ Ra}_L^{1/4} = 98.12$ , which is 13 percent lower. Then,

$$\begin{aligned} h &= \frac{k}{L} \text{Nu} = \frac{0.02808 \text{ W/m}\cdot\text{K}}{0.6 \text{ m}} (113.3) = 5.302 \text{ W/m}^2\cdot\text{K} \\ A_s &= L^2 = (0.6 \text{ m})^2 = 0.36 \text{ m}^2 \end{aligned}$$

and

$$\dot{Q} = hA_s(T_s - T_\infty) = (5.302 \text{ W/m}^2\cdot\text{K})(0.36 \text{ m}^2)(90 - 30)^\circ\text{C} = 115 \text{ W}$$

(b) *Horizontal with hot surface facing up.* The characteristic length and the Rayleigh number in this case are

$$L_c = \frac{A_s}{p} = \frac{L^2}{4L} = \frac{L}{4} = \frac{0.6 \text{ m}}{4} = 0.15 \text{ m}$$

$$\text{Ra}_L = \frac{g\beta(T_s - T_\infty)L_c^3}{\nu^2 \text{Pr}}$$

$$= \frac{(9.81 \text{ m/s}^2)[1/(333 \text{ K})](90 - 30 \text{ K})(0.15 \text{ m})^3}{(1.896 \times 10^{-5} \text{ m}^2/\text{s})^2 (0.7202)} = 1.195 \times 10^7$$

The natural convection Nusselt number can be determined from Eq. 9–22 to be

$$\text{Nu} = 0.54\text{Ra}_L^{1/4} = 0.54(1.195 \times 10^7)^{1/4} = 31.75$$

Then,

$$h = \frac{k}{L_c} \text{Nu} = \frac{0.02808 \text{ W/m}\cdot\text{K}}{0.15 \text{ m}} (31.75) = 5.944 \text{ W/m}^2\cdot\text{K}$$

and

$$\dot{Q} = hA_s(T_s - T_\infty) = (5.944 \text{ W/m}^2\cdot\text{K})(0.36 \text{ m}^2)(90 - 30)^\circ\text{C} = 128 \text{ W}$$

(c) *Horizontal with hot surface facing down.* The characteristic length and the Rayleigh number in this case are the same as those determined in (b). But the natural convection Nusselt number is to be determined from Eq. 9–24,

$$\text{Nu} = 0.27\text{Ra}_L^{1/4} = 0.27(1.195 \times 10^7)^{1/4} = 15.87$$

Then,

$$h = \frac{k}{L_c} \text{Nu} = \frac{0.02808 \text{ W/m}\cdot\text{K}}{0.15 \text{ m}} (15.87) = 2.971 \text{ W/m}^2\cdot\text{K}$$

and

$$\dot{Q} = hA_s(T_s - T_\infty) = (2.971 \text{ W/m}^2\cdot\text{K})(0.36 \text{ m}^2)(90 - 30)^\circ\text{C} = 64.2 \text{ W}$$

Note that the natural convection heat transfer is the lowest in the case of the hot surface facing down. This is not surprising, since the hot air is “trapped” under the plate in this case and cannot get away from the plate easily. As a result, the cooler air in the vicinity of the plate will have difficulty reaching the plate, which results in a reduced rate of heat transfer.

**Discussion** The plate will lose heat to the surroundings by radiation as well as by natural convection. Assuming the surface of the plate to be black (emissivity  $\varepsilon = 1$ ) and the inner surfaces of the walls of the room to be at room temperature, the radiation heat transfer in this case is determined to be

$$\begin{aligned} \dot{Q}_{\text{rad}} &= \varepsilon A_s \sigma (T_s^4 - T_{\text{surr}}^4) \\ &= (1)(0.36 \text{ m}^2)(5.67 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4)[(90 + 273 \text{ K})^4 - (30 + 273 \text{ K})^4] \\ &= 182 \text{ W} \end{aligned}$$

which is larger than that for natural convection heat transfer for each case. Therefore, radiation can be significant and needs to be considered in surfaces cooled by natural convection.

**FIGURE 9–19**

Natural convection flow through a channel between two isothermal vertical plates.

## 9–4 ▪ NATURAL CONVECTION FROM FINNED SURFACES AND PCBs

Natural convection flow through a channel formed by two parallel plates as shown in Fig. 9–19 is commonly encountered in practice. When the plates are hot ( $T_s < T_\infty$ ), the ambient fluid at  $T_\infty$  enters the channel from the lower end, rises as it is heated under the effect of buoyancy, and the heated fluid leaves the channel from the upper end. The plates could be the fins of a finned heat sink, or the PCBs (printed circuit boards) of an electronic device. The plates can be approximated as being isothermal ( $T_s = \text{constant}$ ) in the first case, and isoflux ( $\dot{q}_s = \text{constant}$ ) in the second case.

Boundary layers start to develop at the lower ends of opposing surfaces, and eventually merge at the midplane if the plates are vertical and sufficiently long. In this case, we will have fully developed channel flow after the merger of the boundary layers, and the natural convection flow is analyzed as channel flow. But when the plates are short or the spacing is large, the boundary layers of opposing surfaces never reach each other, and the natural convection flow on a surface is not affected by the presence of the opposing surface. In that case, the problem should be analyzed as natural convection from two independent plates in a quiescent medium, using the relations given for surfaces, rather than natural convection flow through a channel.

### Natural Convection Cooling of Finned Surfaces ( $T_s = \text{constant}$ )

Finned surfaces of various shapes, called *heat sinks*, are frequently used in the cooling of electronic devices. Energy dissipated by these devices is transferred to the heat sinks by conduction and from the heat sinks to the ambient air by natural or forced convection, depending on the power dissipation requirements. Natural convection is the preferred mode of heat transfer since it involves no moving parts, like the electronic components themselves. However, in the natural convection mode, the components are more likely to run at a higher temperature and thus undermine reliability. A properly selected heat sink may considerably lower the operation temperature of the components and thus reduce the risk of failure.

Natural convection from vertical finned surfaces of rectangular shape has been the subject of numerous studies, mostly experimental. Bar-Cohen and Rohsenow (1984) have compiled the available data under various boundary conditions, and developed correlations for the Nusselt number and optimum spacing. The characteristic length for vertical parallel plates used as fins is usually taken to be the spacing between adjacent fins  $S$ , although the fin height  $L$  could also be used. The Rayleigh number is expressed as

$$\text{Ra}_S = \frac{g\beta(T_s - T_\infty)S^3}{\nu^2} \text{Pr} \quad \text{and} \quad \text{Ra}_L = \frac{g\beta(T_s - T_\infty)L^3}{\nu^2} \text{Pr} = \text{Ra}_S \frac{L^3}{S^3} \quad (9-30)$$

The recommended relation for the average Nusselt number for vertical isothermal parallel plates is

$$T_s = \text{constant}: \quad \text{Nu} = \frac{hS}{k} = \left[ \frac{576}{(\text{Ra}_S S/L)^2} + \frac{2.873}{(\text{Ra}_S S/L)^{0.5}} \right]^{-0.5} \quad (9-31)$$

A question that often arises in the selection of a heat sink is whether to select one with *closely packed fins* or *widely spaced fins* for a given base area (Fig. 9–20). A heat sink with closely packed fins will have greater surface area for heat transfer but a smaller heat transfer coefficient because of the extra resistance the additional fins introduce to fluid flow through the interfin passages. A heat sink with widely spaced fins, on the other hand, will have a higher heat transfer coefficient but a smaller surface area. Therefore, there must be an *optimum spacing* that maximizes the natural convection heat transfer from the heat sink for a given base area  $WL$ , where  $W$  and  $L$  are the width and height of the base of the heat sink, respectively, as shown in Fig. 9–21. When the fins are essentially isothermal and the fin thickness  $t$  is small relative to the fin spacing  $S$ , the optimum fin spacing for a vertical heat sink is determined by Bar-Cohen and Rohsenow to be

$$T_s = \text{constant: } S_{\text{opt}} = 2.714 \left( \frac{S^3 L}{\text{Ra}_S} \right)^{0.25} = 2.714 \frac{L}{\text{Ra}_L^{0.25}} \quad (9-32)$$

It can be shown by combining the three equations above that when  $S = S_{\text{opt}}$ , the Nusselt number is a constant and its value is 1.307,

$$S = S_{\text{opt}}; \quad \text{Nu} = \frac{h S_{\text{opt}}}{k} = 1.307 \quad (9-33)$$

The rate of heat transfer by natural convection from the fins can be determined from

$$\dot{Q} = h(2nLH)(T_s - T_\infty) \quad (9-34)$$

where  $n = W/(S + t) \approx W/S$  is the number of fins on the heat sink and  $T_s$  is the surface temperature of the fins. All fluid properties are to be evaluated at the average temperature  $T_{\text{avg}} = (T_s + T_\infty)/2$ .

## Natural Convection Cooling of Vertical PCBs ( $\dot{q}_s = \text{constant}$ )

Arrays of printed circuit boards used in electronic systems can often be modeled as parallel plates subjected to constant heat flux  $\dot{q}_s$  (Fig. 9–22). The plate temperature in this case increases with height, reaching a maximum at the upper edge of the board. The modified Rayleigh number for constant heat flux on both plates is expressed as

$$\text{Ra}_S^* = \frac{g\beta\dot{q}_s S^4}{k\nu^2} \text{Pr} \quad (9-35)$$

The Nusselt number at the upper edge of the plate where maximum temperature occurs is determined from [Bar-Cohen and Rohsenow (1984)]

$$\text{Nu}_L = \frac{h_L S}{k} = \left[ \frac{48}{\text{Ra}_S^* S/L} + \frac{2.51}{(\text{Ra}_S^* S/L)^{0.4}} \right]^{-0.5} \quad (9-36)$$

FIGURE 9-20

Heat sinks with (a) widely spaced and (b) closely packed fins.

© Yunus A. Cengel

FIGURE 9-21

Various dimensions of a finned surface oriented vertically.

FIGURE 9-22

Arrays of vertical printed circuit boards (PCBs) cooled by natural convection.

The optimum fin spacing for the case of constant heat flux on both plates is given as

$$\dot{q}_s = \text{constant:} \quad S_{\text{opt}} = 2.12 \left( \frac{S^4 L}{\text{Ra}_s^*} \right)^{0.2} \quad (9-37)$$

The total rate of heat transfer from the plates is

$$\dot{Q} = \dot{q}_s A_s = \dot{q}_s (2nLH) \quad (9-38)$$

where  $n = W/(S + t) \approx W/S$  is the number of plates. The critical surface temperature  $T_L$  occurs at the upper edge of the plates, and it can be determined from

$$\dot{q}_s = h_L(T_L - T_\infty) \quad (9-39)$$

All fluid properties are to be evaluated at the average temperature  $T_{\text{avg}} = (T_L + T_\infty)/2$ .

## Mass Flow Rate through the Space between Plates

As we mentioned earlier, the magnitude of the natural convection heat transfer is directly related to the mass flow rate of the fluid, which is established by the dynamic balance of two opposing effects: *buoyancy* and *friction*.

The fins of a heat sink introduce both effects: *inducing extra buoyancy* as a result of the elevated temperature of the fin surfaces and *slowing down the fluid* by acting as an added obstacle on the flow path. As a result, increasing the number of fins on a heat sink can either enhance or reduce natural convection, depending on which effect is dominant. The buoyancy-driven fluid flow rate is established at the point where these two effects balance each other. The friction force increases as more and more solid surfaces are introduced, seriously disrupting fluid flow and heat transfer. Under some conditions, the increase in friction may more than offset the increase in buoyancy. This in turn will tend to reduce the flow rate and thus the heat transfer. For that reason, heat sinks with closely spaced fins are not suitable for natural convection cooling.

When the heat sink involves closely spaced fins, the narrow channels formed tend to block or “suffocate” the fluid, especially when the heat sink is long. As a result, the blocking action produced overwhelms the extra buoyancy and downgrades the heat transfer characteristics of the heat sink. Then, at a fixed power setting, the heat sink runs at a higher temperature relative to the no-shroud case. When the heat sink involves widely spaced fins, the shroud does not introduce a significant increase in resistance to flow, and the buoyancy effects dominate. As a result, heat transfer by natural convection may improve, and at a fixed power level the heat sink may run at a lower temperature.

When extended surfaces such as fins are used to enhance natural convection heat transfer between a solid and a fluid, the flow rate of the fluid in the vicinity of the solid adjusts itself to incorporate the changes in buoyancy and friction. It is obvious that this enhancement technique will work to advantage only when the increase in buoyancy is greater than the additional friction introduced. One does not need to be concerned with pressure drop or pumping power when studying natural convection since no pumps or blowers are

used in this case. Therefore, an enhancement technique in natural convection is evaluated on heat transfer performance alone.

The failure rate of an electronic component increases almost exponentially with operating temperature. The cooler the electronic device operates, the more reliable it is. A rule of thumb is that the semiconductor failure rate is halved for each 10°C reduction in junction operating temperature. The desire to lower the operating temperature without having to resort to forced convection has motivated researchers to investigate enhancement techniques for natural convection. Sparrow and Prakash (1987) have demonstrated that, under certain conditions, the use of discrete plates in lieu of continuous plates of the same surface area increases heat transfer considerably. In other experimental work, using transistors as the heat source, Çengel and Zing (1987) have demonstrated that temperature recorded on the transistor case dropped by as much as 30°C when a shroud was used, as opposed to the corresponding no-shroud case.

### EXAMPLE 9–3 Optimum Fin Spacing of a Heat Sink

A 12-cm-wide and 18-cm-high vertical hot surface in 30°C air is to be cooled by a heat sink with equally spaced fins of rectangular profile (Fig. 9–23). The fins are 0.1 cm thick and 18 cm long in the vertical direction and have a height of 2.4 cm from the base. Determine the optimum fin spacing and the rate of heat transfer by natural convection from the heat sink if the base temperature is 80°C.

**SOLUTION** A heat sink with equally spaced rectangular fins is to be used to cool a hot surface. The optimum fin spacing and the rate of heat transfer are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Air is an ideal gas. 3 The atmospheric pressure at that location is 1 atm. 4 The thickness  $t$  of the fins is very small relative to the fin spacing  $S$  so that Eq. 9–32 for optimum fin spacing is applicable. 5 All fin surfaces are isothermal at base temperature.

**Properties** The properties of air at the film temperature of  $T_f = (T_s + T_\infty)/2 = (80 + 30)/2 = 55^\circ\text{C}$  and 1 atm pressure are (Table A–15)

$$\begin{aligned} k &= 0.02772 \text{ W/m}\cdot\text{K} & \text{Pr} &= 0.7215 \\ \nu &= 1.847 \times 10^{-5} \text{ m}^2/\text{s} & \beta &= 1/T_f = 1/328 \text{ K} \end{aligned}$$

**Analysis** We take the characteristic length to be the length of the fins in the vertical direction (since we do not know the fin spacing). Then the Rayleigh number becomes

$$\begin{aligned} \text{Ra}_L &= \frac{g\beta(T_s - T_\infty)L^3}{\nu^2} \text{Pr} = \frac{(9.81 \text{ m/s}^2)[1/(328 \text{ K})](80 - 30 \text{ K})(0.18 \text{ m})^3}{(1.847 \times 10^{-5} \text{ m}^2/\text{s})^2} (0.7215) \\ &= 1.845 \times 10^7 \end{aligned}$$

The optimum fin spacing is determined from Eq. 9–32 to be

$$S_{\text{opt}} = 2.714 \frac{L}{\text{Ra}_L^{0.25}} = 2.714 \frac{0.18 \text{ m}}{(1.845 \times 10^7)^{0.25}} = 7.45 \times 10^{-3} \text{ m} = \mathbf{7.45 \text{ mm}}$$

**FIGURE 9–23**  
Schematic for Example 9–3.

which is about seven times the thickness of the fins. Therefore, the assumption of negligible fin thickness in this case is acceptable. The number of fins and the heat transfer coefficient for this optimum fin spacing case are

$$n = \frac{W}{S + t} = \frac{0.12 \text{ m}}{(0.00745 + 0.001) \text{ m}} \approx 14 \text{ fins}$$

The convection coefficient for this optimum fin spacing case is, from Eq. 9-33,

$$h = \text{Nu}_{\text{opt}} \frac{k}{S_{\text{opt}}} = 1.307 \frac{0.02772 \text{ W/m}\cdot\text{K}}{0.00745 \text{ m}} = 4.863 \text{ W/m}^2\cdot\text{K}$$

Then the rate of natural convection heat transfer becomes

$$\begin{aligned} \dot{Q} &= hA_s(T_s - T_\infty) = h(2nLH)(T_s - T_\infty) \\ &= (4.863 \text{ W/m}^2\cdot\text{K})[2 \times 14(0.18 \text{ m})(0.024 \text{ m})](80 - 30)^\circ\text{C} = 29.4 \text{ W} \end{aligned}$$

Therefore, this heat sink can dissipate heat by natural convection at a rate of 29.4 W.

**FIGURE 9-24**

Convective currents in a vertical rectangular enclosure.

**FIGURE 9-25**

Convective currents in a horizontal enclosure with (a) hot plate at the top and (b) hot plate at the bottom.

## 9-5 • NATURAL CONVECTION INSIDE ENCLOSURES

A considerable portion of heat loss from a typical residence occurs through the windows. We certainly would insulate the windows, if we could, in order to conserve energy. The problem is finding an insulating material that is transparent. An examination of the thermal conductivities of the insulating materials reveals that *air* is a *better insulator* than most common insulating materials. Besides, it is transparent. Therefore, it makes sense to insulate the windows with a layer of air. Of course, we need to use another sheet of glass to trap the air. The result is an *enclosure*, which is known as a *double-pane window* in this case. Other examples of enclosures include wall cavities, solar collectors, and cryogenic chambers involving concentric cylinders or spheres.

Enclosures are frequently encountered in practice, and heat transfer through them is of practical interest. Heat transfer in enclosed spaces is complicated by the fact that the fluid in the enclosure, in general, does not remain stationary. In a vertical enclosure, the fluid adjacent to the hotter surface rises and the fluid adjacent to the cooler one falls, setting off a rotary motion within the enclosure that enhances heat transfer through the enclosure. Typical flow patterns in vertical and horizontal rectangular enclosures are shown in Figs. 9-24 and 9-25.

The characteristics of heat transfer through a horizontal enclosure depend on whether the hotter plate is at the top or at the bottom, as shown in Fig. 9-25. When the hotter plate is at the *top*, no convection currents develop in the enclosure, since the lighter fluid is always on top of the heavier fluid. Heat transfer in this case is by *pure conduction*, and we have  $\text{Nu} = 1$ . When the hotter plate is at the *bottom*, the heavier fluid will be on top of the lighter fluid, and there will be a tendency for the lighter fluid to topple the heavier fluid and rise to the top, where it comes in contact with the cooler plate and cools down. Until that happens, however, heat transfer is still by *pure conduction* and  $\text{Nu} = 1$ . When  $\text{Ra}_L > 1708$ , the buoyant force overcomes the fluid resistance and initiates natural convection currents, which are observed to be

in the form of hexagonal cells called *Bénard cells*. For  $\text{Ra}_L < 3 \times 10^5$ , the cells break down and the fluid motion becomes turbulent.

The Rayleigh number for an enclosure is determined from

$$\text{Ra}_L = \frac{g\beta(T_1 - T_2)L_c^3}{\nu^2} \text{Pr} \quad (9-40)$$

where the characteristic length  $L_c$  is the distance between the hot and cold surfaces, and  $T_1$  and  $T_2$  are the temperatures of the hot and cold surfaces, respectively. All fluid properties are to be evaluated at the average fluid temperature  $T_{\text{avg}} = (T_1 + T_2)/2$ .

## Effective Thermal Conductivity

When the Nusselt number is known, the rate of heat transfer through the enclosure can be determined from

$$\dot{Q} = hA_s(T_1 - T_2) = k\text{Nu}A_s \frac{T_1 - T_2}{L_c} \quad (9-41)$$

since  $h = k\text{Nu}/L$ . The rate of steady heat conduction across a layer of thickness  $L_c$ , area  $A_s$ , and thermal conductivity  $k$  is expressed as

$$\dot{Q}_{\text{cond}} = kA_s \frac{T_1 - T_2}{L_c} \quad (9-42)$$

where  $T_1$  and  $T_2$  are the temperatures on the two sides of the layer. A comparison of this relation with Eq. 9-41 reveals that the convection heat transfer in an enclosure is analogous to heat conduction across the fluid layer in the enclosure provided that the thermal conductivity  $k$  is replaced by  $k\text{Nu}$ . That is, *the fluid in an enclosure behaves like a fluid whose thermal conductivity is  $k\text{Nu}$  as a result of convection currents*. Therefore, the quantity  $k\text{Nu}$  is called the **effective thermal conductivity** of the enclosure. That is,

$$k_{\text{eff}} = k\text{Nu} \quad (9-43)$$

Note that for the special case of  $\text{Nu} = 1$ , the effective thermal conductivity of the enclosure becomes equal to the conductivity of the fluid. This is expected since this case corresponds to pure conduction (Fig. 9-26).

Natural convection heat transfer in enclosed spaces has been the subject of many experimental and numerical studies, and numerous correlations for the Nusselt number exist. Simple power-law type relations in the form of  $\text{Nu} = CRa_L^n$ , where  $C$  and  $n$  are constants, are sufficiently accurate, but they are usually applicable to a narrow range of Prandtl and Rayleigh numbers and aspect ratios. The relations that are more comprehensive are naturally more complex. Next we present some widely used relations for various types of enclosures.

## Horizontal Rectangular Enclosures

We need no Nusselt number relations for the case of the hotter plate being at the top, since there are no convection currents in this case and heat transfer is downward by conduction ( $\text{Nu} = 1$ ). When the hotter plate is at the bottom, however, significant convection currents set in for  $\text{Ra}_L > 1708$ , and the rate of heat transfer increases (Fig. 9-27).

**FIGURE 9-26**

A Nusselt number of 3 for an enclosure indicates that heat transfer through the enclosure by *natural convection* is three times that by *pure conduction*.

**FIGURE 9-27**

A horizontal rectangular enclosure with isothermal surfaces.

For horizontal enclosures that contain air, Jakob (1949) recommends the following simple correlations

$$\text{Nu} = 0.195 \text{Ra}_L^{1/4} \quad 10^4 < \text{Ra}_L < 4 \times 10^5 \quad (9-44)$$

$$\text{Nu} = 0.068 \text{Ra}_L^{1/3} \quad 4 \times 10^5 < \text{Ra}_L < 10^7 \quad (9-45)$$

These relations can also be used for other gases with  $0.5 < \text{Pr} < 2$ . Using water, silicone oil, and mercury in their experiments, Globe and Dropkin (1959) obtained this correlation for horizontal enclosures heated from below,

$$\text{Nu} = 0.069 \text{Ra}_L^{1/3} \text{Pr}^{0.074} \quad 3 \times 10^5 < \text{Ra}_L < 7 \times 10^9 \quad (9-46)$$

Based on experiments with air, Hollands et al. (1976) recommend this correlation for horizontal enclosures,

$$\text{Nu} = 1 + 1.44 \left[ 1 - \frac{1708}{\text{Ra}_L} \right]^+ + \left[ \frac{\text{Ra}_L^{1/3}}{18} - 1 \right]^+ \quad \text{Ra}_L < 10^8 \quad (9-47)$$

The notation  $[ ]^+$  indicates that if the quantity in the bracket is negative, it should be set equal to zero. This relation also correlates data well for liquids with moderate Prandtl numbers for  $\text{Ra}_L < 10^5$ , and thus it can also be used for water.

## Inclined Rectangular Enclosures

Air spaces between two inclined parallel plates are commonly encountered in flat-plate solar collectors (between the glass cover and the absorber plate) and the double-pane skylights on inclined roofs. Heat transfer through an inclined enclosure depends on the **aspect ratio**  $H/L$  as well as the tilt angle  $\theta$  from the horizontal (Fig. 9–28).

For large aspect ratios ( $H/L \geq 12$ ), this equation [Hollands et al. (1976)] correlates experimental data extremely well for tilt angles up to  $70^\circ$ ,

$$\text{Nu} = 1 + 1.44 \left[ 1 - \frac{1708}{\text{Ra}_L \cos \theta} \right]^+ \left( 1 - \frac{1708(\sin 1.8\theta)^{1.6}}{\text{Ra}_L \cos \theta} \right) + \left[ \frac{(\text{Ra}_L \cos \theta)^{1/3}}{18} - 1 \right]^+ \quad (9-48)$$

for  $\text{Ra}_L < 10^5$ ,  $0 < \theta < 70^\circ$ , and  $H/L \geq 12$ . Again, any quantity in  $[ ]^+$  should be set equal to zero if it is negative. This is to ensure that  $\text{Nu} = 1$  for  $\text{Ra}_L \cos \theta < 1708$ . Note that this relation reduces to Eq. 9–47 for horizontal enclosures for  $\theta = 0^\circ$ , as expected.

For enclosures with smaller aspect ratios ( $H/L < 12$ ), the next correlation can be used provided that the tilt angle is less than the critical value  $\theta_{\text{cr}}$  listed in Table 9–2 [Catton (1978)].

$$\text{Nu} = \text{Nu}_{\theta=0^\circ} \left( \frac{\text{Nu}_{\theta=90^\circ}}{\text{Nu}_{\theta=0^\circ}} \right)^{\theta/\theta_{\text{cr}}} (\sin \theta_{\text{cr}})^{\theta/(4\theta_{\text{cr}})} \quad 0^\circ < \theta < \theta_{\text{cr}} \quad (9-49)$$

For tilt angles greater than the critical value ( $\theta_{\text{cr}} < \theta < 90^\circ$ ), the Nusselt number can be obtained by multiplying the Nusselt number for a vertical enclosure by  $(\sin \theta)^{1/4}$  [Ayyaswamy and Catton (1973)],

$$\text{Nu} = \text{Nu}_{\theta=90^\circ} (\sin \theta)^{1/4} \quad \theta_{\text{cr}} < \theta < 90^\circ, \text{ any } H/L \quad (9-50)$$

**FIGURE 9–28**

An inclined rectangular enclosure with isothermal surfaces.

**TABLE 9–2**

Critical angles for inclined rectangular enclosures

| Aspect ratio,<br>$H/L$ | Critical angle,<br>$\theta_{\text{cr}}$ |
|------------------------|---|
| 1                      | $25^\circ$                              |
| 3                      | $53^\circ$                              |
| 6                      | $60^\circ$                              |
| 12                     | $67^\circ$                              |
| $>12$                  | $70^\circ$                              |

For enclosures tilted more than  $90^\circ$ , the recommended relation is [Arnold et al. (1974)]

$$\text{Nu} = 1 + (\text{Nu}_{\theta=90^\circ} - 1) \sin \theta \quad 90^\circ < \theta < 180^\circ, \text{ any } H/L \quad (9-51)$$

More recent but more complex correlations are also available in the literature [e.g., ElSherbiny et al. (1982)].

## Vertical Rectangular Enclosures

For vertical enclosures (Fig. 9–29), Catton (1978) recommends these two correlations due to Berkovsky and Polevikov (1977),

$$\text{Nu} = 0.18 \left( \frac{\text{Pr}}{0.2 + \text{Pr}} \text{Ra}_L \right)^{0.29} \quad \begin{aligned} 1 < H/L &< 2 \\ \text{any Prandtl number} & \\ \text{Ra}_L \text{Pr}/(0.2 + \text{Pr}) &> 10^3 \end{aligned} \quad (9-52)$$

$$\text{Nu} = 0.22 \left( \frac{\text{Pr}}{0.2 + \text{Pr}} \text{Ra}_L \right)^{0.28} \left( \frac{H}{L} \right)^{-1/4} \quad \begin{aligned} 2 < H/L &< 10 \\ \text{any Prandtl number} & \\ \text{Ra}_L &< 10^{10} \end{aligned} \quad (9-53)$$

For vertical enclosures with larger aspect ratios, the following correlations can be used [MacGregor and Emery (1969)]

$$\text{Nu} = 0.42 \text{Ra}_L^{1/4} \text{Pr}^{0.012} \left( \frac{H}{L} \right)^{-0.3} \quad \begin{aligned} 10 < H/L &< 40 \\ 1 < \text{Pr} &< 2 \times 10^4 \\ 10^4 < \text{Ra}_L &< 10^7 \end{aligned} \quad (9-54)$$

$$\text{Nu} = 0.046 \text{Ra}_L^{1/3} \quad \begin{aligned} 1 < H/L &< 40 \\ 1 < \text{Pr} &< 20 \\ 10^6 < \text{Ra}_L &< 10^9 \end{aligned} \quad (9-55)$$

Again, all fluid properties are to be evaluated at the average temperature  $(T_1 + T_2)/2$ .

FIGURE 9–29

A vertical rectangular enclosure with isothermal surfaces.

## Concentric Cylinders

Consider two long concentric horizontal cylinders maintained at uniform but different temperatures of  $T_i$  and  $T_o$ , as shown in Fig. 9–30. The diameters of the inner and outer cylinders are  $D_i$  and  $D_o$ , respectively, and the characteristic length is the spacing between the cylinders,  $L_c = (D_o - D_i)/2$ . The rate of heat transfer through the annular space between the cylinders by natural convection per unit length is expressed as

$$\dot{Q} = \frac{2\pi k_{\text{eff}}}{\ln(D_o/D_i)} (T_i - T_o) \quad (\text{W/m}) \quad (9-56)$$

The recommended relation for effective thermal conductivity is [Raithby and Hollands (1975)]

$$\frac{k_{\text{eff}}}{k} = 0.386 \left( \frac{\text{Pr}}{0.861 + \text{Pr}} \right)^{1/4} (F_{\text{cyl}} \text{Ra}_L)^{1/4} \quad (9-57)$$

FIGURE 9–30

Two concentric horizontal isothermal cylinders.

where the geometric factor for concentric cylinders  $F_{\text{cyl}}$  is

$$F_{\text{cyl}} = \frac{[\ln(D_o/D_i)]^4}{L_c^3(D_i^{-3/5} + D_o^{-3/5})^5} \quad (9-58)$$

**FIGURE 9-31**

Two concentric isothermal spheres.

The  $k_{\text{eff}}$  relation in Eq. 9-57 is applicable for  $0.70 \leq \text{Pr} \leq 6000$  and  $10^2 \leq F_{\text{cyl}}\text{Ra}_L \leq 10^7$ . For  $F_{\text{cyl}}\text{Ra}_L < 100$ , natural convection currents are negligible and thus  $k_{\text{eff}} = k$ . Note that  $k_{\text{eff}}$  cannot be less than  $k$ , and thus we should set  $k_{\text{eff}} = k$  if  $k_{\text{eff}}/k < 1$ . The fluid properties are evaluated at the average temperature of  $(T_i + T_o)/2$ .

### Concentric Spheres

For concentric isothermal spheres, the rate of heat transfer through the gap between the spheres by natural convection is expressed as (Fig. 9-31)

$$\dot{Q} = k_{\text{eff}} \frac{\pi D_i D_o}{L_c} (T_i - T_o) \quad (\text{W}) \quad (9-59)$$

where  $L_c = (D_o - D_i)/2$  is the characteristic length. The recommended relation for effective thermal conductivity is [Raithby and Hollands (1975)]

$$\frac{k_{\text{eff}}}{k} = 0.74 \left( \frac{\text{Pr}}{0.861 + \text{Pr}} \right)^{1/4} (F_{\text{sph}}\text{Ra}_L)^{1/4} \quad (9-60)$$

where the geometric factor for concentric spheres  $F_{\text{sph}}$  is

$$F_{\text{sph}} = \frac{L_c}{(D_i D_o)^4 (D_i^{-7/5} + D_o^{-7/5})^5} \quad (9-61)$$

The  $k_{\text{eff}}$  relation in Eq. 9-60 is applicable for  $0.70 \leq \text{Pr} \leq 4200$  and  $10^2 \leq F_{\text{sph}}\text{Ra}_L \leq 10^4$ . If  $k_{\text{eff}}/k < 1$ , we should set  $k_{\text{eff}} = k$ .

### Combined Natural Convection and Radiation

Gases are nearly transparent to radiation, and thus heat transfer through a gas layer is by simultaneous convection (or conduction, if the gas is quiescent) and radiation. Natural convection heat transfer coefficients are typically very low compared to those for forced convection. Therefore, radiation is usually disregarded in forced convection problems, but it must be considered in natural convection problems that involve a gas. This is especially the case for surfaces with high emissivities. For example, about half of the heat transfer through the air space of a double-pane window is by radiation. The total rate of heat transfer is determined by adding the convection and radiation components,

$$\dot{Q}_{\text{total}} = \dot{Q}_{\text{conv}} + \dot{Q}_{\text{rad}} \quad (9-62)$$

Radiation heat transfer from a surface at temperature  $T_s$  surrounded by surfaces at a temperature  $T_{\text{surr}}$  (both in K) is determined from

$$\dot{Q}_{\text{rad}} = \varepsilon \sigma A_s (T_s^4 - T_{\text{surr}}^4) \quad (\text{W}) \quad (9-63)$$

where  $\varepsilon$  is the emissivity of the surface,  $A_s$  is the surface area, and  $\sigma = 5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$  is the Stefan–Boltzmann constant.

When the end effects are negligible, radiation heat transfer between two large parallel plates at temperatures  $T_1$  and  $T_2$  is expressed as (see Chapter 13 for details)

$$\dot{Q}_{\text{rad}} = \frac{\sigma A_s (T_1^4 - T_2^4)}{1/\varepsilon_1 + 1/\varepsilon_2 - 1} = \varepsilon_{\text{effective}} \sigma A_s (T_1^4 - T_2^4) \quad (\text{W}) \quad (9-64)$$

where  $\varepsilon_1$  and  $\varepsilon_2$  are the emissivities of the plates, and  $\varepsilon_{\text{effective}}$  is the *effective emissivity* defined as

$$\varepsilon_{\text{effective}} = \frac{1}{1/\varepsilon_1 + 1/\varepsilon_2 - 1} \quad (9-65)$$

The emissivity of an ordinary glass surface, for example, is 0.84. Therefore, the effective emissivity of two parallel glass surfaces facing each other is 0.72. Radiation heat transfer between concentric cylinders and spheres is discussed in Chapter 13.

Note that in some cases the temperature of the surrounding medium may be below the surface temperature ( $T_\infty < T_s$ ), while the temperature of the surrounding surfaces is above the surface temperature ( $T_{\text{surr}} < T_s$ ). In such cases, convection and radiation heat transfers are subtracted from each other instead of being added since they are in opposite directions. Also, for a metal surface, the radiation effect can be reduced to negligible levels by polishing the surface and thus lowering the surface emissivity to a value near zero.

#### EXAMPLE 9-4 Heat Loss through a Double-Pane Window

The vertical 0.8-m-high, 2-m-wide double-pane window shown in Fig. 9-32 consists of two sheets of glass separated by a 2-cm air gap at atmospheric pressure. If the glass surface temperatures across the air gap are measured to be 12°C and 2°C, determine the rate of heat transfer through the window.

**SOLUTION** Two glasses of a double-pane window are maintained at specified temperatures. The rate of heat transfer through the window is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Air is an ideal gas.

3 Radiation heat transfer is not considered.

**Properties** The properties of air at the average temperature of  $T_{\text{avg}} = (T_1 + T_2)/2 = (12 + 2)/2 = 7^\circ\text{C}$  and 1 atm pressure are (Table A-15)

$$k = 0.02416 \text{ W/m}\cdot\text{K} \quad \text{Pr} = 0.7344$$

$$\nu = 1.400 \times 10^{-5} \text{ m}^2/\text{s} \quad \beta = \frac{1}{T_{\text{avg}}} = \frac{1}{280 \text{ K}}$$

**Analysis** We have a rectangular enclosure filled with air. The characteristic length in this case is the distance between the two glasses,  $L_c = L = 0.02 \text{ m}$ . Then the Rayleigh number becomes

$$\begin{aligned} \text{Ra}_L &= \frac{g\beta(T_1 - T_2)L_c^3}{\nu^2} \text{Pr} \\ &= \frac{(9.81 \text{ m/s}^2)[1/(280 \text{ K})](12 - 2 \text{ K})(0.02 \text{ m})^3}{(1.400 \times 10^{-5} \text{ m}^2/\text{s})^2} (0.7344) = 1.050 \times 10^4 \end{aligned}$$

**FIGURE 9-32**  
Schematic for Example 9-4.

The aspect ratio of the geometry is  $H/L = 0.8/0.02 = 40$ . Then the Nusselt number in this case can be determined from Eq. 9–54 to be

$$\begin{aligned}\text{Nu} &= 0.42\text{Ra}_L^{1/4} \text{Pr}^{0.012} \left(\frac{H}{L}\right)^{-0.3} \\ &= 0.42(1.050 \times 10^4)^{1/4}(0.7344)^{0.012} \left(\frac{0.8}{0.02}\right)^{-0.3} = 1.40\end{aligned}$$

Then,

$$A_s = H \times W = (0.8 \text{ m})(2 \text{ m}) = 1.6 \text{ m}^2$$

and

$$\begin{aligned}\dot{Q} &= hA_s(T_1 - T_2) = k\text{Nu}A_s \frac{T_1 - T_2}{L} \\ &= (0.02416 \text{ W/m}\cdot\text{K})(1.40)(1.6 \text{ m}^2) \frac{(12 - 2)^\circ\text{C}}{0.02 \text{ m}} = 27.1 \text{ W}\end{aligned}$$

Therefore, heat is lost through the window at a rate of 27.1 W.

**Discussion** Recall that a Nusselt number of  $\text{Nu} = 1$  for an enclosure corresponds to pure conduction heat transfer through the enclosure. The air in the enclosure in this case remains still, and no natural convection currents occur in the enclosure. The Nusselt number in our case is 1.40, which indicates that heat transfer through the enclosure is 1.40 times that by pure conduction. The increase in heat transfer is due to the natural convection currents that develop in the enclosure.

**FIGURE 9–33**

Schematic for Example 9–5.

### PtD EXAMPLE 9–5 Pipe Insulation for Thermal Burn Prevention

In a chemical plant, a 3-m-diameter spherical tank contains a hot fluid that causes the surface temperature to be  $150^\circ\text{C}$  (Fig. 9–33). For safety purposes, the tank is enclosed by a 3.15-m-diameter concentric outer spherical cover. The concentric enclosure provides an air gap that serves as an insulation layer. To prevent workplace hazards such as thermal burn on the skin, the outer cover surface temperature should be kept below  $45^\circ\text{C}$ . The temperature of ambient air outside the tank is  $20^\circ\text{C}$  and the outer cover surface of the tank is covered with paint that gives an emissivity of 0.9. Determine whether the air gap is sufficient to keep the outer cover surface temperature below  $45^\circ\text{C}$  to prevent thermal burns. Assume that the properties of air in the enclosure and at the outer surface can be evaluated at  $95^\circ\text{C}$  and  $30^\circ\text{C}$  and 1 atm pressure, respectively.

**SOLUTION** In this example, the concepts of PtD are applied in conjunction with the concepts of natural convection over a surface and in an enclosure.

**Assumptions** 1 Steady operating conditions exist. 2 Surface temperatures are constant. 3 Air is an ideal gas with constant properties. 4 Heat loss by radiation is negligible. 5 The air pressure is at 1 atm. 6 The surrounding air temperature is  $T_{\text{surr}} = T_\infty$ .

**Properties** The properties of air in the enclosure at the assumed average temperature  $T_{\text{avg}} = (T_i + T_o)/2 = 95^\circ\text{C}$  and 1 atm pressure are  $k = 0.03060 \text{ W/m}\cdot\text{K}$ ,  $\nu = 2.254 \times 10^{-5} \text{ m}^2/\text{s}$ ,  $\text{Pr} = 0.7122$  (Table A-15), and  $\beta = 1/T_{\text{avg}} = 1/368 \text{ K}$ .

The properties of air surrounding the outer surface at the assumed film temperature  $T_f = (T_o + T_\infty)/2 = 30^\circ\text{C}$  and 1 atm pressure are  $k = 0.02588 \text{ W/m}\cdot\text{K}$ ,  $\nu = 1.608 \times 10^{-5} \text{ m}^2/\text{s}$ ,  $\text{Pr} = 0.7282$  (Table A-15), and  $\beta = 1/T_f = 1/303 \text{ K}$ . The emissivity of the outer surface is given as  $\varepsilon = 0.9$ .

**Analysis** For natural convection in the concentric enclosure, with the assumed  $T_{\text{avg}} = 95^\circ\text{C}$ , the outer surface temperature is estimated as

$$T_o = 2T_{\text{avg}} - T_i = 2(95) - 150 = 40^\circ\text{C}$$

The Rayleigh number is

$$\begin{aligned} \text{Ra}_L &= \frac{g\beta(T_i - T_o)L_c^3}{\nu^2} \text{Pr} \\ &= \frac{(9.81 \text{ m/s}^2)(95 + 273 \text{ K})^{-1}(150 - 40) \text{ K} (0.075 \text{ m})^3}{(2.254 \times 10^{-5} \text{ m}^2/\text{s})^2} (0.7122) = 1.7342 \times 10^6 \end{aligned}$$

where  $L_c = (D_o - D_i)/2 = (3.15 - 3.0)/2 = 0.075 \text{ m}$

The effective thermal conductivity is

$$\begin{aligned} F_{\text{sph}} &= \frac{L_c}{(D_i D_o)^4 (D_i^{-7/5} + D_o^{-7/5})^5} \\ &= \frac{0.075 \text{ m}}{[(3.0 \text{ m})(3.15 \text{ m})]^4 [(3.0 \text{ m})^{-7/5} + (3.15 \text{ m})^{-7/5}]^5} = 0.0007602 \end{aligned}$$

$$\begin{aligned} k_{\text{eff}} &= 0.74k \left( \frac{\text{Pr}}{0.861 + \text{Pr}} \right)^{1/4} (F_{\text{sph}} \text{Ra})^{1/4} \\ &= 0.74(0.03060 \text{ W/m}\cdot\text{K}) \left( \frac{0.7122}{0.861 + 0.7122} \right)^{1/4} [(0.0007602)(1.7342 \times 10^6)]^{1/4} \\ &= 0.1119 \text{ W/m}\cdot\text{K} \end{aligned}$$

For natural convection at the outer surface with the surrounding air, the Rayleigh number is

$$\begin{aligned} \text{Ra}_D &= \frac{g\beta(T_o - T_\infty)D_o^3}{\nu^2} \text{Pr} \\ &= \frac{(9.81 \text{ m/s}^2)(30 + 273 \text{ K})^{-1}(40 - 20) \text{ K} (3.15 \text{ m})^3}{(1.608 \times 10^{-5} \text{ m}^2/\text{s})^2} (0.7282) = 5.6999 \times 10^{10} \end{aligned}$$

The Nusselt number and the natural convection heat transfer coefficient at the outer surface are

$$\text{Nu} = 2 + \frac{0.589 \text{Ra}_D^{1/4}}{\left[ 1 + \left( \frac{0.469}{\text{Pr}} \right)^{9/16} \right]^{4/9}} = 2 + \frac{0.589(5.6999 \times 10^{10})^{1/4}}{\left[ 1 + \left( \frac{0.469}{0.7282} \right)^{9/16} \right]^{4/9}} = 224.69$$

$$h = \frac{k}{D_o} \text{Nu} = \frac{0.02588 \text{ W/m}\cdot\text{K}}{3.15 \text{ m}} (224.69) = 1.846 \text{ W/m}^2\cdot\text{K}$$

The outer surface temperature can be solved from rate of heat balance at the outer surface as

$$\dot{Q}_{\text{encl}} = \dot{Q}_{\text{conv}} + \dot{Q}_{\text{rad}}$$

$$k_{\text{eff}} \pi \left( \frac{D_i D_o}{L_c} \right) (T_i - T_o) = h(\pi D_o^2)(T_o - T_\infty) + \varepsilon \sigma (\pi D_o^2)(T_o^4 - T_{\text{surr}}^4) \rightarrow T_o = 40.6^\circ\text{C}$$

**Discussion** The air gap between the concentric spheres and the high emissivity of the painted outer surface are sufficient to keep the outer cover surface temperature below 45°C to alleviate thermal burn hazards.

The assumed average temperature  $T_{\text{avg}} = 95^\circ\text{C}$  and film temperature  $T_f = 30^\circ\text{C}$  are appropriate for evaluating the air properties in the enclosure and at the outer surface, respectively. The determined  $T_o = 40.6^\circ\text{C}$  would give  $T_{\text{avg}} = 95.3^\circ\text{C}$  and  $T_f = 30.3^\circ\text{C}$ .

**FIGURE 9-34**

Schematic for Example 9-6.

### EXAMPLE 9-6 Heating Water in a Tube by Solar Energy

A solar collector consists of a horizontal aluminum tube having an outer diameter of 2 in enclosed in a concentric thin glass tube of 4-in-diameter (Fig. 9-34). Water is heated as it flows through the tube, and the annular space between the aluminum and the glass tubes is filled with air at 1 atm pressure. The pump circulating the water fails during a clear day, and the water temperature in the tube starts rising. The aluminum tube absorbs solar radiation at a rate of 30 Btu/h per foot length, and the temperature of the ambient air outside is 70°F. Disregarding any heat loss by radiation, determine the temperature of the aluminum tube when steady operation is established (i.e., when the rate of heat loss from the tube equals the amount of solar energy gained by the tube).

**SOLUTION** The circulating pump of a solar collector that consists of a horizontal tube and its glass cover fails. The equilibrium temperature of the tube is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The tube and its cover are isothermal. 3 Air is an ideal gas. 4 Heat loss by radiation is negligible.

**Properties** The properties of air should be evaluated at the average temperature. But we do not know the exit temperature of the air in the duct, and thus we cannot determine the bulk fluid and glass cover temperatures at this point, and we cannot evaluate the average temperatures. Therefore, we assume the glass temperature to be 110°F, and use properties at an anticipated average temperature of  $(70 + 110)/2 = 90^\circ\text{F}$  (Table A-15E),

$$k = 0.01505 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F} \quad \text{Pr} = 0.7275$$

$$\nu = 1.753 \times 10^{-4} \text{ ft}^2/\text{s} \quad \beta = \frac{1}{T_{\text{avg}}} = \frac{1}{550 \text{ R}}$$

**Analysis** We have a horizontal cylindrical enclosure filled with air at 1 atm pressure. The problem involves heat transfer from the aluminum tube to the glass cover and from the outer surface of the glass cover to the surrounding ambient air. When steady operation is reached, these two heat transfer rates must equal the rate of heat gain. That is,

$$\dot{Q}_{\text{tube-glass}} = \dot{Q}_{\text{glass-ambient}} = \dot{Q}_{\text{solar gain}} = 30 \text{ Btu/h} \quad (\text{per foot of tube})$$

The heat transfer surface area of the glass cover is

$$A_o = A_{\text{glass}} = (\pi D_o L) = \pi(4/12 \text{ ft})(1 \text{ ft}) = 1.047 \text{ ft}^2 \quad (\text{per foot of tube})$$

To determine the Rayleigh number, we need to know the surface temperature of the glass, which is not available. Therefore, it is clear that the solution will

require a trial-and-error approach. Assuming the glass cover temperature to be 110°F, the Rayleigh number, the Nusselt number, the convection heat transfer coefficient, and the rate of natural convection heat transfer from the glass cover to the ambient air are determined to be

$$\begin{aligned}\text{Ra}_{D_o} &= \frac{g\beta(T_s - T_\infty)D_o^3}{\nu^2} \text{Pr} \\ &= \frac{(32.2 \text{ ft/s}^2)[1/(550 \text{ R})](110 - 70 \text{ R})(4/12 \text{ ft})^3}{(1.753 \times 10^{-4} \text{ ft}^2/\text{s})^2} (0.7275) = 2.054 \times 10^6 \\ \text{Nu} &= \left\{ 0.6 + \frac{0.387 \text{ Ra}_D^{1/6}}{[1 + (0.559/\text{Pr})^{9/16}]^{8/27}} \right\}^2 = \left\{ 0.6 + \frac{0.387(2.054 \times 10^6)^{1/6}}{[1 + (0.559/0.7275)^{9/16}]^{8/27}} \right\}^2 \\ &= 17.89 \\ h_o &= \frac{k}{D_o} \text{Nu} = \frac{0.01505 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}}{4/12 \text{ ft}} (17.89) = 0.8077 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F} \\ \dot{Q}_o &= h_o A_o (T_o - T_\infty) = (0.8077 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F})(1.047 \text{ ft}^2)(110 - 70)^\circ\text{F} \\ &= 33.8 \text{ Btu/h}\end{aligned}$$

which is more than 30 Btu/h. Therefore, the assumed temperature of 110°F for the glass cover is high. Repeating the calculations with lower temperatures, the glass cover temperature corresponding to 30 Btu/h is determined to be 106°F.

The temperature of the aluminum tube is determined in a similar manner using the natural convection relations for two horizontal concentric cylinders. The characteristic length in this case is the distance between the two cylinders, which is

$$L_c = (D_o - D_i)/2 = (4 - 2)/2 = 1 \text{ in} = 1/12 \text{ ft}$$

We start the calculations by assuming the tube temperature to be 200°F, and thus an average temperature of  $(106 + 200)/2 = 153^\circ\text{F} = 613 \text{ R}$ . Using air properties at this temperature gives

$$\begin{aligned}\text{Ra}_L &= \frac{g\beta(T_i - T_o)L_c^3}{\nu^2} \text{Pr} \\ &= \frac{(32.2 \text{ ft/s}^2)[1/613 \text{ R}](200 - 106 \text{ R})(1/12 \text{ ft})^3}{(2.117 \times 10^{-4} \text{ ft}^2/\text{s})^2} (0.7184) = 4.580 \times 10^4\end{aligned}$$

The effective thermal conductivity is

$$\begin{aligned}F_{\text{cyl}} &= \frac{[\ln(D_o/D_i)]^4}{L_c^3(D_i^{-3/5} + D_o^{-3/5})^5} \\ &= \frac{[\ln(4/2)]^4}{(1/12 \text{ ft})^3[(2/12 \text{ ft})^{-3/5} + (4/12 \text{ ft})^{-3/5}]^5} = 0.1466 \\ k_{\text{eff}} &= 0.386k \left( \frac{\text{Pr}}{0.861 + \text{Pr}} \right)^{1/4} (F_{\text{cyl}} \text{Ra}_L)^{1/4} \\ &= 0.386(0.01653 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}) \left( \frac{0.7184}{0.861 + 0.7184} \right)^{1/4} \\ &\quad \times (0.1466 \times 4.580 \times 10^4)^{1/4} \\ &= 0.04743 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}\end{aligned}$$

Then the rate of heat transfer between the cylinders becomes

$$\begin{aligned}\dot{Q} &= \frac{2\pi k_{\text{eff}}}{\ln(D_o/D_i)} (T_i - T_o) \\ &= \frac{2\pi(0.04743 \text{ Btu/h}\cdot\text{ft}\cdot^{\circ}\text{F})}{\ln(4/2)} (200 - 106)^{\circ}\text{F} = 40.4 \text{ Btu/h}\end{aligned}$$

which is more than 30 Btu/h. Therefore, the assumed temperature of 200°F for the tube is high. By trying other values, the tube temperature corresponding to 30 Btu/h is determined to be 180°F. Therefore, the tube will reach an equilibrium temperature of 180°F when the pump fails.

**Discussion** Note that we have not considered heat loss by radiation in the calculations, and thus the tube temperature determined is probably too high. This problem is considered in Chapter 13 by accounting for the effect of radiation heat transfer.

## 9–6 • COMBINED NATURAL AND FORCED CONVECTION

The presence of a temperature gradient in a fluid in a gravity field always gives rise to natural convection currents, and thus heat transfer by natural convection. Therefore, forced convection is always accompanied by natural convection.

We mentioned earlier that the convection heat transfer coefficient, natural or forced, is a strong function of the fluid velocity. Heat transfer coefficients encountered in forced convection are typically much higher than those encountered in natural convection because of the higher fluid velocities associated with forced convection. As a result, we tend to ignore natural convection in heat transfer analyses that involve forced convection, although we recognize that natural convection always accompanies forced convection. The error involved in ignoring natural convection is negligible at high velocities but may be considerable at low velocities. Therefore, it is desirable to have a criterion to assess the relative magnitude of natural convection in the presence of forced convection.

For a given fluid, it is observed that the parameter  $\text{Gr}/\text{Re}^2$  represents the importance of natural convection relative to forced convection. This is not surprising since the convection heat transfer coefficient is a strong function of the Reynolds number  $\text{Re}$  in forced convection and the Grashof number  $\text{Gr}$  in natural convection.

A plot of the nondimensionalized heat transfer coefficient for combined natural and forced convection on a vertical plate is given in Fig. 9–35 for different fluids. We note from this figure that natural convection is negligible when  $\text{Gr}/\text{Re}^2 < 0.1$ , forced convection is negligible when  $\text{Gr}/\text{Re}^2 < 10$ , and neither is negligible when  $0.1 < \text{Gr}/\text{Re}^2 < 10$ . Therefore, both natural and forced convection must be considered in heat transfer calculations when the  $\text{Gr}$  and  $\text{Re}^2$  are of the same order of magnitude (one is within a factor of 10 times the other). Note that forced convection is small relative to natural convection only in the rare case of extremely low forced flow velocities. From the above discussion and the Nusselt number correlations presented in

FIGURE 9–35

Variation of the local Nusselt number  $\text{Nu}_x$  for combined natural and forced convection from a hot isothermal vertical plate.

From Lloyd and Sparrow, 1970.

## FIGURE 9–36

Natural convection can *enhance* or *inhibit* heat transfer, depending on the relative directions of *buoyancy-induced motion* and the *forced convection motion*.

Chapters 7 and 8 for external and internal forced convection, and Chapter 9 for natural convection, it can be concluded that for forced convection  $Nu = f(Re_L, Pr)$ , for natural convection  $Nu = f(Gr_L, Pr)$ , and for combined natural and forced (mixed) convection  $Nu = f(Re_L, Gr_L, Pr)$ .

Natural convection may *help* or *hurt* forced convection heat transfer, depending on the relative directions of *buoyancy-induced* and the *forced convection* motions (Fig. 9-36):

1. In *assisting flow*, the buoyant motion is in the *same* direction as the forced motion. Therefore, natural convection assists forced convection and *enhances* heat transfer. An example is upward forced flow over a hot surface (Fig. 9–36a).
  2. In *opposing flow*, the buoyant motion is in the *opposite* direction to the forced motion. Therefore, natural convection resists forced convection and *decreases* heat transfer. An example is upward forced flow over a cold surface (Fig. 9–36b).
  3. In *transverse flow*, the buoyant motion is *perpendicular* to the forced motion. Transverse flow enhances fluid mixing and thus *enhances* heat transfer. An example is horizontal forced flow over a hot or cold cylinder or sphere (Fig. 9–36c).

When determining heat transfer under combined natural and forced (mixed) convection conditions, it is tempting to add the contributions of natural and forced convection in assisting flows and to subtract them in opposing flows. However, the evidence indicates differently. A review of experimental data suggests a correlation of the form

$$\text{Nu}_{\text{combined}} = (\text{Nu}_{\text{forced}}^n \pm \text{Nu}_{\text{natural}}^n)^{1/n} \quad (9-66)$$

where  $Nu_{forced}$  and  $Nu_{natural}$  are determined from the correlations for *pure forced* and *pure natural convection*, respectively. The plus sign is for *assisting* and *transverse flows* and the minus sign is for *opposing flows*. The value of

the exponent  $n$  varies between 3 and 4, depending on the geometry involved. It is observed that  $n = 3$  correlates experimental data for vertical surfaces well. Larger values of  $n$  are better suited for horizontal surfaces. An example of Eq. 9–66 is the mixed convection correlation developed by Tam and Ghajar (2006) for the calculation of Nusselt number in the transition region (Eq. 8–87).

A question that frequently arises in the cooling of heat-generating equipment such as electronic components is whether to use a fan or a pump (if the cooling medium is a liquid)—that is, whether to utilize *natural* or *forced* convection in the cooling of the equipment. The answer depends on the maximum allowable operating temperature. Recall that the convection heat transfer rate from a surface at temperature  $T_s$  in a medium at  $T_\infty$  is given by

$$\dot{Q}_{\text{conv}} = hA_s(T_s - T_\infty)$$

where  $h$  is the convection heat transfer coefficient and  $A_s$  is the surface area. Note that for a fixed value of power dissipation and surface area,  $h$  and  $T_s$  are *inversely proportional*. Therefore, the device operates at a *higher* temperature when  $h$  is low (typical of natural convection) and at a *lower* temperature when  $h$  is high (typical of forced convection).

Natural convection is the preferred mode of heat transfer, since no blowers or pumps are needed and thus all the problems associated with these, such as noise, vibration, power consumption, and malfunctioning, are avoided. Natural convection is adequate for cooling *low-power-output* devices, especially when they are attached to extended surfaces such as heat sinks. For *high-power-output* devices, however, we have no choice but to use a blower or a pump to keep the operating temperature below the maximum allowable level. For *very-high-power-output* devices, even forced convection may not be sufficient to keep the surface temperature at the desirable levels. In such cases, we may have to use *boiling* and *condensation* to take advantage of the very high heat transfer coefficients associated with phase-change processes.

As mentioned earlier, natural convection is the preferred mode of heat transfer, since it does not require the use of a fluid mover (pump or blower). However, the major drawback for this mode of heat transfer is that the heat transfer coefficients encountered under normal operating conditions are typically much lower than those encountered in forced convection. The rates of heat transfer in natural convection can be made comparable to or even exceed the forced convection heat transfer rates by operating in the near-critical or supercritical regions of fluids. In these regions, fluids behave much differently than they do at states away from the critical point. Small changes in temperature or pressure in the vicinity of the critical point produce large changes in the fluid thermophysical properties (Figure 9–37). A large change in fluid thermophysical properties can be associated with large changes in the rates of convective heat transfer. Simple yet highly accurate relations to predict the peculiar behavior of thermophysical properties of several fluids in the near-critical region are available in the literature [Najjar and Ghajar (1983) and Asgerisson and Ghajar (1986)].

High rates of heat transfer in the near-critical and supercritical regions have become increasingly important in connection with applications like the use of near-critical helium to cool the coils of superconducting electromagnets and superconducting electronic or power-transmission equipment, the use

(a) Specific heat

(b) Thermal conductivity

**FIGURE 9–37**

The variation of specific heat and thermal conductivity with temperature for carbon dioxide at different pressures.  
From Ghajar and Asadi, 1986.

of supercritical hydrogen as a working fluid for both chemical and nuclear rockets, the use of supercritical steam generators in electric utility plants, and the use of methane as a coolant and fuel for the supersonic transport. For horizontal wires and vertical plates, the following relation can be used to predict natural convection heat transfer in the near-critical region [Ghorbani-Tari and Ghajar (1985)]

$$\text{Nu}_\infty = a(\text{Gr}_\infty \text{Pr}_\infty)^b \left( \frac{\rho_w}{\rho_\infty} \right)^c \left( \frac{\bar{c}_p}{c_{p_\infty}} \right)^d \left( \frac{k_w}{k_\infty} \right)^e \left( \frac{\mu_w}{\mu_\infty} \right)^f$$

Here  $a$ ,  $b$ ,  $c$ ,  $d$ ,  $e$ , and  $f$  are curve-fitted constants, and the subscripts  $\infty$  and  $w$  indicate properties to be evaluated at the freestream and wall temperatures, respectively. The term  $\bar{c}_p$  is the mean-integral heat capacity, which is the ratio of the difference of the enthalpies of the fluid evaluated at the freestream and wall temperatures over the differences of the freestream and wall temperatures. The correlation predicted the results of eight different experiments covering a Rayleigh number range of  $0.2 < \text{Ra}_\infty < 4 \times 10^{13}$ , with an absolute average deviation that ranged from 6.7% to 15.6%.

### EXAMPLE 9–7 Heat Transfer in the Presence of Assisting and Opposing Flows

A  $0.2 \text{ m} \times 0.2 \text{ m}$  vertical plate has a surface temperature that is maintained at  $40^\circ\text{C}$ . Air at  $20^\circ\text{C}$  is flowing in parallel over the plate with a velocity of  $0.4 \text{ m/s}$ . Determine the Nusselt number for both assisting flow and opposing flow (Fig. 9–38).

**SOLUTION** Air is flowing over a vertical plate. Nusselt numbers for both assisting and opposing flows are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Properties are constant. 3 The surface temperature is constant. 4 Air is an ideal gas. 5 Heat transfer by radiation is negligible.

**FIGURE 9–38**  
Schematic for Example 9–7.

**Properties** The properties of air (1 atm) at 30°C are  $k = 0.02588 \text{ W/m}\cdot\text{K}$ ,  $\nu = 1.608 \times 10^{-5} \text{ m}^2/\text{s}$ , and  $\text{Pr} = 0.7282$  (Table A-15). Also,  $\beta = 1/T_f = 0.0033 \text{ K}^{-1}$ .

**Analysis** The Reynolds and Grashof numbers are

$$\text{Re} = \frac{VL}{\nu} = \frac{(0.4 \text{ m/s})(0.2 \text{ m})}{1.608 \times 10^{-5} \text{ m}^2/\text{s}} = 4975$$

$$\text{Gr}_L = \frac{g\beta(T_s - T_\infty)L^3}{\nu^2} = \frac{(9.81 \text{ m/s}^2)(0.0033 \text{ K}^{-1})(40 - 20)\text{K}(0.2 \text{ m})^3}{(1.608 \times 10^{-5})^2 \text{ m}^4/\text{s}^2}$$

$$= 2.003 \times 10^7$$

Hence,

$$\frac{\text{Gr}_L}{\text{Re}^2} = \frac{2.003 \times 10^7}{(4975)^2} = 0.809$$

Noting that  $\text{Gr}_L/\text{Re}^2 \approx 1$ , both natural convection and forced convection are significant, and we have mixed flow. The Nusselt numbers for the natural and forced convection cases are determined from relevant relations to be

$$\text{Nu}_{\text{natural}} = 0.59\text{Ra}_L^{1/4} = 0.59(2.003 \times 10^7 \times 0.7282)^{1/4} = 36.46$$

$$\text{Nu}_{\text{forced}} = 0.664 \text{ Re}^{0.5} \text{ Pr}^{1/3} = 0.664(4975)^{0.5}(0.7282)^{1/3} = 42.14$$

Finally, the combined Nusselt numbers for the cases of assisting flow (flowing upward) and opposing flow (flowing downward) become

$$\text{Assisting flow: Nu}_{\text{combined}} = (\text{Nu}_{\text{forced}}^3 + \text{Nu}_{\text{natural}}^3)^{1/3} = (42.14^3 + 36.46^3)^{1/3} = 49.8$$

$$\text{Opposing flow: Nu}_{\text{combined}} = (\text{Nu}_{\text{forced}}^3 - \text{Nu}_{\text{natural}}^3)^{1/3} = (42.14^3 - 36.46^3)^{1/3} = 29.8$$

**Discussion** Note that the Nusselt number for the assisting flow is about 67 percent higher than that for the opposing flow. Therefore, natural convection must be taken into consideration when it is significant.

## TOPIC OF SPECIAL INTEREST\*

### Heat Transfer through Windows

Windows are *glazed apertures* in the building envelope that typically consist of single or multiple glazing (glass or plastic), framing, and shading. In a building envelope, windows offer the least resistance to heat transfer. In a typical house, about one-third of the total heat loss in winter occurs through the windows. Also, most air infiltration occurs at the edges of the windows. The solar heat gain through the windows is responsible for much of the cooling load in summer. The net effect of a window on the heat balance of a building depends on the characteristics and orientation of the window as well as the solar and weather data. Workmanship is very important in the construction and installation of windows to provide effective sealing around the edges while allowing them to be opened and closed easily.

\*This section can be skipped without a loss of continuity.

Despite being so undesirable from an energy conservation point of view, windows are an essential part of any building envelope since they enhance the appearance of the building, allow daylight and solar heat to come in, and allow people to view and observe outside without leaving their home. For low-rise buildings, windows also provide easy exit areas during emergencies such as fire. Important considerations in the selection of windows are *thermal comfort* and *energy conservation*. A window should have a good light transmittance while providing effective resistance to heat transfer. The lighting requirements of a building can be minimized by maximizing the use of natural daylight. Heat loss in winter through the windows can be minimized by using airtight double- or triple-pane windows with spectrally selective films or coatings, and letting in as much solar radiation as possible. Heat gain and thus cooling load in summer can be minimized by using effective internal or external shading on the windows.

Even in the absence of solar radiation and air infiltration, heat transfer through the windows is more complicated than it appears to be. This is because the structure and properties of the frame are quite different than the glazing. As a result, heat transfer through the frame and the edge section of the glazing adjacent to the frame is two-dimensional. Therefore, it is customary to consider the window in three regions when analyzing heat transfer through it: (1) the *center-of-glass*, (2) the *edge-of-glass*, and (3) the *frame* regions, as shown in Fig. 9–39. Then the total rate of heat transfer through the window is determined by adding the heat transfer through each region as

$$\begin{aligned}\dot{Q}_{\text{window}} &= \dot{Q}_{\text{center}} + \dot{Q}_{\text{edge}} + \dot{Q}_{\text{frame}} \\ &= U_{\text{window}} A_{\text{window}} (T_{\text{indoors}} - T_{\text{outdoors}})\end{aligned}\quad (9-67)$$

where

$$U_{\text{window}} = (U_{\text{center}} A_{\text{center}} + U_{\text{edge}} A_{\text{edge}} + U_{\text{frame}} A_{\text{frame}})/A_{\text{window}} \quad (9-68)$$

is the ***U-factor*** or the **overall heat transfer coefficient** of the window;  $A_{\text{window}}$  is the window area;  $A_{\text{center}}$ ,  $A_{\text{edge}}$ , and  $A_{\text{frame}}$  are the areas of the center, edge, and frame sections of the window, respectively; and  $U_{\text{center}}$ ,  $U_{\text{edge}}$ , and  $U_{\text{frame}}$  are the heat transfer coefficients for the center, edge, and frame sections of the window. Note that  $A_{\text{window}} = A_{\text{center}} + A_{\text{edge}} + A_{\text{frame}}$ , and the overall *U*-factor of the window is determined from the area-weighted *U*-factors of each region of the window. Also, the inverse of the *U*-factor is the ***R-value***, which is the unit thermal resistance of the window (thermal resistance for a unit area).

Consider steady one-dimensional heat transfer through a single-pane glass of thickness  $L$  and thermal conductivity  $k$ . The thermal resistance network of this problem consists of surface resistances on the inner and outer surfaces and the conduction resistance of the glass in series, as shown in Fig. 9–40, and the total resistance on a unit area basis can be expressed as

$$R_{\text{total}} = R_{\text{inside}} + R_{\text{glass}} + R_{\text{outside}} = \frac{1}{h_i} + \frac{L_{\text{glass}}}{k_{\text{glass}}} + \frac{1}{h_o} \quad (9-69)$$

Using common values of 3 mm for the thickness and 0.92 W/m·K for the thermal conductivity of the glass and the winter design values of 8.29 and

FIGURE 9–39

The three regions of a window considered in heat transfer analysis.

FIGURE 9–40

The thermal resistance network for heat transfer through a single glass.

34.0 W/m<sup>2</sup>·K for the inner and outer surface heat transfer coefficients, the thermal resistance of the glass is determined to be

$$R_{\text{total}} = \frac{1}{8.29 \text{ W/m}^2\cdot\text{K}} + \frac{0.003 \text{ m}}{0.92 \text{ W/m}\cdot\text{K}} + \frac{1}{34.0 \text{ W/m}^2\cdot\text{K}}$$

$$= 0.121 + 0.003 + 0.029 = 0.153 \text{ m}^2\cdot\text{K/W}$$

Note that the ratio of the glass resistance to the total resistance is

$$\frac{R_{\text{glass}}}{R_{\text{total}}} = \frac{0.003 \text{ m}^2\cdot\text{K/W}}{0.153 \text{ m}^2\cdot\text{K/W}} = 2.0\%$$

That is, the glass layer itself contributes about 2 percent of the total thermal resistance of the window, which is negligible. The situation would not be much different if we used acrylic, whose thermal conductivity is 0.19 W/m·K, instead of glass. Therefore, we cannot reduce the heat transfer through the window effectively by simply increasing the thickness of the glass. But we can reduce it by trapping still air between two layers of glass. The result is a **double-pane window**, which has become the norm in window construction.

The thermal conductivity of air at room temperature is  $k_{\text{air}} = 0.025 \text{ W/m}\cdot\text{K}$ , which is one-thirtieth that of glass. Therefore, the thermal resistance of 1-cm-thick still air is equivalent to the thermal resistance of a 30-cm-thick glass layer. Disregarding the thermal resistances of glass layers, the thermal resistance and  $U$ -factor of a double-pane window can be expressed as (Fig. 9-41)

$$\frac{1}{U_{\text{double-pane (center region)}}} \approx \frac{1}{h_i} + \frac{1}{h_{\text{space}}} + \frac{1}{h_o} \quad (9-70)$$

where  $h_{\text{space}} = h_{\text{rad, space}} + h_{\text{conv, space}}$  is the combined radiation and convection heat transfer coefficient of the space trapped between the two glass layers.

Roughly half of the heat transfer through the air space of a double-pane window is by radiation, and the other half is by conduction (or convection, if there is any air motion). Therefore, there are two ways to minimize  $h_{\text{space}}$  and thus the rate of heat transfer through a double-pane window:

**1. Minimize radiation heat transfer through the air space.** This can be done by reducing the emissivity of glass surfaces by coating them with low-emissivity (or “low-e” for short) material. Recall that the *effective emissivity* of two parallel plates of emissivities  $\varepsilon_1$  and  $\varepsilon_2$  is given by

$$\varepsilon_{\text{effective}} = \frac{1}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1} \quad (9-71)$$

The emissivity of an ordinary glass surface is 0.84. Therefore, the effective emissivity of two parallel glass surfaces facing each other is 0.72. But when the glass surfaces are coated with a film that has an emissivity of 0.1, the effective emissivity reduces to 0.05, which is one-fourteenth of 0.72. Then for the same surface temperatures, radiation heat transfer will also go

FIGURE 9-41

The thermal resistance network for heat transfer through the center section of a double-pane window (the resistances of the glasses are neglected).

**TABLE 9–3**

The heat transfer coefficient  $h_{\text{space}}$  for the air space trapped between the two vertical parallel glass layers for 13-mm- and 6-mm-thick air spaces (from Building Materials and Structures, Report 151, U.S. Dept. of Commerce)

| (a) Air space thickness = 13 mm |                 |   |     | (b) Air space thickness = 6 mm |     |   |     |

down by a factor of 14. Even if only one of the surfaces is coated, the overall emissivity reduces to 0.1, which is the emissivity of the coating. Thus it is no surprise that about one-fourth of all windows sold for residences have a low-e coating. The heat transfer coefficient  $h_{\text{space}}$  for the air space trapped between the two vertical parallel glass layers is given in Table 9–3 for 13-mm- ( $\frac{1}{2}$ -in) and 6-mm- ( $\frac{1}{4}$ -in) thick air spaces for various effective emissivities and temperature differences.

It can be shown that coating just one of the two parallel surfaces facing each other by a material of emissivity  $\epsilon$  reduces the effective emissivity nearly to  $\epsilon$ . Therefore, it is usually more economical to coat only one of the facing surfaces. Note from Fig. 9–42 on the next page that coating one of the interior surfaces of a double-pane window with a material having an emissivity of 0.1 reduces the rate of heat transfer through the center section of the window by half.

**2. Minimize conduction heat transfer through air space.** This can be done by increasing the distance  $d$  between the two glasses. However, this cannot be done indefinitely, since increasing the spacing beyond a critical value initiates convection currents in the enclosed air space, which increases the heat transfer coefficient and thus defeats the purpose. Besides, increasing the spacing also increases the thickness of the necessary framing and the cost of the window. Experimental studies have shown that when the spacing  $d$  is less than about 13 mm, there is no convection, and heat transfer through the air is by conduction. But as the spacing is increased further, convection currents appear in the air space, and the increase in heat transfer coefficient offsets any benefit obtained by the thicker air layer. As a

**FIGURE 9-42**

The variation of the *U*-factor for the center section of double- and triple-pane windows with uniform spacing between the panes

From ASHRAE Handbook of Fundamentals, Chap. 27, Fig. 1.

result, the heat transfer coefficient remains nearly constant, as shown in Fig. 9-42. Therefore, it makes no sense to use an air space thicker than 13 mm in a double-pane window unless a thin polyester film is used to divide the air space into two halves to suppress convection currents. The film provides added insulation without adding much to the weight or cost of the double-pane window. The thermal resistance of the window can be increased further by using triple- or quadruple-pane windows whenever it is economical to do so. Note that using a triple-pane window instead of a double-pane reduces the rate of heat transfer through the center section of the window by about one-third.

Another way of reducing conduction heat transfer through a double-pane window is to use a *less-conducting fluid* such as argon or krypton to fill the gap between the glasses instead of air. The gap in this case needs to be well sealed to prevent the gas from leaking outside. Of course, another alternative is to evacuate the gap between the glasses completely, but it is not practical to do so.

### Edge-of-Glass *U*-Factor of a Window

The glasses in double- and triple-pane windows are kept apart from each other at a uniform distance by **spacers** made of metals or insulators like aluminum, fiberglass, wood, and butyl. Continuous spacer strips are placed around the glass perimeter to provide an edge seal as well as uniform spacing. However, the spacers also serve as undesirable “thermal bridges”

between the glasses, which are at different temperatures, and this short circuiting may increase heat transfer through the window considerably. Heat transfer in the edge region of a window is two-dimensional, and lab measurements indicate that the edge effects are limited to a 6.5-cm-wide band around the perimeter of the glass.

The  $U$ -factor for the edge region of a window is given in Fig. 9–43 relative to the  $U$ -factor for the center region of the window. The curve would be a straight diagonal line if the two  $U$ -values were equal to each other. Note that this is almost the case for insulating spacers such as wood and fiberglass. But the  $U$ -factor for the edge region can be twice that of the center region for conducting spacers such as those made of aluminum. Values for steel spacers fall between the two curves for metallic and insulating spacers. The edge effect is not applicable to single-pane windows.

## Frame $U$ -Factor

The framing of a window consists of the entire window except the glazing. Heat transfer through the framing is difficult to determine because of the different window configurations, different sizes, different constructions, and different combination of materials used in the frame construction. The type of glazing such as single pane, double pane, and triple pane affects the thickness of the framing and thus heat transfer through the frame. Most frames are made of *wood*, *aluminum*, *vinyl*, or *fiberglass*. However, using a combination of these materials (such as aluminum-clad wood and vinyl-clad aluminum) is also common to improve appearance and durability.

Aluminum is a popular framing material because it is inexpensive, durable, and easy to manufacture, and does not rot or absorb water like wood. However, from a heat transfer point of view, it is the least desirable framing material because of its high thermal conductivity. It will come as no surprise that the  $U$ -factor of solid aluminum frames is the highest, and thus a window with aluminum framing will lose much more heat than a comparable window with wood or vinyl framing. Heat transfer through the aluminum framing members can be reduced by using plastic inserts between components to serve as thermal barriers. The thickness of these inserts greatly affects heat transfer through the frame. For aluminum frames without the plastic strips, the primary resistance to heat transfer is due to the interior surface heat transfer coefficient. The  $U$ -factors for various frames are listed in Table 9–4 as a function of spacer materials and the glazing unit thicknesses. Note that the  $U$ -factor of metal framing and thus the rate of heat transfer through a metal window frame is more than three times that of a wood or vinyl window frame.

## Interior and Exterior Surface Heat Transfer Coefficients

Heat transfer through a window is also affected by the convection and radiation heat transfer coefficients between the glass surfaces and surroundings. The effects of convection and radiation on the inner and outer surfaces of glazings are usually combined into the combined convection and radiation heat transfer coefficients  $h_i$  and  $h_o$ , respectively. Under still

TABLE 9-4

Representative frame  $U$ -factors for fixed vertical windows (from ASHRAE Handbook of Fundamentals, Chap. 27, Table 2.)

| Frame material         | $U$ -factor, W/m <sup>2</sup> ·K* |
|------------------------|-----------------------------------|
| Aluminum:              |                                   |
| Single glazing (3 mm)  | 10.1                              |
| Double glazing (18 mm) | 10.1                              |
| Triple glazing (33 mm) | 10.1                              |
| Wood or vinyl:         |                                   |
| Single glazing (3 mm)  | 2.9                               |
| Double glazing (18 mm) | 2.8                               |
| Triple glazing (33 mm) | 2.7                               |

\*Multiply by 0.176 to convert to Btu/h·ft<sup>2</sup>·°F

air conditions, the combined heat transfer coefficient at the inner surface of a vertical window can be determined from

$$h_i = h_{\text{conv}} + h_{\text{rad}} = 1.77(T_g - T_i)^{0.25} + \frac{\varepsilon_g \sigma (T_g^4 - T_i^4)}{T_g - T_i} \quad (\text{W/m}^2 \cdot \text{K}) \quad (9-72)$$

where  $T_g$  = glass temperature in K,  $T_i$  = indoor air temperature in K,  $\varepsilon_g$  = emissivity of the inner surface of the glass exposed to the room (taken to be 0.84 for uncoated glass), and  $\sigma = 5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$  is the Stefan–Boltzmann constant. Here the temperature of the interior surfaces facing the window is assumed to be equal to the indoor air temperature. This assumption is reasonable when the window faces mostly interior walls, but it becomes questionable when the window is exposed to heated or cooled surfaces or to other windows. The commonly used value of  $h_i$  for peak load calculation is

$$h_i = 8.29 \text{ W/m}^2 \cdot \text{K} = 1.46 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F} \quad (\text{winter and summer})$$

which corresponds to the winter design conditions of  $T_i = 22^\circ\text{C}$  and  $T_g = -7^\circ\text{C}$  for uncoated glass with  $\varepsilon_g = 0.84$ . But the same value of  $h_i$  can also be used for summer design conditions as it corresponds to summer conditions of  $T_i = 24^\circ\text{C}$  and  $T_g = 32^\circ\text{C}$ . The values of  $h_i$  for various temperatures and glass emissivities are given in Table 9–5. The commonly used values of  $h_o$  for peak load calculations are the same as those used for outer wall surfaces (34.0 W/m<sup>2</sup>·K for winter and 22.7 W/m<sup>2</sup>·K for summer).

**TABLE 9–5**

## Overall U-Factor of Windows

The overall *U*-factors for various kinds of windows and skylights are evaluated using computer simulations and laboratory testing for winter design conditions; representative values are given in Table 9–6. Test data may provide more accurate information for specific products and should be preferred when available. However, the values listed in the table can be used to obtain satisfactory results under various conditions in the absence of product-specific data. The *U*-factor of a fenestration product that differs considerably from the ones in the table can be determined by (1) determining the fractions of the area that are frame, center-of-glass, and edge-of-glass (assuming a 65-mm-wide band around the perimeter of each glazing), (2) determining the *U*-factors for each section (the center-of-glass and edge-of-glass *U*-factors can be taken from the first two columns of Table 9–6 and the frame *U*-factor can be taken from Table 9–5 or other sources), and (3) multiplying the area fractions and the *U*-factors for each section and adding them up.

Glazed wall systems can be treated as fixed windows. Also, the data for double-door windows can be used for single-glass doors. Several observations can be made from the data in the table:

1. Skylight *U*-factors are considerably greater than those of vertical windows. This is because the skylight area, including the curb, can be 13 to 240 percent greater than the rough opening area. The slope of the skylight also has some effect.

| 12.7 mm argon space   | 0.80                            | 1.92              | 1.25   | 1.77            | 2.51               | 4.86                | 1.18             | 1.01               | 1.33  | 1.17   | 2.55  | 2.28   |

**Notes:**

(1) Multiply by 0.176 to obtain *U*-factors in Btu/h·ft<sup>2</sup>·°F.

(2) The *U*-factors in this table include the effects of surface heat transfer coefficients and are based on winter conditions of  $-18^{\circ}\text{C}$  outdoor air and  $21^{\circ}\text{C}$  indoor air temperature, with 24 km/h (15 mph) winds outdoors and zero solar flux. Small changes in indoor and outdoor temperatures will not affect the overall *U*-factors much. Windows are assumed to be vertical, and the skylights are tilted  $20^{\circ}$  from the horizontal with upward heat flow. Insulation spacers are wood, fiberglass, or butyl. Edge-of-glass effects are assumed to extend the 65-mm band around perimeter of each glazing. The product sizes are 1.2 m  $\times$  1.8 m for fixed windows, 1.8 m  $\times$  2.0 m for double-door windows, and 1.2 m  $\times$  0.6 m for the skylights, but the values given can also be used for products of similar sizes. All data are based on 3-mm (⅛-in) glass unless noted otherwise.

2. The  $U$ -factor of multiple-glazed units can be reduced considerably by filling cavities with argon gas instead of dry air. The performance of  $\text{CO}_2$ -filled units is similar to those filled with argon. The  $U$ -factor can be reduced even further by filling the glazing cavities with krypton gas.
3. Coating the glazing surfaces with low-e (low-emissivity) films reduces the  $U$ -factor significantly. For multiple-glazed units, it is adequate to coat one of the two surfaces facing each other.
4. The thicker the air space in multiple-glazed units, the lower the  $U$ -factor, for a thickness of up to 13 mm ( $\frac{1}{2}$  in) of air space. For a specified number of glazings, the window with thicker air layers will have a lower  $U$ -factor. For a specified overall thickness of glazing, the higher the number of glazings, the lower the  $U$ -factor. Therefore, a triple-pane window with air spaces of 6.4 mm (two such air spaces) will have a lower  $U$ -value than a double-pane window with an air space of 12.7 mm.
5. Wood or vinyl frame windows have a considerably lower  $U$ -value than comparable metal-frame windows. Therefore, wood or vinyl frame windows are called for in energy-efficient designs.

### EXAMPLE 9–8 U-Factor for Center-of-Glass Section of Windows

Determine the  $U$ -factor for the center-of-glass section of a double-pane window with a 6-mm air space for winter design conditions (Fig. 9–44). The glazings are made of clear glass that has an emissivity of 0.84. Take the average air space temperature at design conditions to be  $0^\circ\text{C}$ .

**SOLUTION** The  $U$ -factor for the center-of-glass section of a double-pane window is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the window is one-dimensional. 3 The thermal resistance of glass sheets is negligible.

**Properties** The emissivity of clear glass is 0.84.

**Analysis** Disregarding the thermal resistance of glass sheets, which are small, the  $U$ -factor for the center region of a double-pane window is determined from

$$\frac{1}{U_{\text{center}}} \cong \frac{1}{h_i} + \frac{1}{h_{\text{space}}} + \frac{1}{h_o}$$

where  $h_i$ ,  $h_{\text{space}}$ , and  $h_o$  are the heat transfer coefficients at the inner surface of the window, the air space between the glass layers, and the outer surface of the window, respectively. The values of  $h_i$  and  $h_o$  for winter design conditions were given earlier to be  $h_i = 8.29 \text{ W/m}^2\cdot\text{K}$  and  $h_o = 34.0 \text{ W/m}^2\cdot\text{K}$ . The effective emissivity of the air space of the double-pane window is

$$\varepsilon_{\text{effective}} = \frac{1}{1/\varepsilon_1 + 1/\varepsilon_2 - 1} = \frac{1}{1/0.84 + 1/0.84 - 1} = 0.72$$

FIGURE 9–44

Schematic of Example 9–8.

For this value of emissivity and an average air space temperature of 0°C, we read  $h_{\text{space}} = 7.2 \text{ W/m}^2\cdot\text{K}$  from Table 9–3 for 6-mm-thick air space. Therefore,

$$\frac{1}{U_{\text{center}}} = \frac{1}{8.29} + \frac{1}{7.2} + \frac{1}{34.0} \rightarrow U_{\text{center}} = 3.46 \text{ W/m}^2\cdot\text{K}$$

**Discussion** The center-of-glass  $U$ -factor value of 3.24 W/m<sup>2</sup>·K in Table 9–6 (fourth row and second column) is obtained by using a standard value of  $h_o = 29 \text{ W/m}^2\cdot\text{K}$  (instead of 34.0 W/m<sup>2</sup>·K) and  $h_{\text{space}} = 6.5 \text{ W/m}^2\cdot\text{K}$  at an average air space temperature of –15°C.

### EXAMPLE 9–9 Heat Loss through Aluminum Framed Windows

A fixed aluminum-framed window with glass glazing is being considered for an opening that is 4 ft high and 6 ft wide in the wall of a house that is maintained at 72°F (Fig. 9–45). Determine the rate of heat loss through the window and the inner surface temperature of the window glass facing the room when the outdoor air temperature is 15°F if the window is selected to be (a)  $\frac{1}{8}$ -in single glazing, (b) double glazing with an air space of  $\frac{1}{2}$  in, and (c) low-e-coated triple glazing with an air space of  $\frac{1}{2}$  in.

**SOLUTION** The rate of heat loss through an aluminum framed window and the inner surface temperature are to be determined from the cases of single-pane, double-pane, and low-e triple-pane windows.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the window is one-dimensional. 3 Thermal properties of the windows and the heat transfer coefficients are constant.

**Properties** The  $U$ -factors of the windows are given in Table 9–6.

**Analysis** The rate of heat transfer through the window can be determined from

$$\dot{Q}_{\text{window}} = U_{\text{overall}} A_{\text{window}} (T_i - T_o)$$

where  $T_i$  and  $T_o$  are the indoor and outdoor air temperatures, respectively;  $U_{\text{overall}}$  is the  $U$ -factor (the overall heat transfer coefficient) of the window; and  $A_{\text{window}}$  is the window area, which is determined to be

$$A_{\text{window}} = \text{Height} \times \text{Width} = (4 \text{ ft})(6 \text{ ft}) = 24 \text{ ft}^2$$

The  $U$ -factors for the three cases can be determined directly from Table 9–6 to be 6.63, 3.51, and 1.92 W/m<sup>2</sup>·K, respectively, to be multiplied by the factor 0.176 to convert them to Btu/h·ft<sup>2</sup>·°F. Also, the inner surface temperature of the window glass can be determined from

$$\dot{Q}_{\text{window}} = h_i A_{\text{window}} (T_i - T_{\text{glass}}) \rightarrow T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}}$$

where  $h_i$  is the heat transfer coefficient on the inner surface of the window, which is determined from Table 9–5 to be  $h_i = 8.3 \text{ W/m}^2\cdot\text{K} = 1.46 \text{ Btu/h}\cdot\text{ft}^2\cdot\text{°F}$ .

**FIGURE 9–45**  
Schematic for Example 9–9.

Then the rate of heat loss and the interior glass temperature for each case are determined as follows:

(a) Single glazing:

$$\dot{Q}_{\text{window}} = (6.63 \times 0.176 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})(24 \text{ ft}^2)(72 - 15){}^\circ\text{F} = 1596 \text{ Btu/h}$$

$$T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}} = 72{^\circ}\text{F} - \frac{1596 \text{ Btu/h}}{(1.46 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})(24 \text{ ft}^2)} = 26.5{^\circ}\text{F}$$

(b) Double glazing ( $\frac{1}{2}$  in air space):

$$\dot{Q}_{\text{window}} = (3.51 \times 0.176 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})(24 \text{ ft}^2)(72 - 15){}^\circ\text{F} = 845 \text{ Btu/h}$$

$$T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}} = 72{^\circ}\text{F} - \frac{845 \text{ Btu/h}}{(1.46 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})(24 \text{ ft}^2)} = 47.9{^\circ}\text{F}$$

(c) Triple glazing ( $\frac{1}{2}$  in air space, low-e coated):

$$\dot{Q}_{\text{window}} = (1.92 \times 0.176 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})(24 \text{ ft}^2)(72 - 15){}^\circ\text{F} = 462 \text{ Btu/h}$$

$$T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}} = 72{^\circ}\text{F} - \frac{462 \text{ Btu/h}}{(1.46 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})(24 \text{ ft}^2)} = 58.8{^\circ}\text{F}$$

Therefore, heat loss through the window will be reduced by 47 percent in the case of double glazing and by 71 percent in the case of triple glazing relative to the single-glazing case. Also, in the case of single glazing, the low inner-glass surface temperature will cause considerable discomfort in the occupants because of the excessive heat loss from the body by radiation. It is raised from 26.5°F, which is below freezing, to 47.9°F in the case of double glazing and to 58.8°F in the case of triple glazing.

**FIGURE 9-46**

Schematic for Example 9-10.

### EXAMPLE 9-10 U-Factor of a Double-Door Window

Determine the overall *U*-factor for a double-door-type, wood-framed double-pane window with metal spacers, and compare your result to the value listed in Table 9-6. The overall dimensions of the window are 1.80 m × 2.00 m, and the dimensions of each glazing are 1.72 m × 0.94 m (Fig. 9-46).

**SOLUTION** The overall *U*-factor for a double-door type window is to be determined, and the result is to be compared to the tabulated value.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the window is one-dimensional.

**Properties** The *U*-factors for the various sections of windows are given in Tables 9-4 and 9-6.

**Analysis** The areas of the window, the glazing, and the frame are

$$A_{\text{window}} = \text{Height} \times \text{Width} = (1.8 \text{ m})(2.0 \text{ m}) = 3.60 \text{ m}^2$$

$$A_{\text{glazing}} = 2 \times (\text{Height} \times \text{Width}) = 2(1.72 \text{ m})(0.94 \text{ m}) = 3.23 \text{ m}^2$$

$$A_{\text{frame}} = A_{\text{window}} - A_{\text{glazing}} = 3.60 - 3.23 = 0.37 \text{ m}^2$$

The edge-of-glass region consists of a 6.5-cm-wide band around the perimeter of the glazings, and the areas of the center and edge sections of the glazing are determined to be

$$A_{\text{center}} = 2 \times (\text{Height} \times \text{Width}) = 2(1.72 - 0.13 \text{ m})(0.94 - 0.13 \text{ m}) = 2.58 \text{ m}^2$$

$$A_{\text{edge}} = A_{\text{glazing}} - A_{\text{center}} = 3.23 - 2.58 = 0.65 \text{ m}^2$$

The  $U$ -factor for the frame section is determined from Table 9–4 to be  $U_{\text{frame}} = 2.8 \text{ W/m}^2\text{-K}$ . The  $U$ -factors for the center and edge sections are determined from Table 9–6 (fifth row, second and third columns) to be  $U_{\text{center}} = 3.24 \text{ W/m}^2\text{-K}$  and  $U_{\text{edge}} = 3.71 \text{ W/m}^2\text{-K}$ . Then the overall  $U$ -factor of the entire window becomes

$$\begin{aligned} U_{\text{window}} &= (U_{\text{center}} A_{\text{center}} + U_{\text{edge}} A_{\text{edge}} + U_{\text{frame}} A_{\text{frame}})/A_{\text{window}} \\ &= (3.24 \times 2.58 + 3.71 \times 0.65 + 2.8 \times 0.37)/3.60 = \mathbf{3.28 \text{ W/m}^2\text{-K}} \end{aligned}$$

The overall  $U$ -factor listed in Table 9–6 for the specified type of window is  $3.20 \text{ W/m}^2\text{-K}$ , which is sufficiently close to the value obtained above.

## SUMMARY

In this chapter, we have considered natural convection heat transfer where any fluid motion occurs by natural means such as buoyancy. The volume expansion coefficient of a substance represents the variation of the density of that substance with temperature at constant pressure, and for an ideal gas, it is expressed as  $\beta = 1/T$ , where  $T$  is the absolute temperature in K or R.

The flow regime in natural convection is governed by a dimensionless number called the *Grashof number*, which represents the ratio of the buoyancy force to the viscous force acting on the fluid and is expressed as

$$\text{Gr}_L = \frac{g\beta(T_s - T_\infty)L_c^3}{\nu^2}$$

where  $L_c$  is the *characteristic length*, which is the height  $L$  for a vertical plate and the diameter  $D$  for a horizontal cylinder. The correlations for the Nusselt number  $\text{Nu} = hL_c/k$  in natural convection are expressed in terms of the *Rayleigh number* defined as

$$\text{Ra}_L = \text{Gr}_L \text{Pr} = \frac{g\beta(T_s - T_\infty)L_c^3}{\nu^2} \text{Pr}$$

Nusselt number relations for various surfaces are given in Table 9–1. All fluid properties are evaluated at the film temperature of  $T_f = \frac{1}{2}(T_s + T_\infty)$ . The outer surface of a vertical cylinder can be treated as a vertical plate when the curvature effects are negligible. The characteristic length for a horizontal surface is  $L_c = A_s/p$ , where  $A_s$  is the surface area and  $p$  is the perimeter.

The average Nusselt number for vertical isothermal *parallel plates* of spacing  $S$  and height  $L$  is given as

$$\text{Nu} = \frac{hS}{k} = \left[ \frac{576}{(\text{Ra}_S S/L)^2} + \frac{2.873}{(\text{Ra}_S S/L)_{0.5}} \right]^{-0.5}$$

The optimum fin spacing for a vertical heat sink and the Nusselt number for optimally spaced fins is

$$S_{\text{opt}} = 2.714 \left( \frac{S^3 L}{\text{Ra}_S} \right)^{0.25} = 2.714 \frac{L}{\text{Ra}_L^{0.25}} \text{ and } \text{Nu} = \frac{hS_{\text{opt}}}{k} = 1.307$$

In a *horizontal rectangular enclosure* with the hotter plate at the top, heat transfer is by pure conduction and  $\text{Nu} = 1$ . When the hotter plate is at the bottom, the Nusselt number is

$$\text{Nu} = 1 + 1.44 \left[ 1 - \frac{1708}{\text{Ra}_L} \right]^+ + \left[ \frac{\text{Ra}_L^{1/3}}{18} - 1 \right]^+ \quad \text{Ra}_L < 10^8$$

The notation  $[ ]^+$  indicates that if the quantity in the bracket is negative, it should be set equal to zero. For *vertical rectangular enclosures*, the Nusselt number can be determined from

$$\text{Nu} = 0.18 \left( \frac{\text{Pr}}{0.2 + \text{Pr}} \text{Ra}_L \right)^{0.29} \quad \begin{array}{l} 1 < H/L < 2 \\ \text{any Prandtl number} \\ \text{Ra}_L \text{Pr}/(0.2 + \text{Pr}) > 10^3 \end{array}$$

$$\text{Nu} = 0.22 \left( \frac{\text{Pr}}{0.2 + \text{Pr}} \text{Ra}_L \right)^{0.28} \left( \frac{H}{L} \right)^{-1/4} \quad \begin{array}{l} 2 < H/L < 10 \\ \text{any Prandtl number} \\ \text{Ra}_L < 10^{10} \end{array}$$

For aspect ratios greater than 10, Eqs. 9–54 and 9–55 should be used. For inclined enclosures, Eqs. 9–48 through 9–51 should be used.

For *concentric horizontal cylinders*, the rate of heat transfer through the annular space between the cylinders by natural convection per unit length is

$$\dot{Q} = \frac{2\pi k_{\text{eff}}}{\ln(D_o/D_i)} (T_i - T_o)$$

where

$$\frac{k_{\text{eff}}}{k} = 0.386 \left( \frac{\text{Pr}}{0.861 + \text{Pr}} \right)^{1/4} (F_{\text{cyl}} \text{Ra}_L)^{1/4}$$

and

$$F_{\text{cyl}} = \frac{[\ln(D_o/D_i)]^4}{L_c^3 (D_i^{-3/5} + D_o^{-3/5})^5}$$

For a *spherical enclosure*, the rate of heat transfer through the space between the spheres by natural convection is expressed as

$$\dot{Q} = k_{\text{eff}} \frac{\pi D_i D_o}{L_c} (T_i - T_o)$$

where

$$\begin{aligned} \frac{k_{\text{eff}}}{k} &= 0.74 \left( \frac{\text{Pr}}{0.861 + \text{Pr}} \right)^{1/4} (F_{\text{sph}} \text{Ra}_L)^{1/4} \\ L_c &= (D_o - D_i)/2 \\ F_{\text{sph}} &= \frac{L_c}{(D_i D_o)^4 (D_i^{-7/5} + D_o^{-7/5})^5} \end{aligned}$$

The quantity  $k_{\text{Nu}}$  is called the *effective thermal conductivity* of the enclosure, since a fluid in an enclosure behaves like a quiescent fluid whose thermal conductivity is  $k_{\text{Nu}}$  as a result of convection currents. The fluid properties are evaluated at the average temperature of  $(T_i + T_o)/2$ .

For a given fluid, the parameter  $\text{Gr}/\text{Re}^2$  represents the importance of natural convection relative to forced convection. Natural convection is negligible when  $\text{Gr}/\text{Re}^2 < 0.1$ , forced convection is negligible when  $\text{Gr}/\text{Re}^2 > 10$ , and neither is negligible when  $0.1 < \text{Gr}/\text{Re}^2 < 10$ .

## PROBLEMS\*

### Physical Mechanism of Natural Convection

**9–1C** What is natural convection? How does it differ from forced convection? What force causes natural convection currents?

\*Problems designated by a "C" are concept questions, and students are encouraged to answer them all. Problems designated by an "E" are in English units, and the SI users can ignore them. Problems with the icon are solved using EES, and complete solutions together with parametric studies are included on the text website. Problems with the icon are comprehensive in nature, and are intended to be solved with an equation solver such as EES. Problems with the icon are Prevention through Design Problems.

**9–2C** In which mode of heat transfer is the convection heat transfer coefficient usually higher, natural convection or forced convection? Why?

**9–3C** Consider a hot boiled egg in a spacecraft that is filled with air at atmospheric pressure and temperature at all times. Will the egg cool faster or slower when the spacecraft is in space instead of on the ground? Explain.

**9–4C** When will the hull of a ship sink in water deeper: when the ship is sailing in fresh water or in seawater? Why?

**9–5C** What is buoyancy force? Compare the relative magnitudes of the buoyancy force acting on a body immersed in these mediums: (a) air, (b) water, (c) mercury, and (d) an evacuated chamber.

**9-6C** Consider a fluid whose volume does not change with temperature at constant pressure. What can you say about natural convection heat transfer in this medium?

**9-7C** Consider two fluids, one with a large coefficient of volume expansion and the other with a small one. In what fluid will a hot surface initiate stronger natural convection currents? Why? Assume the viscosity of the fluids to be the same.

**9-8C** Physically, what does the Grashof number represent? How does the Grashof number differ from the Reynolds number?

**9-9** Show that the volume expansion coefficient of an ideal gas is  $\beta = 1/T$ , where  $T$  is the absolute temperature.

**9-10** Using its definition and the values listed in Table A-9, determine the volume expansion coefficient of saturated liquid water at 70°C. Compare the result with the value tabulated in Table A-9.

**9-11** The density of liquid water can be correlated as  $\rho(T) = 1000 - 0.0736T - 0.00355T^2$  where  $\rho$  and  $T$  are in kg/m<sup>3</sup> and °C, respectively. Determine the volume expansion coefficient at 70°C. Compare the result with the value tabulated in Table A-9.

**9-12** A 10 cm × 10 cm plate has a constant surface temperature of 150°C. Determine the Grashof number if the chip is placed in the following fluids: air (1 atm, 30°C), liquid water (30°C), engine oil (10°C). Discuss how the Grashof number affects the natural convection flow.

**9-13E** A long 2-in-diameter rod with surface temperature of 200°F is submerged in a bath of fluid. Determine the Grashof and Rayleigh numbers if the fluid is (a) liquid water at 40°F, (b) liquid ammonia at 40°F, (c) engine oil at 50°F, and (d) air at 40°F (1 atm).

### Natural Convection over Surfaces

**9-14C** How does the Rayleigh number differ from the Grashof number?

**9-15C** Will a hot horizontal plate whose back side is insulated cool faster or slower when its hot surface is facing down instead of up?

**9-16C** Consider laminar natural convection from a vertical hot-plate. Will the heat flux be higher at the top or at the bottom of the plate? Why?

**9-17C** Under what conditions can the outer surface of a vertical cylinder be treated as a vertical plate in natural convection calculations?

**9-18** A 0.2-m-long and 25-mm-thick vertical plate ( $k = 15 \text{ W/m}\cdot\text{K}$ ) separates the hot water from the cold water. The plate surface exposed to the hot water has a temperature of 100°C, and the temperature of the cold water is 7°C. Determine the temperature of the plate surface exposed to the cold water ( $T_{s,c}$ ). Hint: The  $T_{s,c}$  has to be found iteratively. Start the iteration process with an initial guess of 53.5°C for the  $T_{s,c}$ .

FIGURE P9-18

**9-19** Reconsider Prob. 9-18. Using the EES (or other) software, investigate the effect of the plate thermal conductivity on the surface temperature exposed to the cold water. By varying the plate thermal conductivity from 3 to 200 W/m·K, plot the plate surface temperature on the cold water side as a function of the plate thermal conductivity.

**9-20** A 0.2-m-long and 25-mm-thick vertical plate ( $k = 1.5 \text{ W/m}\cdot\text{K}$ ) separates the hot water from the cold air at 2°C. The plate surface exposed to the hot water has a temperature of 100°C, and the surface exposed to the cold air has an emissivity of 0.73. Determine the temperature of the plate surface exposed to the cold air ( $T_{s,c}$ ). Hint: The  $T_{s,c}$  has to be found iteratively. Start the iteration process with an initial guess of 51°C for the  $T_{s,c}$ .

FIGURE P9-20

**9-21** Reconsider Prob. 9-20. Using the EES (or other) software, evaluate the effect of the plate thickness on the surface temperature exposed to the cold air. By varying the plate thickness from 0.01 to 0.1 m, plot the plate surface temperature on the cold air side as a function of the plate thickness.

**9-22** A 0.5-m-long thin vertical plate is subjected to uniform heat flux on one side, while the other side is exposed to cool air at 5°C. The plate surface has an emissivity of 0.73, and its midpoint temperature is 55°C. Determine the heat flux subjected to the plate surface.

**FIGURE P9–22**

**9–23** A 0.5-m-long thin vertical plate is subjected to a uniform heat flux of  $1200 \text{ W/m}^2$  on one side, while the other side is exposed to hydrogen gas at  $5^\circ\text{C}$ . Assuming that the properties of the hydrogen gas can be evaluated at  $50^\circ\text{C}$ , determine the plate midpoint temperature  $T_{L/2}$ . Is  $50^\circ\text{C}$  an appropriate film temperature for evaluation of the properties of the hydrogen gas?

**FIGURE P9–23**

**9–24** A 0.5-m-long thin vertical copper plate is subjected to a uniform heat flux of  $1000 \text{ W/m}^2$  on one side, while the other side is exposed to air at  $5^\circ\text{C}$ . Determine the plate midpoint temperature for (a) a highly polished surface and (b) a black oxidized surface. Hint: The plate midpoint temperature ( $T_{L/2}$ ) has to be found iteratively. Begin the calculations by using a film temperature of  $30^\circ\text{C}$ .

**FIGURE P9–24**

**9–25** Reconsider Prob. 9–24. Using the EES (or other) software, evaluate the effect of the uniform surface heat flux on the plate midpoint temperature for (a) the highly polished surface and (b) the black oxidized surface. By varying the surface heat flux from 500 to  $1500 \text{ W/m}^2$ , plot the plate midpoint temperature as a function of the surface heat flux.

**9–26** A  $0.2 \text{ m} \times 0.2 \text{ m}$  street sign surface has an absorptivity of 0.6 and an emissivity of 0.7. Solar radiation is incident on the street sign at a rate of  $200 \text{ W/m}^2$ , and the surrounding quiescent air is at  $25^\circ\text{C}$ . Determine the surface temperature of the street sign. Assume the film temperature is  $30^\circ\text{C}$ .

**FIGURE P9–26**

**9–27** Consider a  $1.2 \text{ m}$ -high and  $2 \text{ m}$ -wide glass window with a thickness of 6 mm, thermal conductivity  $k = 0.78 \text{ W/m}\cdot\text{K}$ , and emissivity  $\varepsilon = 0.9$ . The room and the walls that face the window are maintained at  $25^\circ\text{C}$ , and the average temperature of the inner surface of the window is measured to be  $5^\circ\text{C}$ . If the temperature of the outdoors is  $-5^\circ\text{C}$ , determine (a) the convection heat transfer coefficient on the inner surface of the window, (b) the rate of total heat transfer through the window, and (c) the combined natural convection and radiation heat transfer coefficient on the outer surface of the window. Is it reasonable to neglect the thermal resistance of the glass in this case?

**FIGURE P9–27**

**9–28E** Consider a  $2\text{-ft} \times 2\text{-ft}$  thin square plate in a room at  $75^\circ\text{F}$ . One side of the plate is maintained at a temperature of  $130^\circ\text{F}$ , while the other side is insulated. Determine the rate of heat transfer from the plate by natural convection if the plate is (a) vertical, (b) horizontal with hot surface facing up, and (c) horizontal with hot surface facing down.

**9–29E**  Reconsider Prob. 9–28E. Using EES (or other) software, plot the rate of natural convection heat transfer for different orientations of the plate as a function of the plate temperature as the temperature varies from 80°F to 180°F, and discuss the results.

**9–30**  The side surfaces of a 3-m-high cubic industrial furnace burning natural gas are not insulated, and the temperature at the outer surface of this section is measured to be 110°C. The temperature of the furnace room, including its surfaces, is 30°C, and the emissivity of the outer surface of the furnace is 0.7. It is proposed that this section of the furnace wall be insulated with glass wool insulation ( $k = 0.038 \text{ W/m}\cdot\text{K}$ ) wrapped by a reflective sheet ( $\varepsilon = 0.2$ ) in order to reduce the heat loss by 90 percent. Assuming the outer surface temperature of the metal section still remains at about 110°C, determine the thickness of the insulation that needs to be used.

The furnace operates continuously throughout the year and has an efficiency of 78 percent. The price of the natural gas is \$1.10/therm (1 therm = 105,500 kJ of energy content). If the installation of the insulation will cost \$550 for materials and labor, determine how long it will take for the insulation to pay for itself from the energy it saves.

FIGURE P9–30

**9–31** A 50-cm × 50-cm circuit board that contains 121 square chips on one side is to be cooled by combined natural convection and radiation by mounting it on a vertical surface in a room at 25°C. Each chip dissipates 0.18 W of power, and the emissivity of the chip surfaces is 0.7. Assuming the heat transfer from the back side of the circuit board to be negligible, and the temperature of the surrounding surfaces to be the same as the air temperature of the room, determine the surface temperature of the chips. Evaluate air properties at a film temperature of 30°C and 1 atm pressure. Is this a good assumption?

*Answer:* 36.2°C

**9–32** Repeat Prob. 9–31 assuming the circuit board to be positioned horizontally with (a) chips facing up and (b) chips facing down.

**9–33** Consider a 15-cm × 20-cm printed circuit board (PCB) that has electronic components on one side. The board is placed in a room at 20°C. The heat loss from the back surface of the board is negligible. If the circuit board is dissipating 8 W of power in steady operation, determine the average temperature of the hot surface of the board, assuming the board is (a) vertical, (b) horizontal with hot surface facing up, and (c) horizontal with hot surface facing down. Take the emissivity of the surface of the board to be 0.8 and assume the surrounding surfaces to be at the same temperature as the air in the room. Evaluate air properties at a film temperature of 32.5°C and 1 atm pressure. Is this a good assumption?

*Answers:* (a) 46.6°C, (b) 42.6°C, (c) 50.7°C

FIGURE P9–33

**9–34**  Reconsider Prob. 9–33. Using EES (or other) software, investigate the effects of the room temperature and the emissivity of the board on the temperature of the hot surface of the board for different orientations of the board. Let the room temperature vary from 5°C to 35°C and the emissivity from 0.1 to 1.0. Plot the hot surface temperature for different orientations of the board as the functions of the room temperature and the emissivity, and discuss the results.

**9–35** Consider a vertical plate with length  $L$ , placed in quiescent air. If the film temperature is 20°C and the average Nusselt number in natural convection is of the form  $\text{Nu} = CRa_L^{\alpha}$ , show that the average heat transfer coefficient can be expressed as

$$h = 1.51(\Delta T/L)^{1/4} \quad 10^4 < Ra_L < 10^9$$

$$h = 1.19\Delta T^{1/3} \quad 10^{10} < Ra_L < 10^{13}$$

**9–36** Consider a thin 16-cm-long and 20-cm-wide horizontal plate suspended in air at 20°C. The plate is equipped with electric resistance heating elements with a rating of 20 W. Now the heater is turned on and the plate temperature rises. Determine the temperature of the plate when steady operating conditions are reached. The plate has an emissivity of 0.90 and the surrounding surfaces are at 17°C. As an initial guess, assume a surface temperature of 50°C. Is this a good assumption?

**FIGURE P9-36**

- 9-37** A manufacturer makes absorber plates that are  $1.2 \text{ m} \times 0.8 \text{ m}$  in size for use in solar collectors. The back side of the plate is heavily insulated, while its front surface is coated with black chrome, which has an absorptivity of 0.87 for solar radiation and an emissivity of 0.09. Consider such a plate placed horizontally outdoors in calm air at  $25^\circ\text{C}$ . Solar radiation is incident on the plate at a rate of  $600 \text{ W/m}^2$ . Taking the effective sky temperature to be  $10^\circ\text{C}$ , determine the equilibrium temperature of the absorber plate. What would your answer be if the absorber plate is made of ordinary aluminum plate that has a solar absorptivity of 0.28 and an emissivity of 0.07? Evaluate air properties at a film temperature of  $70^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

**FIGURE P9-37**

- 9-38** Repeat Prob. 9-37 for an aluminum plate painted flat black (solar absorptivity 0.98 and emissivity 0.98) and also for a plate painted white (solar absorptivity 0.26 and emissivity 0.90). Evaluate air properties at a film temperature of  $45^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

- 9-39** A circular grill of diameter 0.25 m has an emissivity of 0.8. If the surface temperature is maintained at  $150^\circ\text{C}$ , determine the required electrical power when the room air and surroundings are at  $30^\circ\text{C}$ .

- 9-40** A can of engine oil with a length of 150 mm and a diameter of 100 mm is placed vertically in the trunk of a car. In a hot summer day, the temperature in the trunk is  $43^\circ\text{C}$ . If the surface temperature of the can is  $17^\circ\text{C}$ , determine heat transfer rate from the can surface. Neglect the heat transfer from the ends of the can.

- 9-41** Flue gases from an incinerator are released to atmosphere using a stack that is 0.6 m in diameter and 10.0 m high.

The outer surface of the stack is at  $40^\circ\text{C}$  and the surrounding air is at  $10^\circ\text{C}$ . Determine the rate of heat transfer from the stack assuming (a) there is no wind and (b) the stack is exposed to  $20 \text{ km/h}$  winds.

- 9-42** Water is boiling in a 12-cm-deep pan with an outer diameter of 25 cm that is placed on top of a stove. The ambient air and the surrounding surfaces are at a temperature of  $25^\circ\text{C}$ , and the emissivity of the outer surface of the pan is 0.80. Assuming the entire pan to be at an average temperature of  $98^\circ\text{C}$ , determine the rate of heat loss from the cylindrical side surface of the pan to the surroundings by (a) natural convection and (b) radiation. (c) If water is boiling at a rate of  $1.5 \text{ kg/h}$  at  $100^\circ\text{C}$ , determine the ratio of the heat lost from the side surfaces of the pan to that by the evaporation of water. The enthalpy of vaporization of water at  $100^\circ\text{C}$  is  $2257 \text{ kJ/kg}$ .

Answers: 46.2 W, 47.3 W, 0.099

**FIGURE P9-42**

- 9-43** Repeat Prob. 9-42 for a pan whose outer surface is polished and has an emissivity of 0.1.

- 9-44** In a plant that manufactures canned aerosol paints, the cans are temperature-tested in water baths at  $55^\circ\text{C}$  before they are shipped to ensure that they withstand temperatures up to  $55^\circ\text{C}$  during transportation and shelving (as shown in Fig. P9-44 on the next page). The cans, moving on a conveyor, enter the open hot water bath, which is 0.5 m deep, 1 m wide, and 3.5 m long, and move slowly in the hot water toward the other end. Some of the cans fail the test and explode in the water bath. The water container is made of sheet metal, and the entire container is at about the same temperature as the hot water. The emissivity of the outer surface of the container is 0.7. If the temperature of the surrounding air and surfaces is  $20^\circ\text{C}$ , determine the rate of heat loss from the four side surfaces of the container (disregard the top surface, which is open).

The water is heated electrically by resistance heaters, and the cost of electricity is  $\$0.085/\text{kWh}$ . If the plant operates 24 h a day 365 days a year and thus 8760 h a year, determine the annual cost of the heat losses from the container for this facility.

FIGURE P9-44

**9-45** Reconsider Prob. 9-44. In order to reduce the heating cost of the hot water, it is proposed to insulate the side and bottom surfaces of the container with 5-cm-thick fiberglass insulation ( $k = 0.035 \text{ W/m}\cdot\text{K}$ ) and to wrap the insulation with aluminum foil ( $\epsilon = 0.1$ ) in order to minimize the heat loss by radiation. An estimate is obtained from a local insulation contractor, who proposes to do the insulation job for \$350, including materials and labor. Would you support this proposal? How long will it take for the insulation to pay for itself from the energy it saves? Evaluate air properties at a film temperature of  $23^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

**9-46** A room is to be heated by a coal-burning stove, which is a cylindrical cavity with an outer diameter of 32 cm and a height of 70 cm. The rate of heat loss from the room is estimated to be 1.5 kW when the air temperature in the room is maintained constant at  $24^\circ\text{C}$ . The emissivity of the stove surface is 0.85, and the average temperature of the surrounding wall surfaces is  $14^\circ\text{C}$ . Determine the surface temperature of the stove. Neglect the heat transfer from the bottom surface and take the heat transfer coefficient at the top surface to be the same as that on the side surface.

The heating value of the coal is 30,000 kJ/kg, and the combustion efficiency is 65 percent. Determine the amount of coal burned a day if the stove operates 14 h a day. Evaluate air properties at a film temperature of  $77^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

**9-47** Consider a cylinder with a length of 15 cm and a diameter of 10 cm. The cylinder has a surface temperature of  $43^\circ\text{C}$ , while the room air temperature is  $17^\circ\text{C}$ . Determine whether placing the cylinder horizontally or vertically would achieve higher heat transfer rate.

**9-48** An aluminum soda can of 150 mm in length and 60 mm in diameter is placed horizontally inside a refrigerator compartment that maintains a temperature of  $4^\circ\text{C}$ . If the surface temperature of the can is  $36^\circ\text{C}$ , estimate heat transfer rate from the can. Neglect the heat transfer from the ends of the can.

**9-49** Thermal energy generated by the electrical resistance of a 5-mm-diameter and 4-m-long bare cable is dissipated to the surrounding air at  $20^\circ\text{C}$ . The voltage drop and the electric current across the cable in steady operation are measured to be 60 V and 1.5 A, respectively. Disregarding radiation, estimate the surface temperature of the cable. Evaluate air properties at a film temperature of  $60^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

**9-50** A 10-m-long section of a 6-cm-diameter horizontal hot-water pipe passes through a large room whose temperature is  $27^\circ\text{C}$ . If the temperature and the emissivity of the outer surface of the pipe are  $73^\circ\text{C}$  and 0.8, respectively, determine the rate of heat loss from the pipe by (a) natural convection and (b) radiation.

**9-51** A 300-W cylindrical resistance heater is 0.75 m long and 0.5 cm in diameter. The resistance wire is placed horizontally in a fluid at  $20^\circ\text{C}$ . Determine the outer surface temperature of the resistance wire in steady operation if the fluid is (a) air and (b) water. Ignore any heat transfer by radiation. Use properties at  $500^\circ\text{C}$  for air and  $40^\circ\text{C}$  for water.

**9-52** Thick fluids such as asphalt and waxes and the pipes in which they flow are often heated in order to reduce the viscosity of the fluids and thus to reduce the pumping costs. Consider the flow of such a fluid through a 100-m-long pipe of outer diameter 30 cm in calm ambient air at  $0^\circ\text{C}$ . The pipe is heated electrically, and a thermostat keeps the outer surface temperature of the pipe constant at  $25^\circ\text{C}$ . The emissivity of the outer surface of the pipe is 0.8, and the effective sky temperature is  $-30^\circ\text{C}$ . Determine the power rating of the electric resistance heater, in kW, that needs to be used. Also, determine the cost of electricity associated with heating the pipe during a 10-h period under the above conditions if the price of electricity is \$0.09/kWh.

Answers: 29.1 kW, \$26.2

FIGURE P9-52

**9-53** Reconsider Prob. 9-52. To reduce the heating cost of the pipe, it is proposed to insulate it with sufficiently thick fiberglass insulation ( $k = 0.035 \text{ W/m}\cdot\text{K}$ ) wrapped with aluminum foil ( $\epsilon = 0.1$ ) to cut down the heat losses by 85 percent. Assuming the pipe temperature to remain constant at  $25^\circ\text{C}$ , determine the thickness of the insulation that needs to be used. How much money will the insulation save during this 15-h period? Evaluate air properties at a film temperature of  $5^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

Answers: 1.3 cm, \$22.3

**9-54** A 3-mm-diameter and 12-m-long electric wire is tightly wrapped with a 1.5-mm-thick plastic cover whose thermal conductivity and emissivity are  $k = 0.20 \text{ W/m}\cdot\text{K}$  and  $\epsilon = 0.9$ . Electrical measurements indicate that a current of 10 A passes through the wire and there is a voltage drop of 7 V along

the wire. If the insulated wire is exposed to calm atmospheric air at  $T_\infty = 30^\circ\text{C}$ , determine the temperature at the interface of the wire and the plastic cover in steady operation. Take the surrounding surfaces to be at about the same temperature as the air. Evaluate air properties at a film temperature of  $40^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

**9-55** During a visit to a plastic sheeting plant, it was observed that a 60-m-long section of a 2-in nominal (6.03-cm-outer-diameter) steam pipe extended from one end of the plant to the other with no insulation on it. The temperature measurements at several locations revealed that the average temperature of the exposed surfaces of the steam pipe was  $170^\circ\text{C}$ , while the temperature of the surrounding air was  $20^\circ\text{C}$ . The outer surface of the pipe appeared to be oxidized, and its emissivity can be taken to be 0.7. Taking the temperature of the surrounding surfaces to be  $20^\circ\text{C}$  also, determine the rate of heat loss from the steam pipe.

Steam is generated in a gas furnace that has an efficiency of 78 percent, and the plant pays \$1.10 per therm (1 therm = 105,500 kJ) of natural gas. The plant operates 24 h a day 365 days a year, and thus 8760 h a year. Determine the annual cost of the heat losses from the steam pipe for this facility.

FIGURE P9-55

**9-56** Reconsider Prob. 9-55. Using EES (or other) software, investigate the effect of the surface temperature of the steam pipe on the rate of heat loss from the pipe and the annual cost of this heat loss. Let the surface temperature vary from  $100^\circ\text{C}$  to  $200^\circ\text{C}$ . Plot the rate of heat loss and the annual cost as a function of the surface temperature, and discuss the results.

**9-57** Reconsider Prob. 9-55. In order to reduce heat losses, it is proposed to insulate the steam pipe with 5-cm-thick fiberglass insulation ( $k = 0.038 \text{ W/m}\cdot\text{K}$ ) and to wrap it with aluminum foil ( $\epsilon = 0.1$ ) in order to minimize the radiation losses. Also, an estimate is obtained from a local insulation contractor, who proposed to do the insulation job for \$750, including materials and labor. Would you support this proposal? How long will it take for the insulation to pay for itself from the energy it saves? Assume the temperature of the steam pipe to remain constant at  $170^\circ\text{C}$ . Evaluate air properties at a film temperature of  $27.5^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

**9-58** A 1.5-m-diameter, 4-m-long cylindrical propane tank is initially filled with liquid propane, whose density is  $581 \text{ kg/m}^3$ . The tank is exposed to the ambient air at  $25^\circ\text{C}$  in calm weather. The outer surface of the tank is polished so that the radiation heat transfer is negligible. Now a crack develops at the top of the tank, and the pressure inside drops to 1 atm while the temperature drops to  $-42^\circ\text{C}$ , which is the boiling temperature of propane at 1 atm. The heat of vaporization of propane at 1 atm is  $425 \text{ kJ/kg}$ . The propane is slowly vaporized as a result of the heat transfer from the ambient air into the tank, and the propane vapor escapes the tank at  $-42^\circ\text{C}$  through the crack. Assuming the propane tank to be at about the same temperature as the propane inside at all times, determine how long it will take for the tank to empty if it is not insulated.

FIGURE P9-58

**9-59** Hot water is being transported in a horizontal pipe ( $k = 0.15 \text{ W/m}\cdot\text{K}$ ,  $D_i = 2.5 \text{ cm}$ ,  $D_o = 4.5 \text{ cm}$ ), where the pipe inner surface temperature is at  $100^\circ\text{C}$ . A length of 2 m of the pipe outer surface is exposed to cool air at  $12^\circ\text{C}$ . Assuming that the properties of air can be evaluated at  $40^\circ\text{C}$  and 1 atm pressure, determine the outer surface temperature of the pipe. Is  $40^\circ\text{C}$  an appropriate film temperature for evaluation of the air properties?

**9-60** Hot engine oil is being transported in a horizontal pipe ( $k = 15 \text{ W/m}\cdot\text{K}$ ,  $D_i = 5 \text{ cm}$ ) with a wall thickness of 5 mm. The pipe is covered with a 5-mm-thick layer of insulation ( $k = 0.15 \text{ W/m}\cdot\text{K}$ ). A length of 2 m of the outer surface is exposed to cool air at  $10^\circ\text{C}$ . If the pipe inner surface temperature is at  $90^\circ\text{C}$ , determine the outer surface temperature. Hint: The pipe outer surface temperature has to be found iteratively. Begin the calculations by using a film temperature of  $50^\circ\text{C}$ .

**9-61** Reconsider Prob. 9-60. Using the EES (or other) software, evaluate the effect of the insulation layer thickness on the outer surface temperature. By varying the insulation layer thickness from 5 to 15 mm, plot the outer surface temperature as a function of the thickness of the insulation layer.

**9-62** A hot fluid ( $k_{\text{fluid}} = 0.72 \text{ W/m}\cdot\text{K}$ ) is flowing as a laminar fully-developed flow inside a pipe with an inner diameter of

35 mm and a wall thickness of 5 mm. The pipe is 10 m long and the outer surface is exposed to air at 10°C. The average temperature difference between the hot fluid and the pipe inner surface is  $\Delta T_{\text{avg}} = 10^\circ\text{C}$ , and the inner and outer surface temperatures are constant. Determine the outer surface temperature of the pipe. Evaluate the air properties at 50°C. Is this a good assumption?

**9-63** A hot liquid ( $c_p = 1000 \text{ J/kg}\cdot\text{K}$ ) flows at a flow rate of 0.05 kg/s inside a copper pipe with an inner diameter of 45 mm and a wall thickness of 5 mm. At the pipe exit, the liquid temperature decreases by 10°C from its temperature at the inlet. The outer surface of the 5-m-long copper pipe is black oxidized, which subjects the outer surface to radiation heat transfer. The air temperature surrounding the pipe is 10°C. Assuming that the properties of air can be evaluated at 35°C and 1 atm pressure, determine the outer surface temperature of the pipe. Is 35°C an appropriate film temperature for evaluation of the air properties?

**9-64 PTD** A hot liquid ( $c_p = 1000 \text{ J/kg}\cdot\text{K}$ ) flows at a flow rate of 0.028 kg/s inside a 5-m-long pipe with an inner diameter of 45 mm and a wall thickness of 5 mm. At the pipe exit, the liquid temperature decreases by 10°C from its inlet temperature. The pipe is located in a surrounding with air at 10°C. To prevent thermal burn hazards, the pipe outer surface temperature should be at 45°C or lower. Instead of covering the pipe with insulation, a colleague has suggested to paint the pipe outer surface with black paint ( $\epsilon = 0.88$ ). Determine whether or not painting the pipe outer surface black is sufficient to keep the temperature below 45°C. Evaluate the properties of air at 25°C and 1 atm pressure. Is this a good assumption?

**9-65E** An average person generates heat at a rate of 240 Btu/h while resting in a room at 70°F. Assuming one-quarter of this heat is lost from the head and taking the emissivity of the skin to be 0.9, determine the average surface temperature of the head when it is not covered. The head can be approximated as a 12-in-diameter sphere, and the interior surfaces of the room can be assumed to be at the room temperature.

**9-66** An incandescent lightbulb is an inexpensive but highly inefficient device that converts electrical energy into light. It converts about 10 percent of the electrical energy it consumes into light while converting the remaining 90 percent into heat. The glass bulb of the lamp heats up very quickly as a result of absorbing all that heat and dissipating it to the surroundings by convection and radiation. Consider an 8-cm-diameter 60-W lightbulb in a room at 25°C. The emissivity of the glass is 0.9. Assuming that 10 percent of the energy passes through the glass bulb as light with negligible absorption and the rest of the energy is absorbed and dissipated by the bulb itself by natural convection and radiation, determine the equilibrium temperature of the glass bulb. Assume the interior surfaces of the room to be at room temperature. *Answer: 169°C*

FIGURE P9-66

**9-67** The water in a 40-L tank is to be heated from 15°C to 45°C by a 6-cm-diameter spherical heater whose surface temperature is maintained at 85°C. Determine how long the heater should be kept on.

**9-68** A 2-m-diameter thin-walled stainless steel spherical tank is filled with chemicals undergoing a reaction. The reaction releases heat through the tank, where the tank outer surface temperature is 50°C and is exposed to air at 20°C. The stainless steel surface of the tank has an emissivity of 0.35. Determine the rate of heat release from the chemical reaction inside the tank. Is the given emissivity value reasonable for a stainless steel surface? What is the contribution of natural convection to the overall rate of heat loss at the tank surface?

**9-69** A hot liquid is filled in a spherical tank with an inner diameter of 3 m and a wall thickness of 3 cm. The tank wall is made of a material with a thermal conductivity of 0.15 W/m·K. The hot liquid in the tank causes the inner surface temperature to be 100°C, while the tank outer surface is exposed to air at 20°C and has an emissivity of 0.35. Determine the outer surface temperature of the tank. Assume that the properties of air can be evaluated at 40°C and 1 atm pressure. Is this a good assumption?

**9-70 PTD** A stainless steel spherical tank, with an inner diameter of 3 m and a wall thickness of 10 mm, is used for containing a solution undergoing an exothermic reaction that generates 450 W/m<sup>3</sup> of heat. The tank is located in a surrounding with air at 15°C. To prevent thermal burns on the skin of people working near the vicinity of the tank, the outer surface temperature should be at 45°C or lower. Determine whether the outer surface of the tank should be polished ( $\epsilon = 0.2$ ) or painted in black ( $\epsilon = 0.88$ ). Evaluate the air properties at 30°C and 1 atm pressure. Is this a good assumption?

**9-71 PTD** A spherical tank ( $k = 15 \text{ W/m}\cdot\text{K}$ ) with an inner diameter of 3 m and a wall thickness of 10 mm is used for storing hot liquid. The hot liquid inside the tank causes the inner surface temperature to be as high as 100°C. To prevent thermal burns on the skin of the people working near the vicinity of the tank, the tank is covered with a 7-cm-thick layer of insulation ( $k = 0.15 \text{ W/m}\cdot\text{K}$ ) and the outer

surface is painted to give an emissivity of 0.35. The tank is located in a surrounding with air at 16°C. Determine whether or not the insulation layer is sufficient to keep the outer surface temperature below 45°C to prevent thermal burn hazards. Discuss ways to further decrease the outer surface temperature. Evaluate the air properties at 30°C and 1 atm pressure. Is this a good assumption?

### Natural Convection from Finned Surfaces and PCBs

**9–72C** Why are finned surfaces frequently used in practice? Why are the finned surfaces referred to as heat sinks in the electronics industry?

**9–73C** Why are heat sinks with closely packed fins not suitable for natural convection heat transfer, although they increase the heat transfer surface area more?

**9–74C** Consider a heat sink with optimum fin spacing. Explain how heat transfer from this heat sink will be affected by (a) removing some of the fins on the heat sink and (b) doubling the number of fins on the heat sink by reducing the fin spacing. The base area of the heat sink remains unchanged at all times.

**9–75** Aluminum heat sinks of rectangular profile are commonly used to cool electronic components. Consider a 7.62-cm-long and 9.68-cm-wide commercially available heat sink whose cross section and dimensions are as shown in Fig. P9–75. The heat sink is oriented vertically and is used to cool a power transistor that can dissipate up to 125 W of power. The back surface of the heat sink is insulated. The surface of the heat sink are untreated, and thus they have a low emissivity (under 0.1). Therefore, radiation heat transfer from the heat sink can be neglected. During an experiment conducted in room air at 22°C, the base temperature of the heat sink was measured to be 120°C when the power dissipation of the transistor was 15 W. Assuming the entire heat sink to be at the base temperature, determine the average natural convection heat transfer coefficient for the case.

FIGURE P9–75

**9–76** Reconsider the heat sink in Prob. 9–75. In order to enhance heat transfer, a shroud (a thin rectangular metal plate) whose surface area is equal to the base area of the heat sink is placed very close to the tips of the fins such that the interfin spaces are converted into rectangular channels. The base temperature of the heat sink in this case was measured

to be 108°C. Noting that the shroud loses heat to the ambient air from both sides, determine the average natural convection heat transfer coefficient in this shrouded case. (For complete details, see Çengel and Zing, 1987.)

FIGURE P9–76

**9–77** A 15-cm-wide and 18-cm-high vertical hot surface in 20°C air is to be cooled by a heat sink with equally spaced fins of rectangular profile. The fins are 0.1 cm thick, 4 cm wide, and 18 cm long in the vertical direction. Determine the optimum fin spacing and the rate of heat transfer by natural convection from the heat sink if the base temperature is 85°C.

**9–78E** A 6-in-wide and 8-in-high vertical hot surface in 78°F air is to be cooled by a heat sink with equally spaced fins of rectangular profile. The fins are 0.08 in thick and 8 in long in the vertical direction and have a height of 1.2 in from the base. Determine the optimum fin spacing and the rate of heat transfer by natural convection from the heat sink if the base temperature is 180°F.

**9–79E** Reconsider Prob. 9–78E. Using EES (or other) software, investigate the effect of the length of the fins in the vertical direction on the optimum fin spacing and the rate of heat transfer by natural convection. Let the fin length vary from 2 in to 10 in. Plot the optimum fin spacing and the rate of convection heat transfer as a function of the fin length, and discuss the results.

### Natural Convection inside Enclosures

**9–80C** The upper and lower compartments of a well-insulated container are separated by two parallel sheets of glass with an air space between them. One of the compartments is to be filled with a hot fluid and the other with a cold fluid. If it is desired that heat transfer between the two compartments be minimal, would you recommend putting the hot fluid into the upper or the lower compartment of the container? Why?

**9–81C** Someone claims that the air space in a double-pane window enhances the heat transfer from a house because of

the natural convection currents that occur in the air space and recommends that the double-pane window be replaced by a single sheet of glass whose thickness is equal to the sum of the thicknesses of the two glasses of the double-pane window to save energy. Do you agree with this claim?

**9-82C** Consider a double-pane window consisting of two glass sheets separated by a 1-cm-wide air space. Someone suggests inserting a thin vinyl sheet in the middle of the two glasses to form two 0.5-cm-wide compartments in the window in order to reduce natural convection heat transfer through the window. From a heat transfer point of view, would you be in favor of this idea to reduce heat losses through the window?

**9-83C** What does the effective conductivity of an enclosure represent? How is the ratio of the effective conductivity to thermal conductivity related to the Nusselt number?

**9-84** Show that the thermal resistance of a rectangular enclosure can be expressed as  $R = L_c/(Ak \text{ Nu})$ , where  $k$  is the thermal conductivity of the fluid in the enclosure.

**9-85** Consider a 3-m-high rectangular enclosure consisting of two surfaces separated by a 0.1-m air gap at 1 atm. If the surface temperatures across the air gap are 30°C and -10°C, determine the ratio of the heat transfer rate for the horizontal orientation (with hotter surface at the bottom) to that for vertical orientation.

FIGURE P9-85

**9-86** Flat-plate solar collectors are often tilted up toward the sun in order to intercept a greater amount of direct solar radiation. The tilt angle from the horizontal also affects the rate of heat loss from the collector. Consider a 1.5-m-high and 3-m-wide solar collector that is tilted at an angle  $\theta$  from the horizontal. The back side of the absorber is heavily insulated. The absorber plate and the glass cover, which are spaced 2.5 cm from each other, are maintained at temperatures of 80°C and 40°C, respectively. Determine the rate of heat loss from the absorber plate by natural convection for  $\theta = 0^\circ, 30^\circ$ , and  $90^\circ$ .

FIGURE P9-86

**9-87** A vertical 1.5-m-high and 3.0-m-wide enclosure consists of two surfaces separated by a 0.4-m air gap at atmospheric pressure. If the surface temperatures across the air gap are measured to be 280 K and 336 K and the surface emissivities to be 0.15 and 0.90, determine the fraction of heat transferred through the enclosure by radiation. *Answer: 0.30*

**9-88** A vertical 1.5-m-high, 2.8-m-wide double-pane window consists of two layers of glass separated by a 2.0-cm air gap at atmospheric pressure. The room temperature is 26°C while the inner glass temperature is 18°C. Disregarding radiation heat transfer, determine the temperature of the outer glass layer and the rate of heat loss through the window by natural convection.

**9-89E** A vertical 4-ft-high and 6-ft-wide double-pane window consists of two sheets of glass separated by a 1-in air gap at atmospheric pressure. If the glass surface temperatures across the air gap are measured to be 65°F and 40°F, determine the rate of heat transfer through the window by (a) natural convection and (b) radiation. Also, determine the  $R$ -value of insulation of this window such that multiplying the inverse of the  $R$ -value by the surface area and the temperature difference gives the total rate of heat transfer through the window. The effective emissivity for use in radiation calculations between two large parallel glass plates can be taken to be 0.82.

FIGURE P9-89

**9-90E**  Reconsider Prob. 9-89E. Using EES (or other) software, investigate the effect of the air gap thickness on the rates of heat transfer by natural convection and radiation, and the  $R$ -value of insulation. Let the air gap thickness vary from 0.2 in to 2.0 in. Plot the rates of heat transfer by natural convection and radiation, and the  $R$ -value of insulation as a function of the air gap thickness, and discuss the results.

**9-91** A simple solar collector is built by placing a 5-cm-diameter clear plastic tube around a garden hose whose outer diameter is 1.6 cm. The hose is painted black to maximize solar absorption, and some plastic rings are used to keep the spacing between the hose and the clear plastic cover constant. During a clear day, the temperature of the hose is measured to be 65°C, while the ambient air temperature is 26°C. Determine the rate of heat loss from the water in the hose per meter of its length by natural convection. Also, discuss how the performance of this solar collector can be improved. Evaluate air properties at an average temperature of 50°C and 1 atm pressure. Is this a good assumption? *Answer: 8.2 W*

FIGURE P9-91

**9-92**  Reconsider Prob. 9-91. Using EES (or other) software, plot the rate of heat loss from the water by natural convection as a function of the ambient air temperature as the temperature varies from 4°C to 40°C, and discuss the results.

**9-93** Consider two concentric horizontal cylinders of diameters 55 cm and 65 cm, and length 125 cm. The surfaces of the inner and outer cylinders are maintained at 54°C and 106°C, respectively. Determine the rate of heat transfer between the cylinders by natural convection if the annular space is filled with (a) water and (b) air.

**9-94**  A hot liquid ( $c_p = 950 \text{ J/kg}\cdot\text{K}$ ) flows at a flow rate of 0.005 kg/s inside a tube with a diameter of 25 mm. At the tube exit, the liquid temperature decreases by 8°C from its temperature at the inlet. The hot liquid causes the tube surface temperature to be 120°C. To prevent thermal burn hazards, the tube is enclosed with a concentric outer cover of 5 cm in diameter. Determine whether the outer cover temperature is below 45°C to prevent thermal burns in contact with human skin. Evaluate the properties of air in the concentric enclosure at 80°C and 1 atm pressure. Is this a good assumption?

FIGURE P9-94

**9-95** Two concentric spheres with diameters of 5 cm and 10 cm are having the surface temperatures maintained at 100°C and 200°C, respectively. The enclosure between the two concentric spherical surfaces is filled with nitrogen gas at 1 atm. Determine the rate of heat transfer through the enclosure.

FIGURE P9-95

**9-96** Two concentric spheres of diameters 15 cm and 25 cm are separated by air at 1 atm pressure. The surface temperatures of the two spheres enclosing the air are  $T_1 = 350 \text{ K}$  and  $T_2 = 275 \text{ K}$ , respectively. Determine the rate of heat transfer from the inner sphere to the outer sphere by natural convection.

**9-97**  Reconsider Prob. 9-96. Using EES (or other) software, plot the rate of natural convection heat transfer as a function of the hot surface temperature of the sphere as the temperature varies from 250 K to 450 K, and discuss the results.

**9-98** The two concentric spheres of diameters  $D_i = 20 \text{ cm}$  and  $D_o = 30 \text{ cm}$  are separated by air at 1 atm pressure. The surface temperatures of the two spheres enclosing the air are  $T_i = 320 \text{ K}$  and  $T_o = 280 \text{ K}$ , respectively. Determine the rate of heat transfer from the inner sphere to the outer sphere by natural convection.

FIGURE P9-98

- 9-99**  A spherical tank, with an inner diameter of 3 m, is filled with a solution undergoing an exothermic reaction that generates  $233 \text{ W/m}^3$  of heat and causes the surface temperature to be  $120^\circ\text{C}$ . To prevent thermal burn hazards, the tank is enclosed with a concentric outer cover that provides an air gap of 5 cm in the enclosure. Determine whether the outer cover temperature below  $45^\circ\text{C}$  to prevent thermal burns on human skin. Evaluate the properties of air in the enclosure at  $80^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

FIGURE P9-99

### Combined Natural and Forced Convection

- 9-100C** When is natural convection negligible and when is it not negligible in forced convection heat transfer?

- 9-101C** Under what conditions does natural convection enhance forced convection, and under what conditions does it hurt forced convection?

- 9-102C** When neither natural nor forced convection is negligible, is it correct to calculate each independently and add them to determine the total convection heat transfer?

- 9-103** Consider a 5-m-long vertical plate at  $60^\circ\text{C}$  in water at  $25^\circ\text{C}$ . Determine the forced motion velocity above which natural convection heat transfer from this plate is negligible.

- 9-104** In a production facility, thin square plates  $2 \text{ m} \times 2 \text{ m}$  in size coming out of the oven at  $270^\circ\text{C}$  are cooled by blowing ambient air at  $18^\circ\text{C}$  horizontally parallel to their surfaces. Determine the air velocity above which the natural convection effects on heat transfer are less than 10 percent and thus are negligible.

FIGURE P9-104

- 9-105** A 150-mm-diameter and 1-cm-long vertical rod has water flowing across its outer surface at a velocity of 0.5 m/s. The water temperature is uniform at  $40^\circ\text{C}$ , and the rod surface temperature is maintained at  $120^\circ\text{C}$ . Under these conditions are the natural convection effects important to the heat transfer process?

- 9-106** A 150-mm-diameter and 1-m-long rod is positioned horizontally and has water flowing across its outer surface at a velocity of 0.2 m/s. The water temperature is uniform at  $40^\circ\text{C}$  and the rod surface temperature is maintained at  $120^\circ\text{C}$ . Under these conditions are the natural convection effects important to the heat transfer process?

- 9-107** Consider a 5-m-long vertical plate at  $85^\circ\text{C}$  in air at  $30^\circ\text{C}$ . Determine the forced motion velocity above which natural convection heat transfer from this plate is negligible.

- 9-108**  Reconsider Prob. 9-107. Using EES (or other) software, plot the forced motion velocity above which natural convection heat transfer is negligible as a function of the plate temperature as the temperature varies from  $50^\circ\text{C}$  to  $150^\circ\text{C}$ , and discuss the results.

- 9-109** A 12-cm-high and 20-cm-wide circuit board houses 100 closely spaced logic chips on its surface, each dissipating  $0.05\text{W}$ . The board is cooled by a fan that blows air over the hot surface of the board at  $35^\circ\text{C}$  at a velocity of 0.5 m/s. The heat transfer from the back surface of the board is negligible. Determine the average temperature on the surface of the circuit board assuming the air flows vertically upward along the 12-cm-long side by (a) ignoring natural convection and (b) considering the contribution of natural convection. Disregard any heat transfer by radiation. Evaluate air properties at a film temperature of  $47.5^\circ\text{C}$  and 1 atm pressure. Is this a good assumption?

- 9-110** A 15-cm-diameter horizontal cylinder has a surface temperature that is maintained at  $120^\circ\text{C}$ . Water at  $40^\circ\text{C}$  is flowing across the cylinder with a velocity of 0.2 m/s. Determine the Nusselt number if the water is flowing (a) upward and (b) downward.

FIGURE P9-110

### Special Topic: Heat Transfer through Windows

**9–111C** Why are the windows considered in three regions when analyzing heat transfer through them? Name those regions and explain how the overall  $U$ -value of the window is determined when the heat transfer coefficients for all three regions are known.

**9–112C** Consider three similar double-pane windows with air gap widths of 5, 10, and 20 mm. For which case will the heat transfer through the window will be a minimum?

**9–113C** In an ordinary double-pane window, about half of the heat transfer is by radiation. Describe a practical way of reducing the radiation component of heat transfer.

**9–114C** Consider a double-pane window whose air space width is 20 mm. Now a thin polyester film is used to divide the air space into two 10-mm-wide layers. How will the film affect (a) convection and (b) radiation heat transfer through the window?

**9–115C** Consider a double-pane window whose air space is flashed and filled with argon gas. How will replacing the air in the gap by argon affect (a) convection and (b) radiation heat transfer through the window?

**9–116C** Is the heat transfer rate through the glazing of a double-pane window higher at the center or edge section of the glass area? Explain.

**9–117C** How do the relative magnitudes of  $U$ -factors of windows with aluminum, wood, and vinyl frames compare? Assume the windows are identical except for the frames.

**9–118** Determine the  $U$ -factor for the center-of-glass section of a double-pane window with a 13-mm air space for winter design conditions. The glazings are made of clear glass having an emissivity of 0.84. Take the average air space temperature at design conditions to be  $10^\circ\text{C}$  and the temperature difference across the air space to be  $15^\circ\text{C}$ .

**9–119** The overall  $U$ -factor of a fixed wood-framed window with double glazing is given by the manufacturer to be  $U = 2.76 \text{ W/m}^2\cdot\text{K}$  under the conditions of still air inside and winds of  $12 \text{ km/h}$  outside. What will the  $U$ -factor be when the wind velocity outside is doubled? *Answer:  $2.88 \text{ W/m}^2\cdot\text{K}$*

**9–120** The owner of an older house in Wichita, Kansas, is considering replacing the existing double-door type wood-framed single-pane windows with vinyl-framed double-pane windows with an air space of 6.4 mm. The new windows are of double-door type with metal spacers. The house is maintained at  $22^\circ\text{C}$  at all times, but heating is needed only when the outdoor temperature drops below  $18^\circ\text{C}$  because of the internal heat gain from people, lights, appliances, and the sun. The average winter temperature of Wichita is  $7.1^\circ\text{C}$ , and the house is heated by electric resistance heaters. If the unit cost of electricity is  $\$0.085/\text{kWh}$  and the total window area of the house is  $17 \text{ m}^2$ , determine how much money the new windows will save the home owner per month in winter.

FIGURE P9–120

**9–121** Consider a house in Atlanta, Georgia, that is maintained at  $22^\circ\text{C}$  and has a total of  $14 \text{ m}^2$  of window area. The windows are double-door-type with wood frames and metal spacers. The glazing consists of two layers of glass with 12.7 mm of air space with one of the inner surfaces coated with reflective film. The winter average temperature of Atlanta is  $11.3^\circ\text{C}$ . Determine the average rate of heat loss through the windows in winter. *Answer: 319 W*

**9–122E** Consider an ordinary house with  $R$ -13 walls (walls that have an  $R$ -value of 13  $\text{h}\cdot\text{ft}^2\cdot^\circ\text{F/Btu}$ ). Compare this to the  $R$ -value of the common double-door windows that are double pane with  $\frac{1}{4}$  in of air space and have aluminum frames. If the windows occupy only 20 percent of the wall area, determine if more heat is lost through the windows or through the remaining 80 percent of the wall area. Disregard infiltration losses.

**9–123** A double-door wood-framed window with glass glazing and metal spacers is being considered for an opening that is 1.2 m high and 1.8 m wide in the wall of a house maintained at  $20^\circ\text{C}$ . Determine the rate of heat loss through the window and the inner surface temperature of the window glass facing the room when the outdoor air temperature is  $-8^\circ\text{C}$  if the window is selected to be (a) 3-mm single glazing, (b) double glazing with an air space of 13 mm, and (c) low-e-coated triple glazing with an air space of 13 mm.

FIGURE P9–123

**9–124** Determine the overall  $U$ -factor for a double-door-type wood-framed double-pane window with 13-mm air space and metal spacers, and compare your result with the value listed in Table 9–6. The overall dimensions of the window are  $2.00\text{ m} \times 2.40\text{ m}$ , and the dimensions of each glazing are  $1.92\text{ m} \times 1.14\text{ m}$ .

### Review Problems

**9–125** An electric resistance space heater is designed such that it resembles a rectangular box 50 cm high, 80 cm long, and 15 cm wide filled with 45 kg of oil. The heater is to be placed against a wall, and thus heat transfer from its back surface is negligible. The surface temperature of the heater is not to exceed  $75^\circ\text{C}$  in a room at  $25^\circ\text{C}$  for safety considerations. Disregarding heat transfer from the bottom and top surfaces of the heater in anticipation that the top surface will be used as a shelf, determine the power rating of the heater in W. Take the emissivity of the outer surface of the heater to be 0.8 and the average temperature of the ceiling and wall surfaces to be the same as the room air temperature.

Also, determine how long it will take for the heater to reach steady operation when it is first turned on (i.e., for the oil temperature to rise from  $25^\circ\text{C}$  to  $75^\circ\text{C}$ ). State your assumptions in the calculations.

FIGURE P9–125

**9–126** During a plant visit, it was observed that a 1.5-m-high and 1-m-wide section of the vertical front section of a natural gas furnace wall was too hot to touch. The temperature measurements on the surface revealed that the average temperature of the exposed hot surface was  $110^\circ\text{C}$ , while the temperature of the surrounding air was  $25^\circ\text{C}$ . The surface appeared to be oxidized, and its emissivity can be taken to be 0.7. Taking the temperature of the surrounding surfaces to be  $25^\circ\text{C}$  also, determine the rate of heat loss from this furnace.

The furnace has an efficiency of 79 percent, and the plant pays \$1.20 per therm of natural gas. If the plant operates 10 h a day, 310 days a year, and thus 3100 h a year, determine the annual cost of the heat loss from this vertical hot surface on the front section of the furnace wall.

FIGURE P9–126

**9–127** Consider a 2-m-high electric hot-water heater that has a diameter of 40 cm and maintains the hot water at  $60^\circ\text{C}$ . The tank is located in a small room at  $20^\circ\text{C}$  whose walls and ceiling are at about the same temperature. The tank is placed in a 44-cm-diameter sheet metal shell of negligible thickness, and the space between the tank and the shell is filled with foam insulation. The average temperature and emissivity of the outer surface of the shell are  $40^\circ\text{C}$  and 0.7, respectively. The price of electricity is \$0.08/kWh. Hot-water tank insulation kits large enough to wrap the entire tank are available on the market for about \$60. If such an insulation is installed on this water tank by the home owner himself, how long will it take for this additional insulation to pay for itself? Disregard any heat loss from the top and bottom surfaces, and assume the insulation to reduce the heat losses by 80 percent.

FIGURE P9–127

**9–128** A plate ( $0.5\text{ m} \times 0.5\text{ m}$ ) is inclined at an angle of  $30^\circ$ . The top surface of the plate is well insulated. Estimate the rate of heat loss from the plate when the bottom surface is maintained at  $60^\circ\text{C}$  and the surrounding atmospheric quiescent air is at  $0^\circ\text{C}$ .

**9–129** A group of 25 power transistors, dissipating 1.5 W each, are to be cooled by attaching them to a black-anodized square aluminum plate and mounting the plate on the wall of a room at 30°C. The emissivity of the transistor and the plate surfaces is 0.9. Assuming the heat transfer from the back side of the plate to be negligible and the temperature of the surrounding surfaces to be the same as the air temperature of the room, determine the size of the plate if the average surface temperature of the plate is not to exceed 50°C. *Answer: 43 cm × 43 cm*

FIGURE P9–129

**9–130** Repeat Prob. 9–129 assuming the plate to be positioned horizontally with (a) transistors facing up and (b) transistors facing down.

**9–131** Consider an  $L \times L$  horizontal plate that is placed in quiescent air with the hot surface facing up. If the film temperature is 20°C and the average Nusselt number in natural convection is of the form  $\text{Nu} = CRa_L^n$ , show that the average heat transfer coefficient can be expressed as

$$h = 1.95(\Delta T/L)^{1/4} 10^4 < Ra_L < 10^7$$

$$h = 1.79\Delta T^{1/3} \quad 10^7 < Ra_L < 10^{11}$$

**9–132** Consider a flat-plate solar collector placed horizontally on the flat roof of a house. The collector is 1.5 m wide and 4.5 m long, and the average temperature of the exposed surface of the collector is 42°C. Determine the rate of heat loss from the collector by natural convection during a calm day when the ambient air temperature is 8°C. Also, determine the heat loss by radiation by taking the emissivity of the collector surface to be 0.85 and the effective sky temperature to be –15°C.

*Answers: 1314 W, 1762 W*

**9–133** Skylights or “roof windows” are commonly used in homes and manufacturing facilities since they let natural light in during day time and thus reduce the lighting costs.

However, they offer little resistance to heat transfer, and large amounts of energy are lost through them in winter unless they are equipped with a motorized insulating cover that can be used in cold weather and at nights to reduce heat losses. Consider a 1-m-wide and 2.5-m-long horizontal skylight on the roof of a house that is kept at 20°C. The glazing of the skylight is made of a single layer of 0.5-cm-thick glass ( $k = 0.78 \text{ W/m}\cdot\text{K}$  and  $\epsilon = 0.9$ ). Determine the rate of heat loss through the skylight when the air temperature outside is –10°C and the effective sky temperature is –30°C. Compare your result with the rate of heat loss through an equivalent surface area of the roof that has a common  $R$ -5.34 construction in SI units (i.e., a thickness-to-effective-thermal-conductivity ratio of 5.34  $\text{m}^2\cdot\text{K/W}$ ). Evaluate air properties at a film temperature of –7°C and 1 atm pressure. Is this a good assumption?

FIGURE P9–133

**9–134** An electronic box that consumes 200 W of power is cooled by a fan blowing air into the box enclosure. The dimensions of the electronic box are 15 cm × 50 cm × 50 cm, and all surfaces of the box are exposed to the ambient except the base surface. Temperature measurements indicate that the box is at an average temperature of 32°C when the ambient temperature and the temperature of the surrounding walls are 25°C. If the emissivity of the outer surface of the box is 0.75, determine the fraction of the heat lost from the outer surfaces of the electronic box.

FIGURE P9–134

**9–135E** The components of an electronic system dissipating 180 W are located in a 4-ft-long horizontal duct whose cross section is 6 in × 6 in. The components in the duct are cooled by forced air, which enters at 85°F at a rate of 22 cfm and leaves at 100°F. The surfaces of the sheet metal duct are not painted, and thus radiation heat transfer from the outer surfaces is negligible. If the ambient air temperature is 80°F, determine

(a) the heat transfer from the outer surfaces of the duct to the ambient air by natural convection and (b) the average temperature of the duct. Evaluate air properties at a film temperature of 100°F and 1 atm pressure. Is this a good assumption?

**FIGURE P9–135E**

**9–136E** Repeat Prob. 9–135E assuming the fan fails and thus the entire heat generated inside the duct must be rejected to the ambient air by natural convection through the outer surfaces of the duct. Evaluate air properties at a film temperature of 120°F and 1 atm pressure. Is this a good assumption?

**9–137E** Repeat Prob. 9–135E for a circular horizontal duct of diameter 4 in. Evaluate air properties at a film temperature of 115°F and 1 atm pressure. Is this a good assumption?

**9–138** Exhaust gases from a manufacturing plant are being discharged through a 10-m-tall exhaust stack with outer diameter of 1 m. The exhaust gases are discharged at a rate of 0.125 kg/s, while temperature drop between inlet and exit of the exhaust stack is 30°C, and the constant pressure-specific heat of the exhaust gases is 1600 J/kg·K. On a particular calm day, the surrounding quiescent air temperature is 33°C. Solar radiation is incident on the exhaust stack outer surface at a rate of 500 W/m<sup>2</sup>, and both the emissivity and solar absorptivity of the outer surface are 0.9. Determine the exhaust stack outer surface temperature. Assume the film temperature is 60°C.

**FIGURE P9–138**

**9–139** A 40-cm-diameter, 110-cm-high cylindrical hot-water tank is located in the bathroom of a house maintained at 20°C. The surface temperature of the tank is measured to be 44°C and its emissivity is 0.4. Taking the surrounding surface temperature to be also 20°C, determine the rate of heat loss from all surfaces of the tank by natural convection and radiation.

**9–140** A 10-cm-diameter and 10-m-long cylinder with a surface temperature of 10°C is placed horizontally in air at 40°C. Calculate the steady rate of heat transfer for the cases of (a) free-stream air velocity of 10 m/s due to normal winds and (b) no winds and thus a free stream velocity of zero.

**9–141E** Hot water is flowing at an average velocity of 4 ft/s through a cast iron pipe ( $k = 30 \text{ Btu/h}\cdot\text{ft}^{\circ}\text{F}$ ) whose inner and outer diameters are 1.0 in and 1.2 in, respectively. The pipe passes through a 50-ft-long section of a basement whose temperature is 60°F. The emissivity of the outer surface of the pipe is 0.5, and the walls of the basement are also at about 60°F. If the inlet temperature of the water is 150°F and the heat transfer coefficient on the inner surface of the pipe is 30 Btu/h·ft<sup>2</sup>·°F, determine the temperature drop of water as it passes through the basement. Evaluate air properties at a film temperature of 105°C and 1 atm pressure. Is this a good assumption?

**9–142E** A 0.1-W small cylindrical resistor mounted on a lower part of a vertical circuit board is 0.3 in long and has a diameter of 0.2 in. The view of the resistor is largely blocked by another circuit board facing it, and the heat transfer through the connecting wires is negligible. The air is free to flow through the large parallel flow passages between the boards as a result of natural convection currents. If the air temperature at the vicinity of the resistor is 120°F, determine the approximate surface temperature of the resistor. Evaluate air properties at a film temperature of 170°F and 1 atm pressure. Is this a good assumption? *Answer: 211°F*

**FIGURE P9–142E**

**9–143E** Consider an industrial furnace that resembles a 13-ft-long horizontal cylindrical enclosure 8 ft in diameter whose end surfaces are well insulated. The furnace burns natural gas at a rate of 48 therms/h. The combustion efficiency of the furnace is 82 percent (i.e., 18 percent of the chemical

energy of the fuel is lost through the flue gases as a result of incomplete combustion and the flue gases leaving the furnace at high temperature). If the heat loss from the outer surfaces of the furnace by natural convection and radiation is not to exceed 1 percent of the heat generated inside, determine the highest allowable surface temperature of the furnace. Assume the air and wall surface temperature of the room to be 75°F, and take the emissivity of the outer surface of the furnace to be 0.85. If the cost of natural gas is \$1.15/therm and the furnace operates 2800 h per year, determine the annual cost of this heat loss to the plant. Evaluate properties of air at a film temperature of 107.5°F and 1 atm pressure. Is this a good assumption?

FIGURE P9-143E

**9-144** A 6-m-internal-diameter spherical tank made of 1.5-cm-thick stainless steel ( $k = 15 \text{ W/m}\cdot\text{K}$ ) is used to store iced water at 0°C in a room at 20°C. The walls of the room are also at 20°C. The outer surface of the tank is black (emissivity  $\varepsilon = 1$ ), and heat transfer between the outer surface of the tank and the surroundings is by natural convection and radiation. Assuming the entire steel tank to be at 0°C and thus the thermal resistance of the tank to be negligible, determine (a) the rate of heat transfer to the iced water in the tank and (b) the amount of ice at 0°C that melts during a 24-h period. The heat of fusion of water is 333.7 kJ/kg.

Answers: (a) 15.4 kW, (b) 3988 kg

**9-145** A spherical vessel, with 30.0-cm outside diameter, is used as a reactor for a slow endothermic reaction. The vessel is completely submerged in a large water-filled tank, held at a constant temperature of 30°C. The outside surface temperature of the vessel is 20°C. Calculate the rate of heat transfer in steady operation for the following cases: (a) the water in the tank is still, (b) the water in the tank is still (as in a part a), however, the buoyancy force caused by the difference in water density is assumed to be negligible, and (c) the water in the tank is circulated at an average velocity of 20 cm/s.

**9-146** Consider a 1.2-m-high and 2-m-wide double-pane window consisting of two 3-mm-thick layers of glass ( $k = 0.78 \text{ W/m}\cdot\text{K}$ ) separated by a 3-cm-wide air space. Determine the steady rate of heat transfer through this window and the temperature of its inner surface for a day during which the room is maintained at 20°C while the temperature of the

outdoors is 0°C. Take the heat transfer coefficients on the inner and outer surfaces of the window to be  $h_1 = 10 \text{ W/m}^2\cdot\text{K}$  and  $h_2 = 25 \text{ W/m}^2\cdot\text{K}$  and disregard any heat transfer by radiation. Evaluate air properties at a film temperature of 10°C and 1 atm pressure. Is this a good assumption?

**9-147** A solar collector consists of a horizontal copper tube of outer diameter 5 cm enclosed in a concentric thin glass tube of 9 cm diameter. Water is heated as it flows through the tube, and the annular space between the copper and glass tube is filled with air at 1 atm pressure. During a clear day, the temperatures of the tube surface and the glass cover are measured to be 60°C and 32°C, respectively. Determine the rate of heat loss from the collector by natural convection per meter length of the tube. Answer: 17.4 W

FIGURE P9-147

**9-148** A solar collector consists of a horizontal aluminum tube of outer diameter 5 cm enclosed in a concentric thin glass tube of 7 cm diameter. Water is heated as it flows through the aluminum tube, and the annular space between the aluminum and glass tubes is filled with air at 1 atm pressure. The pump circulating the water fails during a clear day, and the water temperature in the tube starts rising. The aluminum tube absorbs solar radiation at a rate of 20 W per meter length, and the temperature of the ambient air outside is 30°C. Approximating the surfaces of the tube and the glass cover as being black (emissivity  $\varepsilon = 1$ ) in radiation calculations and taking the effective sky temperature to be 20°C, determine the temperature of the aluminum tube when equilibrium is established (i.e., when the net heat loss from the tube by convection and radiation equals the amount of solar energy absorbed by the tube). For evaluation of air properties at 1 atm pressure, assume 33°C for the surface temperature of the glass cover and 45°C for the aluminum tube temperature. Are these good assumptions?

**9-149** Two concentric spheres with diameters of 5 cm and 10 cm are having the surface temperatures maintained at 200°C and 100°C, respectively (see Fig. P9-149 on the next page). The enclosure between the two concentric spherical surfaces is filled with nitrogen gas at 1 atm. If both concentric sphere surfaces are black ( $\varepsilon = 1$ ), determine the rate of heat transfer on the inner surface.

FIGURE P9–149

## Fundamentals of Engineering (FE) Exam Problems

**9–150** Consider a hot, boiled egg in a spacecraft that is filled with air at atmospheric pressure and temperature at all times. Disregarding any radiation effect, will the egg cool faster or slower when the spacecraft is in space instead of on the ground?

- (a) faster
- (b) no difference
- (c) slower
- (d) insufficient information

**9–151** A hot object suspended by a string is to be cooled by natural convection in fluids whose volume changes differently with temperature at constant pressure. In which fluid will the rate of cooling be lowest? With increasing temperature, a fluid whose volume

- (a) increases a lot
- (b) increases slightly
- (c) does not change
- (d) decreases slightly
- (e) decreases a lot.

**9–152** A spherical block of dry ice at  $-79^\circ\text{C}$  is exposed to atmospheric air at  $30^\circ\text{C}$ . The general direction in which the air moves in this situation is

- (a) horizontal
- (b) up
- (c) down
- (d) recirculation around the sphere
- (e) no motion

**9–153** The primary driving force for natural convection is

- (a) shear stress forces
- (b) buoyancy forces
- (c) pressure forces
- (d) surface tension forces
- (e) none of them

**9–154** Consider a horizontal 0.7-m-wide and 0.85-m-long plate in a room at  $30^\circ\text{C}$ . Top side of the plate is insulated while the bottom side is maintained at  $0^\circ\text{C}$ . The rate of heat transfer from the room air to the plate by natural convection is

- (a) 36.8 W
- (b) 43.7 W
- (c) 128.5 W
- (d) 92.7 W
- (e) 69.7 W

(For air, use  $k = 0.02476 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 0.7323$ ,  $v = 1.470 \times 10^{-5} \text{ m}^2/\text{s}$ )

**9–155** A 4-m-long section of a 5-cm-diameter horizontal pipe in which a refrigerant flows passes through a room at  $20^\circ\text{C}$ . The pipe is not well insulated and the outer surface temperature

of the pipe is observed to be  $-10^\circ\text{C}$ . The emissivity of the pipe surface is 0.85, and the surrounding surfaces are at  $15^\circ\text{C}$ . The fraction of heat transferred to the pipe by radiation is

- (a) 0.24
- (b) 0.30
- (c) 0.37
- (d) 0.48
- (e) 0.58

(For air, use  $k = 0.02401 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 0.735$ ,  $v = 1.382 \times 10^{-5} \text{ m}^2/\text{s}$ )

**9–156** Consider a 0.3-m-diameter and 1.8-m-long horizontal cylinder in a room at  $20^\circ\text{C}$ . If the outer surface temperature of the cylinder is  $40^\circ\text{C}$ , the natural convection heat transfer coefficient is

- (a)  $3.0 \text{ W/m}^2\cdot\text{K}$
- (b)  $3.5 \text{ W/m}^2\cdot\text{K}$
- (c)  $3.9 \text{ W/m}^2\cdot\text{K}$
- (d)  $4.6 \text{ W/m}^2\cdot\text{K}$
- (e)  $5.7 \text{ W/m}^2\cdot\text{K}$

**9–157** A 4-m-diameter spherical tank contains iced water at  $0^\circ\text{C}$ . The tank is thin-shelled and thus its outer surface temperature may be assumed to be same as the temperature of the iced water inside. Now the tank is placed in a large lake at  $20^\circ\text{C}$ . The rate at which the ice melts is

- (a)  $0.42 \text{ kg/s}$
- (b)  $0.58 \text{ kg/s}$
- (c)  $0.70 \text{ kg/s}$
- (d)  $0.83 \text{ kg/s}$
- (e)  $0.98 \text{ kg/s}$

(For lake water, use  $k = 0.580 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 9.45$ ,  $v = 0.1307 \times 10^{-5} \text{ m}^2/\text{s}$ ,  $\beta = 0.138 \times 10^{-3} \text{ K}^{-1}$ )

**9–158** A vertical double-pane window consists of two sheets of glass separated by a 1.5-cm air gap at atmospheric pressure. The glass surface temperatures across the air gap are measured to be  $278 \text{ K}$  and  $288 \text{ K}$ . If it is estimated that the heat transfer by convection through the enclosure is 1.5 times that by pure conduction and that the rate of heat transfer by radiation through the enclosure is about the same magnitude as the convection, the effective emissivity of the two glass surfaces is

- (a) 0.47
- (b) 0.53
- (c) 0.61
- (d) 0.65
- (e) 0.72

**9–159** A horizontal 1.5-m-wide, 4.5-m-long double-pane window consists of two sheets of glass separated by a 3.5-cm gap filled with water. If the glass surface temperatures at the bottom and the top are measured to be  $60^\circ\text{C}$  and  $40^\circ\text{C}$ , respectively, the rate of heat transfer through the window is

- (a)  $27.6 \text{ kW}$
- (b)  $39.4 \text{ kW}$
- (c)  $59.6 \text{ kW}$
- (d)  $66.4 \text{ kW}$
- (e)  $75.5 \text{ kW}$

(For water, use  $k = 0.644 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 3.55$ ,  $v = 0.554 \times 10^{-6} \text{ m}^2/\text{s}$ ,  $\beta = 0.451 \times 10^{-3} \text{ K}^{-1}$ . Also, the applicable correlation is  $\text{Nu} = 0.069 \text{ Ra}^{1/3} \text{ Pr}^{0.074}$ ).

**9–160** A vertical 0.9-m-high and 1.8-m-wide double-pane window consists of two sheets of glass separated by a 2.2-cm air gap at atmospheric pressure. If the glass surface temperatures across the air gap are measured to be  $20^\circ\text{C}$  and  $30^\circ\text{C}$ , the rate of heat transfer through the window is

- (a)  $19.8 \text{ W}$
- (b)  $26.1 \text{ W}$
- (c)  $30.5 \text{ W}$
- (d)  $34.7 \text{ W}$
- (e)  $55.0 \text{ W}$

(For air, use  $k = 0.02551 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 0.7296$ ,  $v = 1.562 \times 10^{-5} \text{ m}^2/\text{s}$ . Also, the applicable correlation is  $\text{Nu} = 0.42 \text{ Ra}^{1/4} \text{ Pr}^{0.012} (H/L)^{-0.3}$ )

(For air, use  $k = 0.02588 \text{ W/m}\cdot\text{K}$ ,  $\Pr = 0.7282$ ,  $v = 1.608 \times 10^{-5} \text{ m}^2/\text{s}$ )

**9–161** Two concentric cylinders of diameters  $D_i = 30$  cm and  $D_o = 40$  cm and length  $L = 5$  m are separated by air at 1 atm pressure. Heat is generated within the inner cylinder uniformly at a rate of  $1100 \text{ W/m}^3$ , and the inner surface temperature of the outer cylinder is 300 K. The steady-state outer surface temperature of the inner cylinder is

(d) 442 K      (e) 456 K

(For air, use  $k = 0.03095 \text{ W/m}\cdot\text{K}$ ,  $\text{Pr} = 0.7111$ ,  $v = 2.306 \times 10^{-5} \text{ m}^2/\text{s}$ )

### Design and Essay Problems

**9–162** Write a computer program to evaluate the variation of temperature with time of thin square metal plates that are removed from an oven at a specified temperature and placed vertically in a large room. The thickness, the size, the initial temperature, the emissivity, and the thermophysical properties of the plate as well as the room temperature are to be specified by the user. The program should evaluate the temperature of the plate at specified intervals and tabulate the results against time. The computer should list the assumptions made during calculations before printing the results.

For each step or time interval, assume the surface temperature to be constant and evaluate the heat loss during that time interval and the temperature drop of the plate as a result of this heat loss. This gives the temperature of the plate at the end of a time interval, which is to serve as the initial temperature of the plate for the beginning of the next time interval.

Try your program for 0.2-cm-thick vertical copper plates of  $40 \text{ cm} \times 40 \text{ cm}$  in size initially at  $300^\circ\text{C}$  cooled in a room

at  $25^\circ\text{C}$ . Take the surface emissivity to be 0.9. Use a time interval of 1 s in calculations, but print the results at 10-s intervals for a total cooling period of 15 min.

**9–163** Write a computer program to optimize the spacing between the two glasses of a double-pane window. Assume the spacing is filled with dry air at atmospheric pressure. The program should evaluate the recommended practical value of the spacing to minimize the heat losses and list it when the size of the window (the height and the width) and the temperatures of the two glasses are specified.

**9–164** Contact a manufacturer of aluminum heat sinks and obtain their product catalog for cooling electronic components by natural convection and radiation. Write an essay on how to select a suitable heat sink for an electronic component when its maximum power dissipation and maximum allowable surface temperature are specified.

**9–165** The top surfaces of practically all flat-plate solar collectors are covered with glass in order to reduce the heat losses from the absorber plate underneath. Although the glass cover reflects or absorbs about 15 percent of the incident solar radiation, it saves much more from the potential heat losses from the absorber plate, and thus it is considered to be an essential part of a well-designed solar collector. Inspired by the energy efficiency of double-pane windows, someone proposes to use double glazing on solar collectors instead of a single glass. Investigate if this is a good idea for the town in which you live. Use local weather data and base your conclusion on heat transfer analysis and economic considerations.

## BOILING AND CONDENSATION

### OBJECTIVES

When you finish studying this chapter, you should be able to:

- Differentiate between evaporation and boiling, and gain familiarity with different types of boiling,
- Develop a good understanding of the boiling curve, and the different boiling regimes corresponding to different regions of the boiling curve,
- Calculate the heat flux and its critical value associated with nucleate boiling, and examine the methods of boiling heat transfer enhancement,
- Derive a relation for the heat transfer coefficient in laminar film condensation over a vertical plate,
- Calculate the heat flux associated with condensation on inclined and horizontal plates, vertical and horizontal cylinders or spheres, and tube bundles,
- Examine dropwise condensation and understand the uncertainties associated with them.

We know from thermodynamics that when the temperature of a liquid at a specified pressure is raised to the saturation temperature  $T_{\text{sat}}$  at that pressure, *boiling* occurs. Likewise, when the temperature of a vapor is lowered to  $T_{\text{sat}}$ , *condensation* occurs. In this chapter we study the rates of heat transfer during such liquid-to-vapor and vapor-to-liquid phase transformations.

Although boiling and condensation exhibit some unique features, they are considered to be forms of *convection* heat transfer since they involve fluid motion (such as the rise of the bubbles to the top and the flow of condensate to the bottom). Boiling and condensation differ from other forms of convection in that they depend on the *latent heat of vaporization*  $h_{fg}$  of the fluid and the *surface tension*  $\sigma$  at the liquid–vapor interface, in addition to the properties of the fluid in each phase. Noting that under equilibrium conditions the temperature remains constant during a phase-change process at a fixed pressure, large amounts of heat (due to the large latent heat of vaporization released or absorbed) can be transferred during boiling and condensation essentially at constant temperature. In practice, however, it is necessary to maintain some difference between the surface temperature  $T_s$  and  $T_{\text{sat}}$  for effective heat transfer. Heat transfer coefficients  $h$  associated with boiling and condensation are typically much higher than those encountered in other forms of convection processes that involve a single phase.

We start this chapter with a discussion of the *boiling curve* and the modes of pool boiling such as *free convection boiling*, *nucleate boiling*, and *film boiling*. We then discuss boiling in the presence of forced convection. In the second part of this chapter, we describe the physical mechanism of *film condensation* and discuss condensation heat transfer in several geometrical arrangements and orientations. Finally, we introduce *dropwise condensation* and discuss ways of maintaining it.

## 10–1 • BOILING HEAT TRANSFER

Many familiar engineering applications involve condensation and boiling heat transfer. In a household refrigerator, for example, the refrigerant absorbs heat from the refrigerated space by boiling in the *evaporator* section and rejects heat to the kitchen air by condensing in the *condenser* section (the long coils behind or under the refrigerator). Also, in steam power plants, heat is transferred to the steam in the *boiler* where water is vaporized, and the waste heat is rejected from the steam in the *condenser* where the steam is condensed. Some electronic components are cooled by boiling by immersing them in a fluid with an appropriate boiling temperature.

Boiling is a liquid-to-vapor phase change process just like evaporation, but there are significant differences between the two. **Evaporation** occurs at the *liquid–vapor interface* when the vapor pressure is less than the saturation pressure of the liquid at a given temperature. Water in a lake at 20°C, for example, evaporates to air at 20°C and 60 percent relative humidity since the saturation pressure of water at 20°C is 2.3 kPa and the vapor pressure of air at 20°C and 60 percent relative humidity is 1.4 kPa (evaporation rates are determined in Chapter 14). Other examples of evaporation are the drying of clothes, fruits, and vegetables; the evaporation of sweat to cool the human body; and the rejection of waste heat in wet cooling towers. Note that evaporation involves no bubble formation or bubble motion (Fig. 10–1).

**Boiling**, on the other hand, occurs at the *solid–liquid interface* when a liquid is brought into contact with a surface maintained at a temperature  $T_s$  sufficiently above the saturation temperature  $T_{\text{sat}}$  of the liquid (Fig. 10–2). At 1 atm, for example, liquid water in contact with a solid surface at 110°C boils since the saturation temperature of water at 1 atm is 100°C. The boiling process is characterized by the rapid formation of *vapor bubbles* at the solid–liquid interface that detach from the surface when they reach a certain size and attempt to rise to the free surface of the liquid. When cooking, we do not say water is boiling until we see the bubbles rising to the top. Boiling is a complicated phenomenon because of the large number of variables involved in the process and the complex fluid motion patterns caused by the bubble formation and growth.

As a form of convection heat transfer, the *boiling heat flux* from a solid surface to the fluid is expressed from Newton's law of cooling as

$$\dot{q}_{\text{boiling}} = h(T_s - T_{\text{sat}}) = h\Delta T_{\text{excess}} \quad (\text{W/m}^2) \quad (10-1)$$

where  $\Delta T_{\text{excess}} = T_s - T_{\text{sat}}$  is called the *excess temperature*, which represents the temperature excess of the surface above the saturation temperature of the fluid.

In the preceding chapters we considered forced and free convection heat transfer involving a single phase of a fluid. The analysis of such convection processes involves the thermophysical properties  $\rho$ ,  $\mu$ ,  $k$ , and  $c_p$  of the fluid. The analysis of boiling heat transfer involves these properties of the liquid (indicated by the subscript  $l$ ) or vapor (indicated by the subscript  $v$ ) as well as the properties  $h_{fg}$  (the latent heat of vaporization) and  $\sigma$  (the surface tension). The  $h_{fg}$  represents the energy absorbed as a unit mass of liquid vaporizes at a specified temperature or pressure and is the primary quantity of energy transferred during boiling heat transfer. The  $h_{fg}$  values of water at various temperatures are given in Table A–9.

FIGURE 10–1

A liquid-to-vapor phase change process is called *evaporation* if it originates at a liquid–vapor interface and *boiling* if it occurs at a solid–liquid interface.

FIGURE 10–2

Boiling occurs when a liquid is brought into contact with a surface at a temperature above the saturation temperature of the liquid.

Bubbles owe their existence to the *surface-tension*  $\sigma$  at the liquid–vapor interface due to the attraction force on molecules at the interface toward the liquid phase. The surface tension decreases with increasing temperature and becomes zero at the critical temperature. This explains why no bubbles are formed during boiling at supercritical pressures and temperatures. Surface tension has the unit N/m.

The boiling processes in practice do not occur under *equilibrium* conditions, and normally the bubbles are not in thermodynamic equilibrium with the surrounding liquid. That is, the temperature and pressure of the vapor in a bubble are usually different than those of the liquid. The pressure difference between the liquid and the vapor is balanced by the surface tension at the interface. The temperature difference between the vapor in a bubble and the surrounding liquid is the driving force for heat transfer between the two phases. When the liquid is at a *lower temperature* than the bubble, heat is transferred from the bubble into the liquid, causing some of the vapor inside the bubble to condense and the bubble eventually to collapse. When the liquid is at a *higher temperature* than the bubble, heat is transferred from the liquid to the bubble, causing the bubble to grow and rise to the top under the influence of buoyancy.

Boiling is classified as *pool boiling* or *flow boiling*, depending on the presence of bulk fluid motion (Fig. 10–3). Boiling is called **pool boiling** in the absence of bulk fluid flow and **flow boiling** (or *forced convection boiling*) in the presence of it. In pool boiling, the fluid body is stationary, and any motion of the fluid is due to natural convection currents and the motion of the bubbles under the influence of buoyancy. The boiling of water in a pan on top of a stove is an example of pool boiling. Pool boiling of a fluid can also be achieved by placing a heating coil in the fluid. In flow boiling, the fluid is forced to move in a heated pipe or over a surface by external means such as a pump. Therefore, flow boiling is always accompanied by other convection effects.

Pool and flow boiling are further classified as *subcooled boiling* or *saturated boiling*, depending on the bulk liquid temperature (Fig. 10–4). Boiling is said to be **subcooled** (or *local*) when the temperature of the main body of the liquid is below the saturation temperature  $T_{\text{sat}}$  (i.e., the bulk of the liquid is subcooled) and **saturated** (or *bulk*) when the temperature of the liquid is equal to  $T_{\text{sat}}$  (i.e., the bulk of the liquid is saturated). At the early stages of boiling, the bubbles are confined to a narrow region near the hot surface. This is because the liquid adjacent to the hot surface vaporizes as a result of being heated above its saturation temperature. But these bubbles disappear soon after they move away from the hot surface as a result of heat transfer from the bubbles to the cooler liquid surrounding them. This happens when the bulk of the liquid is at a lower temperature than the saturation temperature. The bubbles serve as “energy movers” from the hot surface into the liquid body by absorbing heat from the hot surface and releasing it into the liquid as they condense and collapse. Boiling in this case is confined to a region in the locality of the hot surface and is appropriately called *local* or *subcooled* boiling. When the entire liquid body reaches the saturation temperature, the bubbles start rising to the top. We can see bubbles throughout the bulk of the liquid, and boiling in this case is called the *bulk* or *saturated* boiling. Next, we consider different boiling regimes in detail.

**FIGURE 10–3**

Classification of boiling on the basis of the presence of bulk fluid motion.

**FIGURE 10–4**

Classification of boiling on the basis of the presence of bulk liquid temperature.

## 10–2 • POOL BOILING

So far we presented some general discussions on boiling. Now we turn our attention to the physical mechanisms involved in *pool boiling*, that is, the boiling of stationary fluids. In pool boiling, the fluid is not forced to flow by a mover such as a pump, and any motion of the fluid is due to natural convection currents and the motion of the bubbles under the influence of buoyancy.

As a familiar example of pool boiling, consider the boiling of tap water in a pan on top of a stove. The water is initially at about 15°C, far below the saturation temperature of 100°C at standard atmospheric pressure. At the early stages of boiling, you will not notice anything significant except some bubbles that stick to the surface of the pan. These bubbles are caused by the release of air molecules dissolved in liquid water and should not be confused with vapor bubbles. As the water temperature rises, you will notice chunks of liquid water rolling up and down as a result of natural convection currents, followed by the first vapor bubbles forming at the bottom surface of the pan. These bubbles get smaller as they detach from the surface and start rising, and eventually collapse in the cooler water above. This is *subcooled boiling* since the bulk of the liquid water has not reached saturation temperature yet. The intensity of bubble formation increases as the water temperature rises further, and you will notice waves of vapor bubbles coming from the bottom and rising to the top when the water temperature reaches the saturation temperature (100°C at standard atmospheric conditions). This full scale boiling is the *saturated boiling*.

### Boiling Regimes and the Boiling Curve

Boiling is probably the most familiar form of heat transfer, yet it remains to be the least understood form. After hundreds of papers written on the subject, we still do not fully understand the process of bubble formation and we must still rely on empirical or semi-empirical relations to predict the rate of boiling heat transfer.

The pioneering work on boiling was done in 1934 by S. Nukiyama, who used electrically heated nichrome and platinum wires immersed in liquids in his experiments. Nukiyama noticed that boiling takes different forms, depending on the value of the excess temperature  $\Delta T_{\text{excess}}$ . Four different boiling regimes are observed: *natural convection boiling*, *nucleate boiling*, *transition boiling*, and *film boiling* (Fig. 10–5). These regimes are illustrated on the **boiling curve** in Fig. 10–6, which is a plot of boiling heat flux versus the excess temperature. Although the boiling curve given in this figure is for water, the general shape of the boiling curve remains the same for different fluids. The specific shape of the curve depends on the fluid–heating surface material combination and the fluid pressure, but it is practically independent of the geometry of the heating surface. We now describe each boiling regime in detail.

### Natural Convection Boiling (to Point A on the Boiling Curve)

We know from thermodynamics that a pure substance at a specified pressure starts boiling when it reaches the saturation temperature at that pressure. But in practice we do not see any bubbles forming on the heating surface until the liquid is heated a few degrees above the saturation temperature (about 2 to 6°C for water). Therefore, the liquid is slightly *superheated* in this case (a *metastable*

**FIGURE 10–5**  
Different boiling regimes in pool boiling.

**FIGURE 10–6**

Typical boiling curve for water at 1 atm pressure.

condition) and evaporates when it rises to the free surface. The fluid motion in this mode of boiling is governed by natural convection currents, and heat transfer from the heating surface to the fluid is by natural convection. For the conditions of Fig. 10–6, natural convection boiling ends at an excess temperature of about 5°C.

### Nucleate Boiling (between Points A and C)

The first bubbles start forming at point A of the boiling curve at various preferential sites on the heating surface. Point A is referred to as the *onset of nucleate boiling (ONB)*. The bubbles form at an increasing rate at an increasing number of nucleation sites as we move along the boiling curve toward point C. From Fig. 10–6, nucleate boiling exists in the range from about 5°C to about 30°C.

The nucleate boiling regime can be separated into two distinct regions. In region A–B ( $5^{\circ}\text{C} \leq \Delta T_{\text{excess}} \leq 10^{\circ}\text{C}$ ), *isolated bubbles* are formed at various preferential nucleation sites on the heated surface. But these bubbles are dissipated in the liquid shortly after they separate from the surface. The space vacated by the rising bubbles is filled by the liquid in the vicinity of the heater surface, and the process is repeated. The stirring and agitation caused by the entrainment of the liquid to the heater surface is primarily responsible for the increased heat transfer coefficient and heat flux in this region of nucleate boiling.

In region B–C ( $10^{\circ}\text{C} \leq \Delta T_{\text{excess}} \leq 30^{\circ}\text{C}$ ), the heater temperature is further increased, and bubbles form at such great rates at such a large number of nucleation sites that they form numerous *continuous columns of vapor* in the liquid. These bubbles move all the way up to the free surface, where they break up and release their vapor content. The large heat fluxes obtainable in this region are caused by the combined effect of liquid entrainment and evaporation.

At large values of  $\Delta T_{\text{excess}}$ , the rate of evaporation at the heater surface reaches such high values that a large fraction of the heater surface is covered by bubbles, making it difficult for the liquid to reach the heater surface and wet it. Consequently, the heat flux increases at a lower rate with increasing  $\Delta T_{\text{excess}}$ , and reaches a maximum at point C. The heat flux at this point is called the **critical (or maximum) heat flux (CHF)**,  $\dot{q}_{\max}$ . For water, the critical heat flux exceeds 1 MW/m<sup>2</sup>. From Newton's law of cooling, the heat transfer coefficient

at point C is  $h = \dot{q}_{\max}/\Delta T_{\text{excess}} = (10^6 \text{ W/m}^2)/30 \text{ K} = 3.3 \times 10^4 \text{ W/m}^2 \cdot \text{K}$ . For the entire nucleate boiling range of Fig. 10–6, the heat transfer coefficient ranges from about 2000 to 30,000  $\text{W/m}^2 \cdot \text{K}$ , which is within the range of values tabulated in Table 1–5 for boiling.

Nucleate boiling is the most desirable boiling regime in practice because high heat transfer rates can be achieved in this regime with relatively small values of  $\Delta T_{\text{excess}}$ , typically under 30°C for water. The photographs in Fig. 10–7 show the nature of bubble formation and bubble motion associated with boiling.

## Transition Boiling (between Points C and D)

As the heater temperature and thus the  $\Delta T_{\text{excess}}$  is increased past point C, the heat flux decreases, as shown in Fig. 10–6. This is because a large fraction of the heater surface is covered by a vapor film, which acts as an insulation due to the low thermal conductivity of the vapor relative to that of the liquid. In the transition boiling regime, both nucleate and film boiling partially occur. Nucleate boiling at point C is completely replaced by film boiling at point D. Operation in the transition boiling regime, which is also called the *unstable film boiling regime*, is avoided in practice. For water, transition boiling occurs over the excess temperature range from about 30°C to about 120°C.

## Film Boiling (beyond Point D)

In this region the heater surface is completely covered by a continuous stable vapor film. Point D, where the heat flux reaches a minimum, is called the **Leidenfrost point**, in honor of J. C. Leidenfrost, who observed in 1756 that liquid droplets on a very hot surface jump around and slowly boil away. The presence of a vapor film between the heater surface and the liquid is responsible for the low heat transfer rates in the film boiling region. The heat transfer rate increases with increasing excess temperature as a result of heat transfer from the heated surface to the liquid through the vapor film by radiation, which becomes significant at high temperatures.

A typical boiling process does not follow the boiling curve beyond point C, as Nukiyama has observed during his experiments. Nukiyama noticed, with surprise, that when the power applied to the nichrome wire immersed in water exceeded  $\dot{q}_{\max}$  even slightly, the wire temperature increased suddenly to the melting point of the wire (1500 K) and *burnout* occurred beyond his control. When he repeated the experiments with platinum wire, which has a much higher melting point (2045 K), he was able to avoid burnout and maintain heat fluxes higher than  $\dot{q}_{\max}$ . When he gradually reduced power, he obtained the cooling curve shown in Fig. 10–8 with a sudden drop in excess temperature when  $\dot{q}_{\min}$  is reached. Note that the boiling process cannot follow the transition boiling part of the boiling curve past point C unless the power applied is reduced suddenly.

The *burnout phenomenon* in boiling can be explained as follows: In order to move beyond point C where  $\dot{q}_{\max}$  occurs, we must increase the heater surface temperature  $T_s$ . To increase  $T_s$ , however, we must increase the heat flux. But the fluid cannot receive this increased energy at an excess temperature just beyond point C. Therefore, the heater surface ends up absorbing the increased energy, causing the heater surface temperature  $T_s$  to rise. But the fluid can receive even less energy at this increased excess temperature, causing the heater surface temperature  $T_s$  to rise even further. This continues until the

**FIGURE 10–8**

The actual boiling curve obtained with heated platinum wire in water as the heat flux is increased and then decreased.

FIGURE 10-9

An attempt to increase the boiling heat flux beyond the critical value often causes the temperature of the heating element to jump suddenly to a value that is above the melting point, resulting in *burnout*.

surface temperature reaches a point at which it no longer rises and the heat supplied can be transferred to the fluid steadily. This is point *E* on the boiling curve, which corresponds to very high surface temperatures. Therefore, any attempt to increase the heat flux beyond  $\dot{q}_{\max}$  will cause the operation point on the boiling curve to jump suddenly from point *C* to point *E*. However, surface temperature that corresponds to point *E* is beyond the melting point of most heater materials, and *burnout* occurs. Therefore, point *C* on the boiling curve is also called the **burnout point**, and the heat flux at this point the **burnout heat flux** (Fig. 10-9).

Most boiling heat transfer equipment in practice operate slightly below  $\dot{q}_{\max}$  to avoid any disastrous burnout. However, in cryogenic applications involving fluids with very low boiling points such as oxygen and nitrogen, point *E* usually falls below the melting point of the heater materials, and steady film boiling can be used in those cases without any danger of burnout.

## Heat Transfer Correlations in Pool Boiling

Boiling regimes discussed above differ considerably in their character, and thus different heat transfer relations need to be used for different boiling regimes (Fig. 10-10). In the *natural convection boiling* regime ( $\Delta T_{\text{excess}} \leq 5^{\circ}\text{C}$ ), boiling is governed by natural convection currents, and heat transfer rates in this case can be determined accurately using natural convection relations presented in Chapter 9.

FIGURE 10-10

Different relations are used to determine the heat flux in different boiling regimes.

## Nucleate Boiling

In the *nucleate boiling* regime ( $5^{\circ}\text{C} \leq \Delta T_{\text{excess}} \leq 30^{\circ}\text{C}$ ), the rate of heat transfer strongly depends on the nature of nucleation (the number of active nucleation sites on the surface, the rate of bubble formation at each site, etc.), which is difficult to predict. The type and the condition of the heated surface also affect the heat transfer. These complications made it difficult to develop theoretical relations for heat transfer in the nucleate boiling regime, and we had to rely on relations based on experimental data. The most widely used correlation for the rate of heat transfer in the nucleate boiling regime was proposed in 1952 by Rohsenow, and expressed as

$$\dot{q}_{\text{nucleate}} = \mu_l h_{fg} \left[ \frac{g(\rho_l - \rho_v)}{\sigma} \right]^{1/2} \left[ \frac{c_{pl}(T_s - T_{\text{sat}})}{C_{sf} h_{fg} \text{Pr}_l^n} \right]^3 \quad (10-2)$$

where

$\dot{q}_{\text{nucleate}}$  = nucleate boiling heat flux,  $\text{W}/\text{m}^2$

$\mu_l$  = viscosity of the liquid,  $\text{kg}/\text{m}\cdot\text{s}$

$h_{fg}$  = enthalpy of vaporization,  $\text{J}/\text{kg}$

$g$  = gravitational acceleration,  $\text{m}/\text{s}^2$

$\rho_l$  = density of the liquid,  $\text{kg}/\text{m}^3$

$\rho_v$  = density of the vapor,  $\text{kg}/\text{m}^3$

$\sigma$  = surface tension of liquid–vapor interface,  $\text{N}/\text{m}$

$c_{pl}$  = specific heat of the liquid,  $\text{J}/\text{kg}\cdot^{\circ}\text{C}$

$T_s$  = surface temperature of the heater,  $^{\circ}\text{C}$

$T_{\text{sat}}$  = saturation temperature of the fluid,  $^{\circ}\text{C}$

$C_{sf}$  = experimental constant that depends on surface–fluid combination

$\text{Pr}_l$  = Prandtl number of the liquid

$n$  = experimental constant that depends on the fluid

It can be shown easily that using property values in the specified units in the Rohsenow equation produces the desired unit W/m<sup>2</sup> for the boiling heat flux, thus saving one from having to go through tedious unit manipulations (Fig. 10–11).

The surface tension at the vapor–liquid interface is given in Table 10–1 for water, and Table 10–2 for some other fluids. Experimentally determined values of the constant  $C_{sf}$  and  $n$  (fluid-dependent experimental constant) are given in Table 10–3 for various fluid–surface combinations. These values can be used for *any geometry* since it is found that the rate of heat transfer during nucleate boiling is essentially independent of the geometry and orientation of the heated surface. The fluid properties in Eq. 10–2 are to be evaluated at the saturation temperature  $T_{\text{sat}}$ .

The *condition* of the heater surface greatly affects heat transfer, and the Rohsenow equation given above is applicable to *clean* and relatively *smooth* surfaces. The results obtained using the Rohsenow equation can be in error by  $\pm 100\%$  for the heat transfer rate for a given excess temperature and by  $\pm 30\%$  for the excess temperature for a given heat transfer rate. Therefore, care should be exercised in the interpretation of the results.

Recall from thermodynamics that the enthalpy of vaporization  $h_{fg}$  of a pure substance decreases with increasing pressure (or temperature) and reaches zero at the critical point. Noting that  $h_{fg}$  appears in the denominator of the Rohsenow equation, we should see a significant rise in the rate of heat transfer at *high pressures* during nucleate boiling. Values of  $h_{fg}$  for different substances are listed in Tables A–2 and A–9 to A–12.

## Peak Heat Flux

In the design of boiling heat transfer equipment, it is extremely important for the designer to have a knowledge of the maximum heat flux in order to avoid the danger of burnout. The *maximum* (or *critical*) *heat flux* in nucleate pool boiling was determined theoretically by S. S. Kutateladze in Russia in 1948 and N. Zuber in the United States in 1958 using quite different approaches, and is expressed as

$$\dot{q}_{\max} = C_{cr} h_{fg} [\sigma g \rho^2 v (\rho_l - \rho_v)]^{1/4} \quad (10-3)$$

where  $C_{cr}$  is a constant whose value depends on the heater geometry. Exhaustive experimental studies by Lienhard and his coworkers indicated that the value of  $C_{cr}$  is about 0.15. Specific values of  $C_{cr}$  for different heater geometries are listed in Table 10–4. Note that the heaters are classified as being large or small based on the value of the parameter  $L^*$ .

Equation 10–3 will give the maximum heat flux in W/m<sup>2</sup> if the properties are used *in the units specified* earlier in their descriptions following Eq. 10–2. The maximum heat flux is independent of the fluid–heating surface combination, as well as the viscosity, thermal conductivity, and the specific heat of the liquid.

Note that  $\rho_v$  increases but  $\sigma$  and  $h_{fg}$  decrease with increasing pressure, and thus the change in  $\dot{q}_{\max}$  with pressure depends on which effect dominates. The experimental studies of Cichelli and Bonilla indicate that  $\dot{q}_{\max}$  increases with pressure up to about one-third of the critical pressure, and then starts to decrease and becomes zero at the critical pressure. Also note that  $\dot{q}_{\max}$  is proportional to  $h_{fg}$ , and large maximum heat fluxes can be obtained using fluids with a large enthalpy of vaporization, such as water.

$$\begin{aligned}\dot{q} &= \left( \frac{\text{kg}}{\text{m} \cdot \text{s}} \right) \left( \frac{\text{J}}{\text{kg}} \right) \\ &\times \left( \frac{\frac{\text{m kg}}{\text{s}^2 \text{m}^3}}{\frac{\text{N}}{\text{m}}} \right)^{1/2} \left( \frac{\frac{\text{J}}{\text{kg} \cdot ^\circ\text{C}}}{\frac{\text{J}}{\text{kg}}} \right)^3 \\ &= \frac{\text{W}}{\text{m}} \left( \frac{1}{\text{m}^2} \right)^{1/2} (1)^3 \\ &= \text{W/m}^2\end{aligned}$$

<sup>1</sup> $K_1 = \sigma/[g(\rho_l - \rho_v)A_{\text{heater}}]$

## Minimum Heat Flux

Minimum heat flux, which occurs at the Leidenfrost point, is of practical interest since it represents the lower limit for the heat flux in the film boiling regime. Using the stability theory, Zuber (1958) derived the following expression for the minimum heat flux for a *large horizontal plate*,

$$\dot{q}_{\min} = 0.09 \rho_v h_{fg} \left[ \frac{\sigma g (\rho_l - \rho_v)}{(\rho_l + \rho_v)^2} \right]^{1/4} \quad (10-4)$$

where the constant 0.09 was determined by Berensen in 1961. He replaced the theoretically determined value of  $\frac{\pi}{24}$  by 0.09 to match the experimental data better. Still, the relation above can be in error by 50 percent or more.

Operation in the *transition boiling* regime ( $30^\circ\text{C} \leq \Delta T_{\text{excess}} \leq 120^\circ\text{C}$ ) is normally avoided in the design of heat transfer equipment, and thus no major attempt has been made to develop general correlations for boiling heat transfer in this regime. However, the upper (*peak heat flux*,  $\dot{q}_{\max}$ ) and the lower (*minimum heat flux*,  $\dot{q}_{\min}$ ) limits of this region are of interest to heat transfer equipment designers.

## Film Boiling

Using an analysis similar to Nusselt's theory on filmwise condensation presented in the next section, Bromley (1950) developed a theory for the prediction of heat flux for stable film boiling on the outside of a horizontal cylinder. The heat flux for film boiling on a *horizontal cylinder* or *sphere* of diameter  $D$  is given by

$$\dot{q}_{\text{film}} = C_{\text{film}} \left[ \frac{g k_v^3 \rho_v (\rho_l - \rho_v) [h_{fg} + 0.4 c_{pv} (T_s - T_{\text{sat}})]}{\mu_v D (T_s - T_{\text{sat}})} \right]^{1/4} (T_s - T_{\text{sat}}) \quad (10-5)$$

where  $k_v$  is the thermal conductivity of the vapor in  $\text{W}/\text{m}\cdot\text{K}$  and

$$C_{\text{film}} = \begin{cases} 0.62 & \text{for horizontal cylinders} \\ 0.67 & \text{for spheres} \end{cases}$$

Other properties are as listed before in connection with Eq. 10–2. We used a modified latent heat of vaporization in Eq. 10–5 to account for the heat transfer associated with the superheating of the vapor.

The *vapor* properties are to be evaluated at the *film temperature*  $T_f = (T_s + T_{\text{sat}})/2$ , which is the *average temperature* of the vapor film. The liquid properties and  $h_{fg}$  are to be evaluated at the saturation temperature at the specified pressure. Again, this relation gives the film boiling heat flux in  $\text{W}/\text{m}^2$  if the properties are used in the units specified earlier in their descriptions following Eq. 10–2.

At high surface temperatures (typically above  $300^\circ\text{C}$ ), heat transfer across the vapor film by *radiation* becomes significant and needs to be considered (Fig. 10–12). Treating the vapor film as a transparent medium sandwiched between two large parallel plates and approximating the liquid as a blackbody, *radiation heat transfer* can be determined from

$$\dot{q}_{\text{rad}} = \varepsilon \sigma (T_s^4 - T_{\text{sat}}^4) \quad (10-6)$$

where  $\varepsilon$  is the emissivity of the heating surface and  $\sigma = 5.67 \times 10^{-8} \text{ W}/\text{m}^2\cdot\text{K}^4$  is the Stefan–Boltzman constant. Note that the temperature in this case must be expressed in K, not  $^\circ\text{C}$ , and that surface tension and the Stefan–Boltzman constant share the same symbol.

**FIGURE 10-12**

At high heater surface temperatures, radiation heat transfer becomes significant during film boiling.

**FIGURE 10-13**

The cavities on a rough surface act as nucleation sites and enhance boiling heat transfer.

**FIGURE 10-14**

The enhancement of boiling heat transfer in Freon-12 by a mechanically roughened surface, thermoexcel-E.

You may be tempted to simply add the convection and radiation heat transfers to determine the total heat transfer during film boiling. However, these two mechanisms of heat transfer adversely affect each other, causing the total heat transfer to be less than their sum. For example, the radiation heat transfer from the surface to the liquid enhances the rate of evaporation, and thus the thickness of the vapor film, which impedes convection heat transfer. For  $\dot{q}_{\text{rad}} < \dot{q}_{\text{film}}$ , Bromley (1950) determined that the relation

$$\dot{q}_{\text{total}} = \dot{q}_{\text{film}} + \frac{3}{4} \dot{q}_{\text{rad}} \quad (10-7)$$

correlates experimental data well.

Note that the gravitational acceleration  $g$ , whose value is approximately  $9.81 \text{ m/s}^2$  at sea level, appears in all of the relations above for boiling heat transfer. The effects of low and high gravity (as encountered in aerospace applications and turbomachinery) are studied experimentally. The studies confirm that the critical heat flux and heat flux in film boiling are proportional to  $g^{1/4}$ . However, they indicate that heat flux in nucleate boiling is practically independent of gravity  $g$ , instead of being proportional to  $g^{1/2}$ , as dictated by Eq. 10-2.

## Enhancement of Heat Transfer in Pool Boiling

The pool boiling heat transfer relations given above apply to smooth surfaces. Below we discuss some methods to enhance heat transfer in pool boiling.

We pointed out earlier that the rate of heat transfer in the nucleate boiling regime strongly depends on the number of active nucleation sites on the surface, and the rate of bubble formation at each site. Therefore, any modification that enhances *nucleation* on the heating surface will also enhance *heat transfer* in nucleate boiling. It is observed that *irregularities* on the heating surface, including roughness and dirt, serve as additional nucleation sites during boiling, as shown in Fig. 10-13. For example, the first bubbles in a pan filled with water are most likely to form at the *scratches* at the bottom surface. These scratches act like “nests” for the bubbles to form and thus increase the rate of bubble formation. Berensen has shown that heat flux in the nucleate boiling regime can be increased by a factor of 10 by *roughening* the heating surface. However, these high heat transfer rates cannot be sustained for long since the effect of surface roughness is observed to decay with time, and the heat flux to drop eventually to values encountered on smooth surfaces. The effect of surface roughness is negligible on the maximum (critical) heat flux and the heat flux in film boiling.

Surfaces that provide enhanced heat transfer in nucleate boiling *permanently* are being manufactured and are available in the market. Enhancement in nucleation and thus heat transfer in such special surfaces is achieved either by *coating* the surface with a thin layer (much less than 1 mm) of very porous material or by *forming cavities* on the surface mechanically to facilitate continuous vapor formation. Such surfaces are reported to enhance heat transfer in the nucleate boiling regime by a factor of up to 10, and the maximum heat flux by a factor of 3. The enhancement provided by one such material prepared by machine roughening, the thermoexcel-E, is shown in Fig. 10-14. The use of finned surfaces is also known to enhance nucleate boiling heat transfer and the maximum heat flux.

Boiling heat transfer can also be enhanced by other techniques such as *mechanical agitation* and *surface vibration*. These techniques are not practical, however, because of the complications involved.

### EXAMPLE 10–1 Nucleate Boiling of Water in a Pan

Water is to be boiled at atmospheric pressure in a mechanically polished stainless steel pan placed on top of a heating unit, as shown in Fig. 10–15. The inner surface of the bottom of the pan is maintained at 108°C. If the diameter of the bottom of the pan is 30 cm, determine (a) the rate of heat transfer to the water and (b) the rate of evaporation of water.

**SOLUTION** Water is boiled at 1 atm pressure on a stainless steel surface. The rate of heat transfer to the water and the rate of evaporation of water are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat losses from the heater and the pan are negligible.

**Properties** The properties of water at the saturation temperature of 100°C are  $\sigma = 0.0589 \text{ N/m}$  (Table 10–1) and, from Table A–9,

$$\begin{aligned}\rho_l &= 957.9 \text{ kg/m}^3 & h_{fg} &= 2257 \times 10^3 \text{ J/kg} \\ \rho_v &= 0.6 \text{ kg/m}^3 & \mu_l &= 0.282 \times 10^{-3} \text{ kg/m}\cdot\text{s} \\ \text{Pr}_l &= 1.75 & c_{pl} &= 4217 \text{ J/kg}\cdot\text{K}\end{aligned}$$

Also,  $C_{sf} = 0.0130$  and  $n = 1.0$  for the boiling of water on a mechanically polished stainless steel surface (Table 10–3). Note that we expressed the properties in units specified under Eq. 10–2 in connection with their definitions in order to avoid unit manipulations.

**Analysis** (a) The excess temperature in this case is  $\Delta T = T_s - T_{\text{sat}} = 108 - 100 = 8^\circ\text{C}$  which is relatively low (less than 30°C). Therefore, nucleate boiling will occur. The heat flux in this case can be determined from the Rohsenow relation to be

$$\begin{aligned}\dot{q}_{\text{nucleate}} &= \mu_l h_{fg} \left[ \frac{g(\rho_l - \rho_v)}{\sigma} \right]^{1/2} \left[ \frac{c_{pl}(T_s - T_{\text{sat}})}{C_{sf} h_{fg} \text{Pr}_l^n} \right]^3 \\ &= (0.282 \times 10^{-3})(2257 \times 10^3) \left[ \frac{9.81 \times (957.9 - 0.6)}{0.0589} \right]^{1/2} \\ &\quad \times \left( \frac{4217(108 - 100)}{0.0130(2257 \times 10^3)1.75} \right)^3 \\ &= 7.21 \times 10^4 \text{ W/m}^2\end{aligned}$$

The surface area of the bottom of the pan is

$$A = \pi D^2/4 = \pi(0.3 \text{ m})^2/4 = 0.07069 \text{ m}^2$$

Then the rate of heat transfer during nucleate boiling becomes

$$\dot{Q}_{\text{boiling}} = A \dot{q}_{\text{nucleate}} = (0.07069 \text{ m}^2)(7.21 \times 10^4 \text{ W/m}^2) = \mathbf{5097 \text{ W}}$$

(b) The rate of evaporation of water is determined from

$$\dot{m}_{\text{evaporation}} = \frac{\dot{Q}_{\text{boiling}}}{h_{fg}} = \frac{5097 \text{ J/s}}{2257 \times 10^3 \text{ J/kg}} = \mathbf{2.26 \times 10^{-3} \text{ kg/s}}$$

That is, water in the pan will boil at a rate of more than 2 grams per second.

**FIGURE 10–15**  
Schematic for Example 10–1.

**FIGURE 10–16**

Schematic for Example 10–2.

**EXAMPLE 10–2 Peak Heat Flux in Nucleate Boiling**

Water in a tank is to be boiled at sea level by a 1-cm-diameter nickel plated steel heating element equipped with electrical resistance wires inside, as shown in Fig. 10–16. Determine the maximum heat flux that can be attained in the nucleate boiling regime and the surface temperature of the heater in that case.

**SOLUTION** Water is boiled at 1 atm pressure on a nickel plated steel surface. The maximum heat flux and the surface temperature are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat losses from the boiler are negligible.

**Properties** The properties of water at the saturation temperature of 100°C are  $\sigma = 0.0589 \text{ N/m}$  (Table 10–1) and, from Table A–9,

$$\begin{aligned} \rho_l &= 957.9 \text{ kg/m}^3 & h_{fg} &= 2257 \times 10^3 \text{ J/kg} \\ \rho_v &= 0.6 \text{ kg/m}^3 & \mu_l &= 0.282 \times 10^{-3} \text{ kg/m}\cdot\text{s} \\ \Pr_l &= 1.75 & c_{pl} &= 4217 \text{ J/kg}\cdot\text{K} \end{aligned}$$

Also,  $C_{sf} = 0.0060$  and  $n = 1.0$  for the boiling of water on a nickel plated surface (Table 10–3). Note that we expressed the properties in units specified under Eqs. 10–2 and 10–3 in connection with their definitions in order to avoid unit manipulations.

**Analysis** The heating element in this case can be considered to be a short cylinder whose characteristic dimension is its radius. That is,  $L = r = 0.005 \text{ m}$ . The dimensionless parameter  $L^*$  and the constant  $C_{cr}$  are determined from Table 10–4 to be

$$L^* = L \left( \frac{g(\rho_l - \rho_v)}{\sigma} \right)^{1/2} = (0.005) \left( \frac{(9.81)(957.9 - 0.6)}{0.0589} \right)^{1/2} = 2.00 > 1.2$$

which corresponds to  $C_{cr} = 0.12$ .

Then the maximum or critical heat flux is determined from Eq. 10–3 to be

$$\begin{aligned} \dot{q}_{\max} &= C_{cr} h_{fg} [\sigma g \rho_v^2 (\rho_l - \rho_v)]^{1/4} \\ &= 0.12(2257 \times 10^3)[0.0589 \times 9.81 \times (0.6)^2(957.9 - 0.6)]^{1/4} \\ &= \mathbf{1.017 \times 10^6 \text{ W/m}^2} \end{aligned}$$

The Rohsenow relation, which gives the nucleate boiling heat flux for a specified surface temperature, can also be used to determine the surface temperature when the heat flux is given. Substituting the maximum heat flux into Eq. 10–2 together with other properties gives

$$\begin{aligned} \dot{q}_{\text{nucleate}} &= \mu_l h_{fg} \left[ \frac{g(\rho_l - \rho_v)}{\sigma} \right]^{1/2} \left[ \frac{c_{pl}(T_s - T_{\text{sat}})}{C_{sf} h_{fg} \Pr_l^n} \right]^3 \\ 1.017 \times 10^6 &= (0.282 \times 10^{-3})(2257 \times 10^3) \left[ \frac{9.81(957.9 - 0.6)}{0.0589} \right]^{1/2} \\ &\quad \times \left[ \frac{4217(T_s - 100)}{0.0130(2257 \times 10^3) 1.75} \right]^3 \end{aligned}$$

$$T_s = \mathbf{119^\circ\text{C}}$$

**Discussion** Note that heat fluxes on the order of 1 MW/m<sup>2</sup> can be obtained in nucleate boiling with a temperature difference of less than 20°C.

**EXAMPLE 10–3** Film Boiling of Water on a Heating Element

Water is boiled at atmospheric pressure by a horizontal polished copper heating element of diameter  $D = 5 \text{ mm}$  and emissivity  $\epsilon = 0.05$  immersed in water, as shown in Fig. 10–17. If the surface temperature of the heating wire is  $350^\circ\text{C}$ , determine the rate of heat transfer from the wire to the water per unit length of the wire.

**SOLUTION** Water is boiled at 1 atm by a horizontal polished copper heating element. The rate of heat transfer to the water per unit length of the heater is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat losses from the boiler are negligible.

**Properties** The properties of water at the saturation temperature of  $100^\circ\text{C}$  are  $h_{fg} = 2257 \times 10^3 \text{ J/kg}$  and  $\rho_l = 957.9 \text{ kg/m}^3$  (Table A–9). The properties of vapor at the film temperature of  $T_f = (T_{\text{sat}} + T_s)/2 = (100 + 350)/2 = 225^\circ\text{C}$  are, from Table A–16,

$$\rho_v = 0.444 \text{ kg/m}^3$$

$$c_{pv} = 1951 \text{ J/kg}\cdot\text{K}$$

$$\mu_v = 1.75 \times 10^{-5} \text{ kg/m}\cdot\text{s}$$

$$k_v = 0.0358 \text{ W/m}\cdot\text{K}$$

Note that we expressed the properties in units that cancel each other in boiling heat transfer relations. Also note that we used vapor properties at 1 atm pressure from Table A–16 instead of the properties of saturated vapor from Table A–9 at  $225^\circ\text{C}$  since the latter are at the saturation pressure of 2.55 MPa.

**Analysis** The excess temperature in this case is  $\Delta T = T_s - T_{\text{sat}} = 350 - 100 = 250^\circ\text{C}$ , which is much larger than  $30^\circ\text{C}$  for water. Therefore, film boiling will occur. The film boiling heat flux in this case can be determined from Eq. 10–5 to be

$$\begin{aligned} \dot{q}_{\text{film}} &= 0.62 \left[ \frac{g k_v^3 \rho_v (\rho_l - \rho_v) [h_{fg} + 0.4 c_{pv} (T_s - T_{\text{sat}})]}{\mu_v D (T_s - T_{\text{sat}})} \right]^{1/4} (T_s - T_{\text{sat}}) \\ &= 0.62 \left[ \frac{9.81(0.0358)^3 (0.444)(957.9 - 0.441)}{(1.75 \times 10^{-5})(5 \times 10^{-3})(250)} \right]^{1/4} \times 250 \\ &= 5.93 \times 10^4 \text{ W/m}^2 \end{aligned}$$

The radiation heat flux is determined from Eq. 10–6 to be

$$\begin{aligned} \dot{q}_{\text{rad}} &= \epsilon \sigma (T_s^4 - T_{\text{sat}}^4) \\ &= (0.05)(5.67 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4)[(350 + 273 \text{ K})^4 - (100 + 273 \text{ K})^4] \\ &= 372 \text{ W/m}^2 \end{aligned}$$

Note that heat transfer by radiation is negligible in this case because of the low emissivity of the surface and the relatively low surface temperature of the heating element. Then the total heat flux becomes (Eq. 10–7)

$$\dot{q}_{\text{total}} = \dot{q}_{\text{film}} + \frac{3}{4} \dot{q}_{\text{rad}} = 5.93 \times 10^4 + \frac{3}{4} \times 372 = 5.96 \times 10^4 \text{ W/m}^2$$

FIGURE 10–17

Schematic for Example 10–3.

Finally, the rate of heat transfer from the heating element to the water is determined by multiplying the heat flux by the heat transfer surface area,

$$\begin{aligned}\dot{Q}_{\text{total}} &= A\dot{q}_{\text{total}} = (\pi DL)\dot{q}_{\text{total}} \\ &= (\pi \times 0.005 \text{ m} \times 1 \text{ m})(5.96 \times 10^4 \text{ W/m}^2) \\ &= \mathbf{936 \text{ W}}\end{aligned}$$

**Discussion** Note that the 5-mm-diameter copper heating element consumes about 1 kW of electric power per unit length in steady operation in the film boiling regime. This energy is transferred to the water through the vapor film that forms around the wire.

FIGURE 10-18

The effect of forced convection on external flow boiling for different flow velocities.

### 10-3 • FLOW BOILING

The pool boiling we considered so far involves a pool of seemingly motionless liquid, with vapor bubbles rising to the top as a result of buoyancy effects. In **flow boiling**, the fluid is forced to move by an external source such as a pump as it undergoes a phase-change process. The boiling in this case exhibits the combined effects of convection and pool boiling. The flow boiling is also classified as either *external* or *internal flow boiling* depending on whether the fluid is forced to flow over a heated surface or inside a heated tube.

*External flow boiling* over a plate or cylinder is similar to pool boiling, but the added motion increases both the nucleate boiling heat flux and the maximum heat flux considerably, as shown in Fig. 10-18. Note that the higher the velocity, the higher the nucleate boiling heat flux and the maximum heat flux. In experiments with water, maximum heat flux values as high as  $35 \text{ MW/m}^2$  have been obtained (compare this to the pool boiling value of  $1.02 \text{ MW/m}^2$  at 1 atm pressure) by increasing the fluid velocity.

*Internal flow boiling*, commonly referred to as *two-phase flow*, is much more complicated in nature because there is no free surface for the vapor to escape, and thus both the liquid and the vapor are forced to flow together. The two-phase flow in a tube exhibits different flow boiling regimes, depending on the relative amounts of the liquid and the vapor phases. This complicates the analysis even further.

The different stages encountered in flow boiling in a heated tube are illustrated in Fig. 10-19 together with the variation of the heat transfer coefficient along the tube. Initially, the liquid is subcooled and heat transfer to the liquid is by *forced convection*. Then bubbles start forming on the inner surfaces of the tube, and the detached bubbles are drafted into the mainstream. This gives the fluid flow a bubbly appearance, and thus the name *bubbly flow regime*. As the fluid is heated further, the bubbles grow in size and eventually coalesce into slugs of vapor. Up to half of the volume in the tube in this *slug-flow regime* is occupied by vapor. After a while the core of the flow consists of vapor only, and the liquid is confined only in the annular space between the vapor core and the tube walls. This is the *annular-flow regime*, and very high heat transfer coefficients are realized in this regime. As the heating continues,

**FIGURE 10-19**

Different flow regimes encountered in flow boiling in a tube under forced convection.

the annular liquid layer gets thinner and thinner, and eventually dry spots start to appear on the inner surfaces of the tube. The appearance of dry spots is accompanied by a sharp decrease in the heat transfer coefficient. This *transition regime* continues until the inner surface of the tube is completely dry. Any liquid at this moment is in the form of droplets suspended in the vapor core, which resembles a mist, and we have a *mist-flow regime* until all the liquid droplets are vaporized. At the end of the mist-flow regime we have saturated vapor, which becomes superheated with any further heat transfer.

Note that the tube contains a liquid before the bubbly flow regime and a vapor after the mist-flow regime. Heat transfer in those two cases can be determined using the appropriate relations for single-phase convection heat transfer. Many correlations are proposed for the determination of heat transfer in the two-phase flow (bubbly flow, slug-flow, annular-flow, and mist-flow) cases, but they are beyond the scope of this introductory text. A crude estimate for heat flux in flow boiling can be obtained by simply adding the forced convection and pool boiling heat fluxes.

## 10-4 • CONDENSATION HEAT TRANSFER

Condensation occurs when the temperature of a vapor is reduced *below* its saturation temperature  $T_{\text{sat}}$ . This is usually done by bringing the vapor into contact with a solid surface whose temperature  $T_s$  is below the saturation temperature  $T_{\text{sat}}$  of the vapor. But condensation can also occur on the free surface of a liquid or even in a gas when the temperature of the liquid or the gas to which the vapor is exposed is below  $T_{\text{sat}}$ . In the latter case, the liquid droplets suspended in the gas form a fog. In this chapter, we consider condensation on solid surfaces only.

Two distinct forms of condensation are observed: *film condensation* and *dropwise condensation*. In **film condensation**, the condensate wets the surface

**FIGURE 10-20**

When a vapor is exposed to a surface at a temperature below  $T_{\text{sat}}$ , condensation in the form of a liquid film or individual droplets occurs on the surface.

and forms a liquid film on the surface that slides down under the influence of gravity. The thickness of the liquid film increases in the flow direction as more vapor condenses on the film. This is how condensation normally occurs in practice. In **dropwise condensation**, the condensed vapor forms droplets on the surface instead of a continuous film, and the surface is covered by countless droplets of varying diameters (Fig. 10-20).

In film condensation, the surface is blanketed by a liquid film of increasing thickness, and this “liquid wall” between solid surface and the vapor serves as a *resistance* to heat transfer. The heat of vaporization  $h_{fg}$  released as the vapor condenses must pass through this resistance before it can reach the solid surface and be transferred to the medium on the other side. In dropwise condensation, however, the droplets slide down when they reach a certain size, clearing the surface and exposing it to vapor. There is no liquid film in this case to resist heat transfer. As a result, heat transfer rates that are more than 10 times larger than those associated with film condensation can be achieved with dropwise condensation. Therefore, dropwise condensation is the preferred mode of condensation in heat transfer applications, and people have long tried to achieve sustained dropwise condensation by using various vapor additives and surface coatings. These attempts have not been very successful, however, since the dropwise condensation achieved did not last long and converted to film condensation after some time. Therefore, it is common practice to be conservative and assume film condensation in the design of heat transfer equipment. For better heat transfer, it is desirable to use short surfaces because of the lower thermal resistance.

## 10-5 • FILM CONDENSATION

We now consider film condensation on a vertical plate, as shown in Fig. 10-21. The liquid film starts forming at the top of the plate and flows downward under the influence of gravity. The thickness of the film  $\delta$  *increases* in the flow direction  $x$  because of continued condensation at the liquid–vapor interface. Heat in the amount  $h_{fg}$  (the latent heat of vaporization) is released during condensation and is *transferred* through the film to the plate surface at temperature  $T_s$ . Note that  $T_s$  must be below the saturation temperature  $T_{\text{sat}}$  of the vapor for condensation to occur.

Typical velocity and temperature profiles of the condensate are also given in Fig. 10-21. Note that the *velocity* of the condensate at the wall is zero because of the “no-slip” condition and reaches a *maximum* at the liquid–vapor interface. The *temperature* of the condensate is  $T_{\text{sat}}$  at the interface and decreases gradually to  $T_s$  at the wall.

As was the case in forced convection involving a single phase, heat transfer in condensation also depends on whether the condensate flow is *laminar* or *turbulent*. Again the criterion for the flow regime is provided by the Reynolds number, which is defined as

$$\text{Re} = \frac{D_h \rho_l V_l}{\mu_l} = \frac{4 A_c \rho_l V_l}{p \mu_l} = \frac{4 \rho_l V_l \delta}{\mu} = \frac{4 \dot{m}}{p \mu_l} \quad (10-8)$$

where

$$D_h = 4A_c/p = 4\delta = \text{hydraulic diameter of the condensate flow, m}$$

$$p = \text{wetted perimeter of the condensate, m}$$

**FIGURE 10-21**

Film condensation on a vertical plate.

$A_c = p\delta$  = wetted perimeter  $\times$  film thickness, m<sup>2</sup>, cross-sectional area of the condensate flow at the lowest part of the flow

$\rho_l$  = density of the liquid, kg/m<sup>3</sup>

$\mu_l$  = viscosity of the liquid, kg/m·s

$V_l$  = average velocity of the condensate at the lowest part of the flow, m/s

$\dot{m} = \rho_l V_l A_c$  = mass flow rate of the condensate at the lowest part, kg/s

The evaluation of the hydraulic diameter  $D_h$  for some common geometries is illustrated in Fig. 10–22. Note that the hydraulic diameter is again defined such that it reduces to the ordinary diameter for flow in a circular tube, as was done in Chapter 8 for internal flow, and it is equivalent to 4 times the thickness of the condensate film at the location where the hydraulic diameter is evaluated. That is,  $D_h = 4\delta$ .

The latent heat of vaporization  $h_{fg}$  is the heat released as a unit mass of vapor condenses, and it normally represents the heat transfer per unit mass of condensate formed during condensation. However, the condensate in an actual condensation process is cooled further to some average temperature between  $T_{sat}$  and  $T_s$ , releasing more heat in the process. Therefore, the actual heat transfer will be larger. Rohsenow showed in 1956 that the cooling of the liquid below the saturation temperature can be accounted for by replacing  $h_{fg}$  by the **modified latent heat of vaporization**  $h_{fg}^*$ , defined as

$$h_{fg}^* = h_{fg} + 0.68c_{pl}(T_{sat} - T_s) \quad (10-9a)$$

where  $c_{pl}$  is the specific heat of the liquid at the average film temperature.

We can have a similar argument for vapor that enters the condenser as **superheated vapor** at a temperature  $T_v$  instead of as saturated vapor. In this case the vapor must be cooled first to  $T_{sat}$  before it can condense, and this heat must be transferred to the wall as well. The amount of heat released as a unit mass of superheated vapor at a temperature  $T_v$  is cooled to  $T_{sat}$  is simply  $c_{pv}(T_v - T_{sat})$ , where  $c_{pv}$  is the specific heat of the vapor at the average temperature of  $(T_v + T_{sat})/2$ . The modified latent heat of vaporization in this case becomes

$$h_{fg}^* = h_{fg} + 0.68c_{pl}(T_{sat} - T_s) + c_{pv}(T_v - T_{sat}) \quad (10-9b)$$

FIGURE 10-22

The wetted perimeter  $p$ , the condensate cross-sectional area  $A_c$ , and the hydraulic diameter  $D_h$  for some common geometries.

**FIGURE 10-23**

Flow regimes during film condensation on a vertical plate.

**FIGURE 10-24**

The volume element of condensate on a vertical plate considered in Nusselt's analysis.

With these considerations, the rate of heat transfer can be expressed as

$$\dot{Q}_{\text{conden}} = hA_s(T_{\text{sat}} - T_s) = \dot{m}h_{fg}^* \quad (10-10)$$

where  $A_s$  is the heat transfer area (the surface area on which condensation occurs). Solving for  $\dot{m}$  from the equation above and substituting it into Eq. 10-8 gives yet another relation for the Reynolds number,

$$\text{Re} = \frac{4\dot{Q}_{\text{conden}}}{p\mu_l h_{fg}^*} = \frac{4A_s h(T_{\text{sat}} - T_s)}{p\mu_l h_{fg}^*} \quad (10-11)$$

This relation is convenient to use to determine the Reynolds number when the condensation heat transfer coefficient or the rate of heat transfer is known.

The temperature of the liquid film varies from  $T_{\text{sat}}$  on the liquid-vapor interface to  $T_s$  at the wall surface. Therefore, the properties of the liquid should be evaluated at the *film temperature*  $T_f = (T_{\text{sat}} + T_s)/2$ , which is approximately the *average* temperature of the liquid. The  $h_{fg}$ , however, should be evaluated at  $T_{\text{sat}}$  since it is not affected by the subcooling of the liquid.

## Flow Regimes

The Reynolds number for condensation on the outer surfaces of vertical tubes or plates increases in the flow direction due to the increase of the liquid film thickness  $\delta$ . The flow of liquid film exhibits *different regimes*, depending on the value of the Reynolds number. It is observed that the outer surface of the liquid film remains *smooth* and *wave-free* for about  $\text{Re} \leq 30$ , as shown in Fig. 10-23, and thus the flow is clearly *laminar*. Ripples or waves appear on the free surface of the condensate flow as the Reynolds number increases, and the condensate flow becomes fully *turbulent* at about  $\text{Re} \approx 1800$ . The condensate flow is called *wavy-laminar* in the range of  $30 < \text{Re} < 1800$  and *turbulent* for  $\text{Re} > 1800$ . However, some disagreement exists about the value of  $\text{Re}$  at which the flow becomes wavy-laminar or turbulent.

## Heat Transfer Correlations for Film Condensation

Below we discuss relations for the average heat transfer coefficient  $h$  for the case of *laminar* film condensation for various geometries.

### 1 Vertical Plates

Consider a vertical plate of height  $L$  and width  $b$  maintained at a constant temperature  $T_s$  that is exposed to vapor at the saturation temperature  $T_{\text{sat}}$ . The downward direction is taken as the positive  $x$ -direction with the origin placed at the top of the plate where condensation initiates, as shown in Fig. 10-24. The surface temperature is below the saturation temperature ( $T_s < T_{\text{sat}}$ ) and thus the vapor condenses on the surface. The liquid film flows downward under the influence of gravity. The film thickness  $\delta$  and thus the mass flow rate of the condensate increases with  $x$  as a result of continued condensation on the existing film. Then heat transfer from the vapor to the plate must occur through the film, which offers resistance to heat transfer. Obviously the thicker the film, the larger its thermal resistance and thus the lower the rate of heat transfer.

The analytical relation for the heat transfer coefficient in film condensation on a vertical plate described above was first developed by Nusselt in 1916 under the following simplifying assumptions:

1. Both the plate and the vapor are maintained at *constant temperatures* of  $T_s$  and  $T_{\text{sat}}$ , respectively, and the temperature across the liquid film varies *linearly*.
2. Heat transfer across the liquid film is by pure *conduction* (no convection currents in the liquid film).
3. The velocity of the vapor is low (or zero) so that it exerts *no drag* on the condensate (no viscous shear on the liquid–vapor interface).
4. The flow of the condensate is *laminar* and the properties of the liquid are constant.
5. The acceleration of the condensate layer is negligible.

Then Newton's second law of motion for the volume element shown in Fig. 10–24 in the vertical  $x$ -direction can be written as

$$\sum F_x = ma_x = 0$$

since the acceleration of the fluid is zero. Noting that the only force acting downward is the weight of the liquid element, and the forces acting upward are the viscous shear (or fluid friction) force at the left and the buoyancy force, the force balance on the volume element becomes

$$F_{\text{downward}} \downarrow = F_{\text{upward}} \uparrow$$

Weight = Viscous shear force + Buoyancy force

$$\rho_l g(\delta - y)(b dx) = \mu_l \frac{du}{dy}(b dx) + \rho_v g(\delta - y)(b dx)$$

Canceling the plate width  $b$  and solving for  $du/dy$  gives

$$\frac{du}{dy} = \frac{g(\rho_l - \rho_v)g(\delta - y)}{\mu_l}$$

Integrating from  $y = 0$  where  $u = 0$  (because of the no-slip boundary condition) to  $y = y$  where  $u = u(y)$  gives

$$u(y) = \frac{g(\rho_l - \rho_v)g}{\mu_l} \left( y\delta - \frac{y^2}{2} \right) \quad (10-12)$$

The mass flow rate of the condensate at a location  $x$ , where the boundary layer thickness is  $\delta$ , is determined from

$$\dot{m}(x) = \int_A \rho_l u(y) dA = \int_{y=0}^{\delta} \rho_l u(y) b dy \quad (10-13)$$

Substituting the  $u(y)$  relation from Equation 10–12 into Eq. 10–13 gives

$$\dot{m}(x) = \frac{gb\rho_l(\rho_l - \rho_v)\delta^3}{3\mu_l} \quad (10-14)$$

whose derivative with respect to  $x$  is

$$\frac{d\dot{m}}{dx} = \frac{gb\rho_l(\rho_l - \rho_v)\delta^2}{\mu_l} \frac{d\delta}{dx} \quad (10-15)$$

which represents the rate of condensation of vapor over a vertical distance  $dx$ . The rate of heat transfer from the vapor to the plate through the liquid film is simply equal to the heat released as the vapor is condensed and is expressed as

$$d\dot{Q} = h_{fg} d\dot{m} = k_l(bdx) \frac{T_{\text{sat}} - T_s}{\delta} \rightarrow \frac{d\dot{m}}{dx} = \frac{k_l b}{h_{fg}} \frac{T_{\text{sat}} - T_s}{\delta} \quad (10-16)$$

Equating Eqs. 10-15 and 10-16 for  $d\dot{m}/dx$  to each other and separating the variables give

$$\delta^3 d\delta = \frac{\mu_l k_l (T_{\text{sat}} - T_s)}{g \rho_l (\rho_l - \rho_v) h_{fg}} dx \quad (10-17)$$

Integrating from  $x = 0$  where  $\delta = 0$  (the top of the plate) to  $x = L$  where  $\delta = \delta(x)$ , the liquid film thickness at any location  $x$  is determined to be

$$\delta(x) = \left[ \frac{4\mu_l k_l (T_{\text{sat}} - T_s)x}{g \rho_l (\rho_l - \rho_v) h_{fg}} \right]^{1/4} \quad (10-18)$$

The heat transfer rate from the vapor to the plate at a location  $x$  can be expressed as

$$\dot{q}_x = h_x(T_{\text{sat}} - T_s) = k_l \frac{T_{\text{sat}} - T_s}{\delta} \rightarrow h_x = \frac{k_l}{\delta(x)} \quad (10-19)$$

Substituting the  $\delta(x)$  expression from Eq. 10-18, the local heat transfer coefficient  $h_x$  is determined to be

$$h_x = \left[ \frac{g \rho_l (\rho_l - \rho_v) h_{fg} k_l^3}{4\mu_l (T_{\text{sat}} - T_s)x} \right]^{1/4} \quad (10-20)$$

The average heat transfer coefficient over the entire plate is determined from its definition by substituting the  $h_x$  relation and performing the integration. It gives

$$h = h_{\text{vert}} = \frac{1}{L} \int_0^L h_x dx = \frac{4}{3} h_{x=L} = 0.943 \left[ \frac{g \rho_l (\rho_l - \rho_v) h_{fg} k_l^3}{\mu_l (T_{\text{sat}} - T_s)L} \right]^{1/4} \quad (10-21)$$

Equation 10-21, which is obtained with the simplifying assumptions stated earlier, provides good insight on the functional dependence of the condensation heat transfer coefficient. However, it is observed to underpredict heat transfer because it does not take into account the effects of the nonlinear temperature profile in the liquid film and the cooling of the liquid below the saturation temperature. Both of these effects can be accounted for by replacing  $h_{fg}$  by  $h_{fg}^*$  given by Eq. 10-9a. With this modification, the *average heat transfer coefficient* for laminar film condensation over a vertical flat plate of height  $L$  is determined to be

$$h_{\text{vert}} = 0.943 \left[ \frac{g \rho_l (\rho_l - \rho_v) h_{fg}^* k_l^3}{\mu_l (T_{\text{sat}} - T_s)L} \right]^{1/4} \quad (\text{W/m}^2 \cdot \text{K}), \quad 0 < \text{Re} < 30 \quad (10-22)$$

where

$g$  = gravitational acceleration,  $\text{m/s}^2$

$\rho_l, \rho_v$  = densities of the liquid and vapor, respectively,  $\text{kg/m}^3$

$\mu_l$  = viscosity of the liquid,  $\text{kg/m}\cdot\text{s}$

$h_{fg}^* = h_{fg} + 0.68c_{pl}(T_{\text{sat}} - T_s)$  = modified latent heat of vaporization,  $\text{J/kg}$

$k_l$  = thermal conductivity of the liquid,  $\text{W/m}\cdot\text{K}$

- $L$  = height of the vertical plate, m  
 $T_s$  = surface temperature of the plate, °C  
 $T_{\text{sat}}$  = saturation temperature of the condensing fluid, °C

At a given temperature,  $\rho_v \ll \rho_l$  and thus  $\rho_l - \rho_v \approx \rho_l$  except near the critical point of the substance. Using this approximation and substituting Eqs. 10–14 and 10–18 at  $x = L$  into Eq. 10–8 by noting that  $\delta_{x=L} = k_l/h_{x=L}$  and  $h_{\text{vert}} = \frac{4}{3}h_{x=L}$  (Eqs. 10–19 and 10–21) give

$$\text{Re} = \frac{4g\rho_l(\rho_l - \rho_v)\delta^3}{3\mu_l^2} = \frac{4g\rho_l^2}{3\mu_l^2} \left( \frac{k_l}{h_{x=L}} \right)^3 = \frac{4g}{3h_l^2} \left( \frac{k_l}{3h_{\text{vert}}/4} \right)^3 \quad (10-23)$$

Then the heat transfer coefficient  $h_{\text{vert}}$  in terms of Re becomes

$$h_{\text{vert}} \cong 1.47k_l \text{Re}^{2/3} \left( \frac{g}{v_l^2} \right)^{1/3}, \quad 0 < \text{Re} < 30 \quad (10-24)$$

The results obtained from the theoretical relations above are in excellent agreement with the experimental results. It can be shown easily that using property values in Eqs. 10–22 and 10–24 in the *specified units* gives the condensation heat transfer coefficient in  $\text{W}/\text{m}^2\cdot\text{K}$ , thus saving one from having to go through tedious unit manipulations each time (Fig. 10–25). This is also true for the equations below. All properties of the liquid are to be evaluated at the film temperature  $T_f = (T_{\text{sat}} + T_s)/2$ . The  $h_{fg}$  and  $\rho_v$  are to be evaluated at the saturation temperature  $T_{\text{sat}}$ .

### Wavy Laminar Flow on Vertical Plates

At Reynolds numbers greater than about 30, it is observed that waves form at the liquid–vapor interface although the flow in liquid film remains laminar. The flow in this case is said to be *wavy laminar*. The waves at the liquid–vapor interface tend to increase heat transfer. But the waves also complicate the analysis and make it very difficult to obtain analytical solutions. Therefore, we have to rely on experimental studies. The increase in heat transfer due to the wave effect is, on average, about 20 percent, but it can exceed 50 percent. The exact amount of enhancement depends on the Reynolds number. Based on his experimental studies, Kutateladze (1963) recommended the following relation for the average heat transfer coefficient in wavy laminar condensate flow for  $\rho_v \ll \rho_l$  and  $30 < \text{Re} < 1800$ ,

$$h_{\text{vert, wavy}} = \frac{\text{Re } k_l}{1.08 \text{Re}^{1.22} - 5.2} \left( \frac{g}{v_l^2} \right)^{1/3}, \quad 30 < \text{Re} < 1800 \quad (10-25)$$

A simpler alternative to the relation above proposed by Kutateladze (1963) is

$$h_{\text{vert, wavy}} = 0.8 \text{Re}^{0.11} h_{\text{vert (smooth)}} \quad (10-26)$$

which relates the heat transfer coefficient in wavy laminar flow to that in wave-free laminar flow. McAdams (1954) went even further and suggested accounting for the increase in heat transfer in the wavy region by simply increasing the heat transfer coefficient determined from Eq. 10–22 for the laminar case by 20 percent. It is also suggested using Eq. 10–22 for the wavy region also, with the understanding that this is a conservative approach that provides a safety margin in thermal design. In this book we use Eq. 10–25.

$$\begin{aligned} h_{\text{vert}} &= \left( \frac{\frac{m}{s^2} \frac{kg}{m^3} \frac{kg}{m^3} \frac{J}{kg} \left( \frac{W}{m \cdot K} \right)^3}{\frac{kg}{m \cdot s} \cdot K \cdot m} \right)^{1/4} \\ &= \left[ \frac{m}{s} \frac{1}{m^6} \frac{W^3}{m^3 \cdot K^3} \frac{J}{K} \right]^{1/4} \\ &= \left( \frac{W^4}{m^8 \cdot K^4} \right)^{1/4} \\ &= W/m^2 \cdot K \end{aligned}$$

FIGURE 10–25

Equation 10–22 gives the condensation heat transfer coefficient in  $\text{W}/\text{m}^2\cdot\text{K}$  when the quantities are expressed in the units specified in their descriptions.

A relation for the Reynolds number in the wavy laminar region can be determined by substituting the  $h$  relation in Eq. 10–25 into the Re relation in Eq. 10–11 and simplifying. It yields

$$\text{Re}_{\text{vert, wavy}} = \left[ 4.81 + \frac{3.70 Lk_l(T_{\text{sat}} - T_s)}{\mu_l h_{fg}^*} \left( \frac{g}{v_l^2} \right)^{1/3} \right]^{0.820}, \quad \rho_v \ll \rho_l \quad (10-27)$$

### Turbulent Flow on Vertical Plates

At a Reynolds number of about 1800, the condensate flow becomes turbulent. Several empirical relations of varying degrees of complexity are proposed for the heat transfer coefficient for turbulent flow. Again assuming  $\rho_v \ll \rho_l$  for simplicity, Labuntsov (1957) proposed the following relation for the turbulent flow of condensate on *vertical plates*:

$$h_{\text{vert, turbulent}} = \frac{\text{Re } k_l}{8750 + 58 \text{Pr}^{-0.5} (\text{Re}^{0.75} - 253)} \left( \frac{g}{v_l^2} \right)^{1/3}, \quad \text{Re} > 1800 \quad (10-28)$$

The physical properties of the condensate are again to be evaluated at the film temperature  $T_f = (T_{\text{sat}} + T_s)/2$ . The Re relation in this case is obtained by substituting the  $h$  relation above into the Re relation in Eq. 10–11, which gives

$$\text{Re}_{\text{vert, turbulent}} = \left[ \frac{0.0690 Lk_l \text{Pr}^{0.5} (T_{\text{sat}} - T_s)}{\mu_l h_{fg}^*} \left( \frac{g}{v_l^2} \right)^{1/3} - 151 \text{Pr}^{0.5} + 253 \right]^{4/3} \quad (10-29)$$

Nondimensionalized heat transfer coefficients for the wave-free laminar, wavy laminar, and turbulent flow of condensate on vertical plates are plotted in Fig. 10–26.

## 2 Inclined Plates

Equation 10–22 was developed for vertical plates, but it can also be used for laminar film condensation on the upper surfaces of plates that are *inclined* by an angle  $\theta$  from the *vertical*, by replacing  $g$  in that equation by  $g \cos \theta$

**FIGURE 10–26**

Nondimensionalized heat transfer coefficients for the wave-free laminar, wavy laminar, and turbulent flow of condensate on vertical plates.

(Fig. 10–27). This approximation gives satisfactory results especially for  $\theta \leq 60^\circ$ . Note that the condensation heat transfer coefficients on vertical and inclined plates are related to each other by

$$h_{\text{inclined}} = h_{\text{vert}} (\cos \theta)^{1/4} \quad (\text{laminar}) \quad (10-30)$$

Equation 10–30 is developed for laminar flow of condensate, but it can also be used for wavy laminar flows as an approximation.

### 3 Vertical Tubes

Equation 10–22 for vertical plates can also be used to calculate the average heat transfer coefficient for laminar film condensation on the outer surfaces of vertical tubes provided that the tube diameter is large relative to the thickness of the liquid film ( $D \gg \delta$ ). In most of the problems encountered in this chapter,  $\delta$  (the thickness of the liquid film at the bottom of the tube) can be calculated by combining Eqs. 10–19 and 10–21 which leads to  $\delta = 4k_l/3h$ .

### 4 Horizontal Tubes and Spheres

Nusselt's analysis of film condensation on vertical plates can also be extended to horizontal tubes and spheres. The average heat transfer coefficient for film condensation on the outer surfaces of a *horizontal tube* is determined to be

$$h_{\text{horiz}} = 0.729 \left[ \frac{g\rho_l(\rho_l - \rho_v) h_{fg}^* k_l^3}{\mu_l(T_{\text{sat}} - T_s)D} \right]^{1/4} \text{ (W/m}^2\cdot\text{K)} \quad (10-31)$$

where  $D$  is the diameter of the horizontal tube. Equation 10–31 can easily be modified for a *sphere* by replacing the constant 0.729 by 0.815.

A comparison of the heat transfer coefficient relations for a vertical tube of height  $L$  and a horizontal tube of diameter  $D$  yields

$$\frac{h_{\text{vert}}}{h_{\text{horiz}}} = 1.29 \left( \frac{D}{L} \right)^{1/4} \quad (10-32)$$

Setting  $h_{\text{vert}} = h_{\text{horiz}}$  gives  $L = 1.29^4 D = 2.77D$ , which implies that for a tube whose length is 2.77 times its diameter, the average heat transfer coefficient for laminar film condensation will be the *same* whether the tube is positioned horizontally or vertically. For  $L > 2.77D$ , the heat transfer coefficient is higher in the horizontal position. Considering that the length of a tube in any practical application is several times its diameter, it is common practice to place the tubes in a condenser *horizontally* to maximize the condensation heat transfer coefficient on the outer surfaces of the tubes.

### 5 Horizontal Tube Banks

Horizontal tubes stacked on top of each other as shown in Fig. 10–28 are commonly used in condenser design. The average thickness of the liquid film at the lower tubes is much larger as a result of condensate falling on top of them from the tubes directly above. Therefore, the average heat transfer coefficient at the lower tubes in such arrangements is smaller. Assuming the condensate from the tubes above to the ones below drain smoothly, the average film condensation heat transfer coefficient for all tubes in a vertical tier can be expressed as

$$h_{\text{horiz}, N \text{ tubes}} = 0.729 \left[ \frac{g\rho_l(\rho_l - \rho_v) h_{fg}^* k_l^3}{\mu_l(T_{\text{sat}} - T_s) ND} \right]^{1/4} = \frac{1}{N^{1/4}} h_{\text{horiz}, 1 \text{ tube}} \quad (10-33)$$

**FIGURE 10-27**

Film condensation on an inclined plate.

**FIGURE 10-28**

Film condensation on a vertical tier of horizontal tubes.

Note that Eq. 10–33 can be obtained from the heat transfer coefficient relation for a horizontal tube (Eq. 10–31) by replacing  $D$  in that relation by  $ND$ , where  $N$  is the number of horizontal tubes in the tier. This relation does not account for the increase in heat transfer due to the ripple formation and turbulence caused during drainage, and thus generally yields conservative results.

## Effect of Vapor Velocity

In the analysis above we assumed the vapor velocity to be small and thus the vapor drag exerted on the liquid film to be negligible, which is usually the case. However, when the vapor velocity is high, the vapor will “pull” the liquid at the interface along since the vapor velocity at the interface must drop to the value of the liquid velocity. If the vapor flows downward (i.e., in the same direction as the liquid), this additional force will increase the average velocity of the liquid and thus decrease the film thickness. This, in turn, will decrease the thermal resistance of the liquid film and thus increase heat transfer. Upward vapor flow has the opposite effects: the vapor exerts a force on the liquid in the opposite direction to flow, thickens the liquid film, and thus decreases heat transfer. Condensation in the presence of high vapor flow is studied [e.g., Shekrladze and Gomelauri (1966)] and heat transfer relations are obtained, but a detailed analysis of this topic is beyond the scope of this introductory text.

## The Presence of Noncondensable Gases in Condensers

Most condensers used in steam power plants operate at pressures well below the atmospheric pressure (usually under 0.1 atm) to maximize cycle thermal efficiency, and operation at such low pressures raises the possibility of air (a noncondensable gas) leaking into the condensers. Experimental studies show that the presence of noncondensable gases in the vapor has a detrimental effect on condensation heat transfer. Even small amounts of a noncondensable gas in the vapor cause significant drops in heat transfer coefficient during condensation. For example, the presence of less than 1 percent (by mass) of air in steam can reduce the condensation heat transfer coefficient by more than half. Therefore, it is common practice to periodically vent out the noncondensable gases that accumulate in the condensers to ensure proper operation.

The drastic reduction in the condensation heat transfer coefficient in the presence of a noncondensable gas can be explained as follows: When the vapor mixed with a noncondensable gas condenses, only the noncondensable gas remains in the vicinity of the surface (Fig. 10–29). This gas layer acts as a *barrier* between the vapor and the surface, and makes it difficult for the vapor to reach the surface. The vapor now must diffuse through the noncondensable gas first before reaching the surface, and this reduces the effectiveness of the condensation process.

Experimental studies show that heat transfer in the presence of a noncondensable gas strongly depends on the nature of the vapor flow and the flow velocity. As you would expect, a *high flow velocity* is more likely to remove the stagnant noncondensable gas from the vicinity of the surface, and thus *improve* heat transfer.

**FIGURE 10–29**

The presence of a noncondensable gas in a vapor prevents the vapor molecules from reaching the cold surface easily, and thus impedes condensation heat transfer.

**EXAMPLE 10–4** Condensation of Steam on a Vertical Plate

Saturated steam at atmospheric pressure condenses on a 2-m-high and 3-m-wide vertical plate that is maintained at 80°C by circulating cooling water through the other side (Fig. 10–30). Determine (a) the rate of heat transfer by condensation to the plate and (b) the rate at which the condensate drips off the plate at the bottom.

**SOLUTION** Saturated steam at 1 atm condenses on a vertical plate. The rates of heat transfer and condensation are to be determined.

- Assumptions** 1 Steady operating conditions exist. 2 The plate is isothermal. 3 The condensate flow is wavy-laminar over the entire plate (will be verified). 4 The density of vapor is much smaller than the density of liquid,  $\rho_v \ll \rho_l$ .

**Properties** The properties of water at the saturation temperature of 100°C are  $h_{fg} = 2257 \times 10^3 \text{ J/kg}$  and  $\rho_v = 0.60 \text{ kg/m}^3$ . The properties of liquid water at the film temperature of  $T_f = (T_{\text{sat}} + T_s)/2 = (100 + 80)/2 = 90^\circ\text{C}$  are (Table A–9)

$$\begin{aligned}\rho_l &= 965.3 \text{ kg/m}^3 & c_{pl} &= 4206 \text{ J/kg}\cdot\text{K} \\ \mu_l &= 0.315 \times 10^{-3} \text{ kg/m}\cdot\text{s} & k_l &= 0.675 \text{ W/m}\cdot\text{K} \\ v_l &= \mu_l/\rho_l = 0.326 \times 10^{-6} \text{ m}^2/\text{s}\end{aligned}$$

**Analysis** (a) The modified latent heat of vaporization is

$$\begin{aligned}h_{fg}^* &= h_{fg} + 0.68c_{pl}(T_{\text{sat}} - T_s) \\ &= 2257 \times 10^3 \text{ J/kg} + 0.68 \times (4206 \text{ J/kg}\cdot\text{K})(100 - 80)^\circ\text{C} \\ &= 2314 \times 10^3 \text{ J/kg}\end{aligned}$$

For wavy-laminar flow, the Reynolds number is determined from Eq. 10–27 to be

$$\begin{aligned}\text{Re} &= \text{Re}_{\text{vert, wavy}} = \left[ 4.81 + \frac{3.70 L k_l (T_{\text{sat}} - T_s)}{\mu_l h_{fg}^*} \left( \frac{g}{v_l^2} \right)^{1/3} \right]^{0.820} \\ &= \left[ 4.81 + \frac{3.70(2 \text{ m})(0.675 \text{ W/m}\cdot\text{K})(100 - 80)^\circ\text{C}}{(0.315 \times 10^{-3} \text{ kg/m}\cdot\text{s})(2314 \times 10^3 \text{ J/kg})} \right. \\ &\quad \left. \times \left( \frac{9.81 \text{ m/s}^2}{(0.326 \times 10^{-6} \text{ m}^2/\text{s})^2} \right)^{1/3} \right]^{0.820} \\ &= 1287\end{aligned}$$

which is between 30 and 1800, and thus our assumption of wavy laminar flow is verified. Then the condensation heat transfer coefficient is determined from Eq. 10–25 to be

$$\begin{aligned}h &= h_{\text{vert, wavy}} = \frac{\text{Re } k_l}{1.08 \text{ Re}^{1.22} - 5.2} \left( \frac{g}{v_l^2} \right)^{1/3} \\ &= \frac{1287 \times (0.675 \text{ W/m}\cdot\text{K})}{1.08(1287)^{1.22} - 5.2} \left( \frac{9.81 \text{ m/s}^2}{(0.326 \times 10^{-6} \text{ m}^2/\text{s})^2} \right)^{1/3} = 5850 \text{ W/m}^2\cdot\text{K}\end{aligned}$$

The heat transfer surface area of the plate is  $A_s = W \times L = (3 \text{ m})(2 \text{ m}) = 6 \text{ m}^2$ . Then the rate of heat transfer during this condensation process becomes

$$\dot{Q} = h A_s (T_{\text{sat}} - T_s) = (5850 \text{ W/m}^2\cdot\text{K})(6 \text{ m}^2)(100 - 80)^\circ\text{C} = 7.02 \times 10^5 \text{ W}$$

**FIGURE 10–30**  
Schematic for Example 10–4.

(b) The rate of condensation of steam is determined from

$$\dot{m}_{\text{condensation}} = \frac{\dot{Q}}{h_{fg}^*} = \frac{7.02 \times 10^5 \text{ J/s}}{2314 \times 10^3 \text{ J/kg}} = 0.303 \text{ kg/s}$$

That is, steam will condense on the surface at a rate of 303 grams per second.

**FIGURE 10-31**  
Schematic for Example 10-5.

### EXAMPLE 10-5 Condensation of Steam on a Tilted Plate

What would your answer be to the preceding example problem if the plate were tilted 30° from the vertical, as shown in Fig. 10-31?

**SOLUTION** (a) The heat transfer coefficient in this case can be determined from the vertical plate relation by replacing  $g$  by  $g \cos \theta$ . But we will use Eq. 10-30 instead since we already know the value for the vertical plate from the preceding example:

$$h = h_{\text{inclined}} = h_{\text{vert}} (\cos \theta)^{1/4} = (5850 \text{ W/m}^2 \cdot \text{K})(\cos 30^\circ)^{1/4} = 5643 \text{ W/m}^2 \cdot \text{K}$$

The heat transfer surface area of the plate is still 6 m<sup>2</sup>. Then the rate of condensation heat transfer in the tilted plate case becomes

$$\dot{Q} = hA_s(T_{\text{sat}} - T_s) = (5643 \text{ W/m}^2 \cdot \text{K})(6 \text{ m}^2)(100 - 80)^\circ\text{C} = 6.77 \times 10^5 \text{ W}$$

(b) The rate of condensation of steam is again determined from

$$\dot{m}_{\text{condensation}} = \frac{\dot{Q}}{h_{fg}^*} = \frac{6.77 \times 10^5 \text{ J/s}}{2314 \mu 10^3 \text{ J/kg}} = 0.293 \text{ kg/s}$$

**Discussion** Note that the rate of condensation decreased by about 3.3 percent when the plate is tilted.

**FIGURE 10-32**  
Schematic for Example 10-6.

### EXAMPLE 10-6 Condensation of Steam on Horizontal Tubes

The condenser of a steam power plant operates at a pressure of 7.38 kPa. Steam at this pressure condenses on the outer surfaces of horizontal tubes through which cooling water circulates. The outer diameter of the pipes is 3 cm, and the outer surfaces of the tubes are maintained at 30°C (Fig. 10-32). Determine (a) the rate of heat transfer to the cooling water circulating in the tubes and (b) the rate of condensation of steam per unit length of a horizontal tube.

**SOLUTION** Saturated steam at a pressure of 7.38 kPa condenses on a horizontal tube at 30°C. The rates of heat transfer and condensation are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The tube is isothermal.

**Properties** The properties of water at the saturation temperature of 40°C corresponding to 7.38 kPa are  $h_{fg} = 2407 \times 10^3 \text{ J/kg}$  and  $\rho_v = 0.05 \text{ kg/m}^3$ . The properties of liquid water at the film temperature of  $T_f = (T_{\text{sat}} + T_s)/2 = (40 + 30)/2 = 35^\circ\text{C}$  are (Table A-9)

$$\rho_l = 994 \text{ kg/m}^3$$

$$c_{pl} = 4178 \text{ J/kg}\cdot\text{K}$$

$$\mu_l = 0.720 \times 10^{-3} \text{ kg/m}\cdot\text{s}$$

$$k_l = 0.623 \text{ W/m}\cdot\text{K}$$

**Analysis** (a) The modified latent heat of vaporization is

$$\begin{aligned} h_{fg}^* &= h_{fg} + 0.68c_{pl}(T_{\text{sat}} - T_s) \\ &= 2407 \times 10^3 \text{ J/kg} + 0.68 \times (4178 \text{ J/kg}\cdot\text{K})(40 - 30)^\circ\text{C} \\ &= 2435 \times 10^3 \text{ J/kg} \end{aligned}$$

Noting that  $\rho_v \ll \rho_l$  (since  $0.05 \ll 994$ ), the heat transfer coefficient for condensation on a single horizontal tube is determined from Eq. 10–31 to be

$$\begin{aligned} h = h_{\text{horiz}} &= 0.729 \left[ \frac{g\rho_l(\rho_l - \rho_v) h_{fg}^* k_l^3}{\mu(T_{\text{sat}} - T_s) D} \right]^{1/4} \cong 0.729 \left[ \frac{g\rho_l^2 h_{fg}^* k_l^3}{\mu_1(T_{\text{sat}} - T_s) D} \right]^{1/4} \\ &= 0.729 \left[ \frac{(9.81 \text{ m/s}^2)(994 \text{ kg/m}^3)^2 (2435 \times 10^3 \text{ J/kg})(0.623 \text{ W/m}\cdot\text{K})^3}{(0.720 \times 10^{-3} \text{ kg/m}\cdot\text{s})(40 - 30)^\circ\text{C}(0.03 \text{ m})} \right]^{1/4} \\ &= 9294 \text{ W/m}^2\cdot\text{K} \end{aligned}$$

The heat transfer surface area of the pipe per unit of its length is  $A_s = \pi DL = \pi(0.03 \text{ m})(1 \text{ m}) = 0.09425 \text{ m}^2$ . Then the rate of heat transfer during this condensation process becomes

$$\dot{Q} = hA_s(T_{\text{sat}} - T_s) = (9292 \text{ W/m}^2\cdot\text{K})(0.09425 \text{ m}^2)(40 - 30)^\circ\text{C} = \mathbf{8760 \text{ W}}$$

(b) The rate of condensation of steam is

$$\dot{m}_{\text{condensation}} = \frac{\dot{Q}}{h_{fg}^*} = \frac{8760 \text{ J/s}}{2435 \times 10^3 \text{ J/kg}} = \mathbf{0.00360 \text{ kg/s}}$$

Therefore, steam will condense on the horizontal tube at a rate of 3.6 g/s or 13.0 kg/h per meter of its length.

### EXAMPLE 10–7 Condensation of Steam on Horizontal Tube Banks

Repeat the preceding example problem for the case of 12 horizontal tubes arranged in a rectangular array of 3 tubes high and 4 tubes wide, as shown in Fig. 10–33.

**SOLUTION** (a) Condensation heat transfer on a tube is not influenced by the presence of other tubes in its neighborhood unless the condensate from other tubes drips on it. In our case, the horizontal tubes are arranged in four vertical tiers, each tier consisting of 3 tubes. The average heat transfer coefficient for a vertical tier of  $N$  horizontal tubes is related to the one for a single horizontal tube by Eq. 10–33 and is determined to be

$$h_{\text{horiz}, N \text{ tubes}} = \frac{1}{N^{1/4}} h_{\text{horiz}, 1 \text{ tube}} = \frac{1}{3^{1/4}} (9294 \text{ W/m}^2\cdot\text{K}) = 7062 \text{ W/m}^2\cdot\text{K}$$

Each vertical tier consists of 3 tubes, and thus the heat transfer coefficient determined above is valid for each of the four tiers. In other words, this value can be taken to be the average heat transfer coefficient for all 12 tubes.

**FIGURE 10–33**  
Schematic for Example 10–7.

The surface area for all 12 tubes per unit length of the tubes is

$$A_s = N_{\text{total}} \pi D L = 12\pi(0.03 \text{ m})(1 \text{ m}) = 1.1310 \text{ m}^2$$

Then the rate of heat transfer during this condensation process becomes

$$\dot{Q} = h A_s (T_{\text{sat}} - T_s) = (7062 \text{ W/m}^2 \cdot \text{K})(1.131 \text{ m}^2)(40 - 30)^\circ\text{C} = 79,870 \text{ W}$$

(b) The rate of condensation of steam is again determined from

$$\dot{m}_{\text{condensation}} = \frac{\dot{Q}}{h_{fg}^*} = \frac{79,870 \text{ J/s}}{2435 \times 10^3 \text{ J/kg}} = 0.0328 \text{ kg/s}$$

Therefore, steam will condense on the horizontal pipes at a rate of 32.8 g/s per meter length of the tubes.

## 10–6 • FILM CONDENSATION INSIDE HORIZONTAL TUBES

So far we have discussed film condensation on the *outer surfaces* of tubes and other geometries, which is characterized by negligible vapor velocity and the unrestricted flow of the condensate. Most condensation processes encountered in refrigeration and air-conditioning applications, however, involve condensation on the *inner surfaces* of horizontal or vertical tubes. Heat transfer analysis of condensation inside tubes is complicated by the fact that it is strongly influenced by the vapor velocity and the rate of liquid accumulation on the walls of the tubes (Fig. 10–34).

At high vapor velocities (Fig. 10–34a), the flow is characterized by two-phase annular conditions. The core of the annulus is occupied by the vapor and its diameter decreases as the condensate thickness increases in the direction of the flow. At low vapor velocities (Fig. 10–34b), the condensate flow is from the upper portion of the tube to the bottom of the tube.

For *low vapor velocities*, Chato (1962) recommends this expression for condensation

$$h_{\text{internal}} = 0.555 \left[ \frac{g \rho_l (\rho_l - \rho_v) k_l^3}{\mu_l (T_{\text{sat}} - T_s) D} \left( h_{fg} + \frac{3}{8} c_{pl} (T_{\text{sat}} - T_s) \right) \right]^{1/4} \quad (10-34)$$

for

$$\text{Re}_{\text{vapor}} = \left( \frac{\rho_v V_v D}{\mu_v} \right)_{\text{inlet}} < 35,000 \quad (10-35)$$

where the Reynolds number of the vapor is to be evaluated at the tube *inlet* conditions using the internal tube diameter as the characteristic length. Heat transfer coefficient correlations for higher vapor velocities are given by Rohsenow (1973).

**FIGURE 10-34**

Condensate flow in a horizontal tube with high and low vapor velocities.

**PtD EXAMPLE 10–8****Prevention of Ammonia Gas Release by Condensing it to Liquid**

Exposure to high concentration of gaseous ammonia can cause respiratory tract and lung damage, and in some cases even death. One way of preventing the release of high concentration ammonia gas is storing it as liquid in pressurized vessels. Consider a process of condensing saturated ammonia vapor inside a horizontal tube. Saturated ammonia vapor enters a 25-mm-diameter tube with a length of 1.5 m, and it is condensed inside the tube at 1003 kPa. The surface temperature of the tube is maintained constant at 15°C. To ensure that the ammonia is fully condensed to liquid at the exit of the 1.5-m-long tube, determine the flow rate of the ammonia entering the tube.

**SOLUTION** In this example, the concepts of Prevention through Design (PtD) are applied in conjunction with the concept of condensation inside a horizontal tube to condense vapor ammonia.

**Assumptions** 1 Steady operating conditions exist. 2 Tube is isothermal. 3 The vapor velocity is low so that  $Re_{vapor} < 35,000$  (will be verified).

**Properties** The saturation temperature of ammonia at 1003 kPa is  $T_{sat} = 25^\circ\text{C}$  (Table A–11). The properties of saturated ammonia at  $T_{sat} = 25^\circ\text{C}$  are  $h_{fg} = 1166 \times 10^3 \text{ J/kg}$ ,  $\rho_v = 7.809 \text{ kg/m}^3$ ,  $\mu_v = 1.037 \times 10^{-5} \text{ kg/m}\cdot\text{s}$ . The properties of saturated ammonia at the film temperature of  $T_f = (T_{sat} + T_s) = (25 + 15)/2 = 20^\circ\text{C}$  are

$$\begin{aligned}\rho_l &= 610.2 \text{ kg/m}^3 \\ \mu_l &= 1.519 \times 10^{-4} \text{ kg/m}\cdot\text{s} \\ c_{pl} &= 4745 \text{ J/kg}\cdot\text{K} \\ k_l &= 0.4927 \text{ W/m}\cdot\text{K}\end{aligned}$$

**Analysis** The heat transfer coefficient for condensation inside a horizontal tube is

$$\begin{aligned}h &= h_{internal} = 0.555 \left[ \frac{8\rho(\rho_l - \rho_v)k_l^3}{\mu_l(T_{sat} - T_s)D} \left( h_{fg} + \frac{3}{8}c_{pl}(T_{sat} - T_s) \right) \right]^{1/4} \\ h &= 0.555 \left[ \frac{(9.81 \text{ m/s}^2)(610.2 \text{ kg/m}^3)(610.2 - 7.809) \text{ kg/m}^3(0.4927 \text{ W/m}\cdot\text{K})^3}{(1.519 \times 10^{-4} \text{ kg/m}\cdot\text{s})(25 - 15)\text{K}(0.025 \text{ m})} \right. \\ &\quad \times \left. \left( 1166 \times 10^3 \text{ J/kg} + \frac{3}{8}(4745 \text{ J/kg}\cdot\text{K})(25 - 15)\text{K} \right) \right]^{1/4} \\ &= 5976.3 \text{ W/m}^2\cdot\text{K}\end{aligned}$$

The heat transfer surface area of the tube is

$$A_s = \pi DL = \pi(0.025 \text{ m})(1.5 \text{ m}) = 0.11781 \text{ m}^2$$

Then the rate of heat transfer during this condensation process becomes

$$\dot{Q} = hA_s(T_{sat} - T_s) = (5976.3 \text{ W/m}^2\cdot\text{K})(0.11781 \text{ m}^2)(25 - 15)\text{K} = 7040.7 \text{ W}$$

The modified latent heat of vaporization in this case is

$$\begin{aligned}h_{fg}^* &= h_{fg} + \frac{3}{8}c_{pl}(T_{sat} - T_s) \\ &= 1166 \times 10^3 \text{ J/kg} + \frac{3}{8}(4745 \text{ J/kg}\cdot\text{K})(25 - 15)\text{K} = 1183.8 \times 10^3 \text{ J/kg}\end{aligned}$$

**FIGURE 10–35**  
Schematic for Example 10–8.

Then, the rate of condensation becomes

$$\dot{m}_{\text{condensation}} = \frac{\dot{Q}}{h_{fg}^*} = \frac{7040.7 \text{ J/s}}{1183.8 \times 10^3 \text{ J/kg}} = 0.005948 \text{ kg/s}$$

Thus,  $\dot{m} \leq 0.00595 \text{ kg/s}$

**Discussion** To ensure that the saturated ammonia vapor is fully condensed to liquid inside the 1.5-m-long tube, the flow rate of the ammonia entering the tube must be lower than the rate of condensation inside the tube.

Note that the low vapor velocity assumption is appropriate for  $\dot{m} \leq 0.005948 \text{ kg/s}$ , since

$$\begin{aligned} \text{Re}_{\text{vapor}} &= \left( \frac{\rho_v V_v D}{\mu_v} \right)_{\text{inlet}} = \frac{4\dot{m}}{\pi D \mu_v} = \frac{4(0.005948 \text{ kg/s})}{\pi(0.025 \text{ m})(1.037 \times 10^{-5} \text{ kg/m}\cdot\text{s})} \\ &= 29,212 < 35,000 \end{aligned}$$

**FIGURE 10–36**

Dropwise condensation of water on a vertical surface.

## 10–7 ■ DROPWISE CONDENSATION

Dropwise condensation, characterized by countless droplets of varying diameters on the condensing surface instead of a continuous liquid film, is one of the most effective mechanisms of heat transfer, and extremely large heat transfer coefficients can be achieved with this mechanism (Fig. 10–36).

In dropwise condensation, the small droplets that form at the nucleation sites on the surface grow as a result of continued condensation, coalesce into large droplets, and slide down when they reach a certain size, clearing the surface and exposing it to vapor. There is no liquid film in this case to resist heat transfer. As a result, with dropwise condensation, heat transfer coefficients can be achieved that are more than 10 times larger than those associated with film condensation. Large heat transfer coefficients enable designers to achieve a specified heat transfer rate with a smaller surface area, and thus a smaller (and less expensive) condenser. Therefore, dropwise condensation is the preferred mode of condensation in heat transfer applications.

The challenge in dropwise condensation is not to achieve it, but rather, to *sustain* it for prolonged periods of time. Dropwise condensation is achieved by *adding* a promoting chemical into the vapor, *treating* the surface with a promoter chemical, or *coating* the surface with a polymer such as teflon or a noble metal such as gold, silver, rhodium, palladium, or platinum. The *promoters* used include various waxes and fatty acids such as oleic, stearic, and linoic acids. They lose their effectiveness after a while, however, because of fouling, oxidation, and the removal of the promoter from the surface. It is possible to sustain dropwise condensation for over a year by the combined effects of surface coating and periodic injection of the promoter into the vapor. However, any gain in heat transfer must be weighed against the cost associated with sustaining dropwise condensation.

Dropwise condensation has been studied experimentally for a number of surface–fluid combinations. Of these, the studies on the condensation of steam on copper surfaces has attracted the most attention because of their

widespread use in steam power plants. P. Griffith (1983) recommends these simple correlations for dropwise condensation of *steam* on *copper surfaces*:

$$h_{\text{dropwise}} = \begin{cases} 51,104 + 2044T_{\text{sat}}, & 22^{\circ}\text{C} < T_{\text{sat}} < 100^{\circ}\text{C} \\ 255,510 & T_{\text{sat}} > 100^{\circ}\text{C} \end{cases} \quad (10-36)$$

$$(10-37)$$

where  $T_{\text{sat}}$  is in  $^{\circ}\text{C}$  and the heat transfer coefficient  $h_{\text{dropwise}}$  is in  $\text{W}/\text{m}^2 \cdot \text{K}$ .

The very high heat transfer coefficients achievable with dropwise condensation are of little significance if the material of the condensing surface is not a good conductor like copper or if the thermal resistance on the other side of the surface is too large. In steady operation, heat transfer from one medium to another depends on the sum of the thermal resistances on the path of heat flow, and a large thermal resistance may overshadow all others and dominate the heat transfer process. In such cases, improving the accuracy of a small resistance (such as one due to condensation or boiling) makes hardly any difference in overall heat transfer calculations.

### TOPIC OF SPECIAL INTEREST\*

#### *Non-Boiling Two-Phase Flow Heat Transfer*

The different flow patterns (regimes) encountered in flow boiling (see Fig. 10–19) can also be observed in non-boiling two-phase flow in both vertical and horizontal tubes (Figs. 10–37 to 10–39). Non-boiling two-phase flow has many industrial applications, such as the flow of oil and natural gas in flow lines and wellbores, in which the knowledge of non-boiling two-phase, two-component (liquid and permanent gas) heat transfer is required. During the production of two-phase hydrocarbon fluids from an oil reservoir to the surface, the temperature of the hydrocarbon fluids changes due to the difference in temperatures of the oil reservoir and the surface. The change in temperature results in heat transfer between the hydrocarbon fluids and the earth surrounding the oil well, and the ability to estimate the flowing temperature profile is necessary to address several design problems in petroleum production engineering.

In subsea oil and natural gas production, hydrocarbon fluids may leave the reservoir with a temperature of  $75^{\circ}\text{C}$  and flow in subsea surroundings of  $4^{\circ}\text{C}$ . As a result of the temperature gradient between the reservoir and the surrounding, the knowledge of heat transfer is critical to prevent gas hydrate and wax deposition blockages. Wax deposition can result in problems including reduction of inner tube diameter causing blockage, increase in surface roughness of tube leading to restricted flow line pressure, decrease in production, along with various mechanical problems.

In situations where low velocity flow is necessary while high heat transfer rates are desirable, heat transfer enhancement schemes such as coil-spring wire insert, twisted tape insert, and helical ribs are used to promote turbulence, thus enhancing heat transfer. Although these heat transfer enhancement schemes have been proven to be effective, they do come with drawbacks, such as fouling, increase in pressure drop, and sometimes even blockage. An alternative

\*This section can be skipped without a loss of continuity.

**FIGURE 10–37**

**FIGURE 10-38**

Flow patterns in downward vertical two-phase flow.

From Ghajar and Tang, 2012.

approach to enhance heat transfer in tube flow is by injecting gas into liquid to promote turbulence.

In the assessment of non-boiling heat transfer, void fraction (ratio of the volume of space occupied by the gas phase to the total volume of the system) and flow patterns (qualitatively defined based on the distribution of one phase with respect to other phase across the pipe cross section) are two critical parameters that need to be taken into consideration. In any gas-liquid system, void fraction has great effects on heat transfer, since the liquid phase generally has significantly larger thermal conductivity than the gas phase. The knowledge of flow patterns in gas-liquid system is also critical in the assessment of non-boiling heat transfer, for example heat transfer in slug flow (bubbles coalesce into gas slugs) is likely to be different than heat transfer in annular flow (core of the flow consists of gas phase with entrained liquid droplets from the surrounding liquid phase). Void fraction, flow pattern and hence the heat transfer are also affected by the tube inclination. Bhagwat and Ghajar (2012) reported that in inclined and vertical upward and downward tubes, the hydrodynamics of two-phase flow is influenced by the balance between buoyancy and gravitational force. The influence of buoyancy and gravitational force affects the slippage between the gas and liquid phases, which in turn affects the void fraction. Tube inclination also affects the flow patterns, which is the reason for the difference in flow patterns between vertical and horizontal flows (see Figs. 10-37 through 10-39). The influence of tube inclination on the hydrodynamics of two-phase flow also leads to its effect on heat transfer. Due to the complexity and the lack of fundamental understanding of void fraction, flow patterns, and non-boiling heat transfer in two-phase flow, the majority of the documented works, whether they are flow pattern maps or correlations for void fraction and heat transfer, are only applicable to selected flow conditions. Non-boiling two-phase flow in tubes with different inclinations have been studied extensively, and two-phase flow heat transfer correlations for a variety of gas-liquid flow patterns, fluid combinations, and tube inclinations are developed. Based on a database of 986 points, Ghajar and Tang (2009) recommended the following general correlation for the two-phase heat transfer coefficient  $h_{tp}$ , which captures 90 percent of the measured data within an error band of  $\pm 25\%$  and 94 percent of the measured data within an error band of  $\pm 30\%$ ,

**FIGURE 10-39**

Flow patterns in horizontal two-phase flow.

From Ghajar and Tang, 2009.

$$h_{tp} = F_p h_l \left[ 1 + 0.55 \left( \frac{x}{1-x} \right)^{0.1} \left( \frac{1-F_p}{F_p} \right)^{0.4} \left( \frac{\text{Pr}_g}{\text{Pr}_l} \right)^{0.25} \left( \frac{\mu_l}{\mu_g} \right)^{0.25} (I^*)^{0.25} \right], \text{ W/m}^2\cdot\text{K}$$
(10-38)

where subscripts  $l$  and  $g$  refer to the liquid phase and gas phase, and

$h_l$  = liquid phase heat transfer coefficient

$$= 0.027 \text{ Re}_l^{4/5} \text{Pr}_l^{1/3} (k_l/D) (\mu_l/\mu_s)^{0.14}, \text{ W/m}^2\cdot\text{K}$$

$\text{Re}_l$  = in situ liquid Reynolds number =  $4\dot{m}_l/(\pi\sqrt{1-\alpha}\mu_l D)$

$$x = \text{flow quality} = \dot{m}_g/(\dot{m}_g + \dot{m}_l)$$

$$I^* = \text{inclination factor} = 1 + \frac{(\rho_l - \rho_g)gD^2}{\sigma} |\sin \theta|$$

$$F_p = \text{flow pattern factor} = (1 - \alpha) + \alpha \left[ \frac{2}{\pi} \tan^{-1} \left( \sqrt{\frac{\rho_g(V_g - V_d)^2}{gD(\rho_l - \rho_g)}} \right) \right]^2$$

Here  $\rho$  is the density in kg/m<sup>3</sup>,  $V$  is the velocity in m/s,  $g$  is the gravitational acceleration in m/s<sup>2</sup>,  $D$  is the tube diameter in m,  $\dot{m}$  is the mass flow rate in kg/s,  $\mu$  is the dynamic viscosity in kg/m·s,  $\text{Pr}$  is the Prandtl number,  $k$  is the thermal conductivity in W/m·K,  $\sigma$  is the surface tension in N/m, and  $\theta$  is the inclination angle in radians.

The void fraction  $\alpha$  in Eq. 10-38 is to be determined from [(Woldesemayat and Ghajar (2007)]

$$\alpha = \frac{V_{sg}}{C_o(V_{sg} + V_{sl}) + u_{gm}} \quad (10-39)$$

where  $C_o$  = two-phase distribution coefficient

$$= \frac{V_{sg}}{V_{sg} + V_{sl}} \left[ 1 + (V_{sl}/V_{sg})^{(\rho_s/\rho_l)^{0.1}} \right]$$

and  $u_{gm}$  = gas drift velocity

$$= 2.9(1.22 + 1.22\sin\theta)^{P_{\text{atm}}/P_{\text{sys}}} \left[ \frac{gD\sigma(1 + \cos\theta)(\rho_l - \rho_g)}{\rho_l^2} \right]^{0.25}, \text{ m/s}$$

Here  $P_{\text{sys}}$  and  $P_{\text{atm}}$  are the system and atmosphere pressures in N/m<sup>2</sup>, and  $V_{sl}$  and  $V_{sg}$  are the superficial liquid and gas velocities in m/s, respectively. In the equations above, all physical properties are evaluated at the *bulk mean temperature*  $T_b = (T_i + T_e)/2$ , except  $\mu_s$ , which is evaluated at the surface temperature.

The non-boiling two-phase flow heat transfer correlation (Eq. 10-38) is based on 986 experimental data points (176 for horizontal flow, 555 for inclined flow, and 255 for upward vertical flow), and is applicable over the following range of parameters:

$$750 \leq \text{Re}_{sl} \leq 127,000, \quad 14 \leq \text{Re}_{sg} \leq 209,000,$$

$$9.99 \times 10^{-3} \leq \text{Pr}_g/\text{Pr}_l \leq 148 \times 10^{-3},$$

and  $3.64 \times 10^{-3} \leq \mu_g/\mu_l \leq 26.3 \times 10^{-3}$

where  $\text{Re}_{sl}$  and  $\text{Re}_{sg}$  are the superficial liquid and gas Reynolds numbers.

The application of the general two-phase flow non-boiling heat transfer correlation given above is illustrated below with a practical example problem dealing with a mixture of air and liquid silicone.

**EXAMPLE 10–9** Air and Silicone (Dow Corning 200® Fluid, 5 cs) Flow in a Vertical Tube

Liquid silicone such as the Dow Corning 200® Fluid, 5 cs, is used primarily as an ingredient in cosmetic and personal care products due to its high spreadability, low surface tension ( $\sigma = 19.7 \times 10^{-3}$  N/m), non-greasy, soft feel, and subtle skin lubricity characteristics. A two-phase flow of air and silicone (Dow Corning 200® Fluid, 5 cs) is being transported in an 11.7-mm-internal-diameter vertical tube. The liquid phase consists of liquid silicone with dynamic viscosity of  $45.7 \times 10^{-4}$  kg/m·s, density of  $913 \text{ kg/m}^3$ , thermal conductivity of  $0.117 \text{ W/m}\cdot\text{K}$ , and Prandtl number of 64. The gas phase consists of air with dynamic viscosity of  $18.4 \times 10^{-6}$  kg/m·s, density of  $1.19 \text{ kg/m}^3$ , and Prandtl number of 0.71. If the two-phase flow has flow quality of  $x = 2.08 \times 10^{-5}$ , void fraction of  $\alpha = 0.011$ , and liquid mass flow rate of  $\dot{m}_l = 0.907 \text{ kg/s}$ , estimate the two-phase heat transfer coefficient  $h_{tp}$ . Assume the dynamic viscosity of liquid silicone evaluated at the tube surface temperature to be  $39.8 \times 10^{-4}$  kg/m·s.

**SOLUTION** A two-phase flow of air and silicone (Dow Corning 200® Fluid, 5 cs) is being transported in an 11.7-mm-diameter vertical tube. Using the non-boiling two-phase heat transfer correlation, the two-phase heat transfer coefficient  $h_{tp}$  is to be determined.

**Assumptions** 1 Steady operating condition exists. 2 Two-phase flow is non-boiling and it does not involve phase change. 3 Fluid properties are constant.

**Properties** The properties of liquid silicone (liquid) are given to be  $\mu_l = 45.7 \times 10^{-4}$  kg/m·s,  $\mu_s = 39.8 \times 10^{-4}$  kg/m·s,  $\rho_l = 913 \text{ kg/m}^3$ ,  $k_l = 0.117 \text{ W/m}\cdot\text{K}$ ,  $\sigma = 19.7 \times 10^{-3}$  N/m, and  $Pr_l = 64$ . The properties of air (gas) are given to be  $\mu_g = 18.4 \times 10^{-6}$  kg/m·s,  $\rho_g = 1.19 \text{ kg/m}^3$ , and  $Pr_g = 0.71$ .

**Analysis** With known liquid mass flow rate  $\dot{m}_l$  and quality  $x$ , the gas mass flow rate  $\dot{m}_g$  is determined using

$$\dot{m}_g = \frac{x}{1 - x} \dot{m}_l = \frac{2.08 \times 10^{-5}}{1 - 2.08 \times 10^{-5}} (0.907 \text{ kg/s}) = 1.89 \times 10^{-5} \text{ kg/s}$$

From the gas and liquid mass flow rates, the superficial gas and liquid velocities can be calculated:

$$V_{sg} = \frac{\dot{m}_g}{\rho_g A} = \frac{4\dot{m}_g}{\rho_g \pi D^2} = \frac{4(1.89 \times 10^{-5} \text{ kg/s})}{(1.19 \text{ kg/m}^3) \pi (0.0117 \text{ m})^2} = 0.148 \text{ m/s}$$

$$V_{sl} = \frac{\dot{m}_l}{\rho_l A} = \frac{4\dot{m}_l}{\rho_l \pi D^2} = \frac{4(0.907 \text{ kg/s})}{(913 \text{ kg/m}^3) \pi (0.0117 \text{ m})^2} = 9.24 \text{ m/s}$$

Using the superficial velocities and void fraction, the gas and liquid velocities are found to be

$$V_g = \frac{V_{sg}}{\alpha} = \frac{0.148 \text{ m/s}}{0.011} = 13.5 \text{ m/s}$$

$$V_l = \frac{V_{sl}}{1 - \alpha} = \frac{9.24 \text{ m/s}}{1 - 0.011} = 9.34 \text{ m/s}$$

The flow pattern factor ( $F_p$ ) can be calculated using

$$\begin{aligned} F_p &= (1 - \alpha) + \alpha \left[ \frac{2}{\pi} \tan^{-1} \left( \sqrt{\frac{\rho_g(V_g - V_l)^2}{gD(\rho_l - \rho_g)}} \right) \right]^2 \\ &= (1 - 0.011) + (0.011) \left[ \frac{2}{\pi} \tan^{-1} \left( \sqrt{\frac{(1.19 \text{ kg/m}^3)(13.5 \text{ m/s} - 9.34 \text{ m/s})^2}{(9.81 \text{ m/s}^2)(0.0117 \text{ m})(913 \text{ kg/m}^3 - 1.19 \text{ kg/m}^3)}} \right) \right]^2 \\ &= 0.9898 \end{aligned}$$

The inclination factor ( $I^*$ ) for vertical tube ( $\theta = 90^\circ$ ) is calculated to be

$$\begin{aligned} I^* &= 1 + \frac{(\rho_l - \rho_g)gD^2}{\sigma} |\sin \theta| \\ &= 1 + \frac{(913 \text{ kg/m}^3 - 1.19 \text{ kg/m}^3)(9.81 \text{ m/s}^2)(0.0117 \text{ m})^2}{19.7 \times 10^{-3} \text{ N/m}} |\sin 90^\circ| \\ &= 63.16 \end{aligned}$$

The liquid phase heat transfer coefficient is calculated using:

$$\begin{aligned} h_l &= 0.027 \text{Re}_l^{4/5} \text{Pr}_l^{1/3} \left( \frac{k_l}{D} \right) \left( \frac{\mu_l}{\mu_s} \right)^{0.14} \\ &= 0.027(21718)^{4/5}(64)^{1/3} \left( \frac{0.117 \text{ W/m}\cdot\text{K}}{0.0117 \text{ m}} \right) \left( \frac{45.7 \times 10^{-4} \text{ kg/m}\cdot\text{s}}{39.8 \times 10^{-4} \text{ kg/m}\cdot\text{s}} \right)^{0.14} \\ &= 3246 \text{ W/m}^2\cdot\text{K} \end{aligned}$$

where the *in situ* liquid Reynolds number is

$$\begin{aligned} \text{Re}_l &= \frac{4\dot{m}_l}{\pi\sqrt{1-\alpha}\mu_l D} = \frac{4(0.907 \text{ kg/s})}{\pi\sqrt{1 - 0.011(45.7 \times 10^{-4} \text{ kg/m}\cdot\text{s})(0.0117 \text{ m})}} \\ &= 21,718 \end{aligned}$$

Using the general two-phase flow heat transfer correlation, Eq. 10–38, the two-phase heat transfer coefficient is estimated to be

$$\begin{aligned} \frac{h_{tp}}{h_l} &= F_p \left[ 1 + 0.55 \left( \frac{x}{1-x} \right)^{0.1} \left( \frac{1-F_p}{F_p} \right)^{0.4} \left( \frac{\text{Pr}_g}{\text{Pr}_l} \right)^{0.25} \left( \frac{\mu_l}{\mu_g} \right)^{0.25} (I^*)^{0.25} \right] \\ &= (0.9898) \left[ 1 + 0.55 \left( \frac{2.08 \times 10^{-5}}{1 - 2.08 \times 10^{-5}} \right)^{0.1} \left( \frac{1 - 0.9898}{0.9898} \right)^{0.4} \left( \frac{0.71}{64} \right)^{0.25} \right. \\ &\quad \left. \times \left( \frac{45.7 \times 10^{-4} \text{ kg/m}\cdot\text{s}}{18.4 \times 10^{-6} \text{ kg/m}\cdot\text{s}} \right)^{0.25} (63.16)^{0.25} \right] \\ &= 1.098 \end{aligned}$$

or

$$h_{tp} = 1.098h_l = 1.098(3246 \text{ W/m}^2\cdot\text{K}) = \mathbf{3560 \text{ W/m}^2\cdot\text{K}}$$

**Discussion** When compared with the measured two-phase heat transfer coefficient of 3480 W/m<sup>2</sup>·K by Rezkallah (1987) in similar flow conditions, the general two-phase flow heat transfer correlation, Eq. 10–38, over-predicted the measured value by 2.3%.

## Application of Reynolds Analogy to Non-Boiling Two-Phase Flow

We have seen in Chapter 6 that using the concept of Reynolds analogy, single phase heat transfer coefficient can be predicted from the knowledge of single phase friction coefficient. Tang and Ghajar (2011) extended the application of Reynolds analogy concept and developed a correlation to predict non-boiling two-phase heat transfer coefficient from the knowledge of two-phase frictional pressure drop in horizontal and upward inclined flows. The correlation predicts more than 87% of the 637 data points within  $\pm 30\%$  error bands. The correlation is expressed in following form,

$$\frac{h_{tp}}{h_l} = F_p^m \left( \frac{\dot{m}_l}{\dot{m}} \right) \left( \frac{\rho_{tp}}{\rho_l} \right)^n \phi_l^p \quad (10-40)$$

where the exponents  $m$ ,  $n$  and  $p$  have the values of 0.5, -0.5 and 0.2 respectively and

$h_l$  = liquid phase heat transfer coefficient

$$= 0.027 \text{ Re}_{sl}^{4/5} \text{ Pr}_l^{1/3} (k_l/D) (\mu_l/\mu_s)^{0.14}, \text{ W/m}^2 \cdot \text{K}$$

$F_p$  = flow pattern factor same as that used in Eq. 10-38

$\rho_{tp}$  = two-phase mixture density =  $(1 - \alpha)\rho_l + \alpha\rho_g$ , kg/m<sup>3</sup>. The void fraction ( $\alpha$ ) can be determined using Woldesemayat and Ghajar (2007) correlation, Eq. 10-39.

$$\phi_l = \text{two-phase frictional multiplier} = \sqrt{\frac{(dP/dL)_{f,ip}}{(dP/dL)_{f,l}}} \text{ (dimensionless quantity)}$$

$(dP/dL)_{f,l}$  and  $(dP/dL)_{f,ip}$  are the single phase liquid and two-phase frictional pressure drop, respectively. The friction factor required for the single phase liquid pressure drop calculation can be obtained using Moody chart (Fig. A-20) or Colebrook equation (Eq. 8-74). In case if the two-phase frictional pressure drop is not known, then correlations recommended by Ghajar and Bhagwat (2014) may be used. The two-phase heat transfer correlation based on Reynolds analogy (Eq. 10-40) was developed using experimental data for horizontal, upward inclined and vertical upward pipe orientations using air-water and air-glycerin fluid combinations and is applicable over following range of parameters:

For air-water :  $700 \leq \text{Re}_{sl} \leq 107,000$ ,  $14 \leq \text{Re}_{sg} \leq 150,000$

For air-glycerin:  $50 \leq \text{Re}_{sl} \leq 83,000$ ,  $40 \leq \text{Re}_{sg} \leq 59,000$

where  $\text{Re}_{sl}$  and  $\text{Re}_{sg}$  are the superficial liquid and gas Reynolds numbers, respectively.

For vertical downward flow, Bhagwat et al. (2012) pointed out that the two phase heat transfer coefficient is less than that measured in vertical upward flow at similar mass flow rates while the two phase pressure drop is considerably higher in the former orientation than the later. Thus Eq. 10-40 with fixed exponents doesn't give satisfactory performance in prediction of two phase heat transfer coefficient for vertical downward flow. Bhagwat et al. (2012) proposed the following form of the Reynolds analogy based correlation that can be used for vertical downward flow.

$$\frac{h_{tp}}{h_l} = \phi_l^{0.55} \quad (10-41)$$

The single phase heat transfer coefficient ( $h_l$ ) and the two-phase frictional multiplier ( $\phi_l$ ) are calculated the same way as that of Eq. 10–40.

Equation 10–41 is based on the 165 data points measured in a vertically downward oriented 0.0127 m stainless steel pipe using air-water fluid combination. This correlation predicts more than 90% of the measured data points within  $\pm 20\%$  error bands and is applicable for  $1400 \leq Re_{sl} \leq 29,000$ , and  $90 \leq Re_{sg} \leq 18,000$ .

It should be noted that both Eqs. (10–38) and (10–40) require accurate information of void fraction. Ghajar and Bhagwat (2013, 2014) have evaluated several void fraction correlations available in the literature against air water data (5162 data points for horizontal, upward and downward inclinations) and refrigerant-vapor (645 data points for horizontal flow). They found the performance of Woldesemayat and Ghajar (2007) correlation acceptable for general application with requisite accuracy. For more specific flow conditions other top performing void fraction correlations shortlisted by Ghajar and Bhagwat (2013, 2014) may be used.

## SUMMARY

Boiling occurs when a liquid is in contact with a surface maintained at a temperature  $T_s$  sufficiently above the saturation temperature  $T_{\text{sat}}$  of the liquid. Boiling is classified as *pool boiling* or *flow boiling* depending on the presence of bulk fluid motion. Boiling is called *pool boiling* in the absence of bulk fluid flow and *flow boiling* (or *forced convection boiling*) in its presence. Pool and flow boiling are further classified as *subcooled boiling* and *saturated boiling* depending on the bulk liquid temperature. Boiling is said to be *subcooled* (or *local*) when the temperature of the main body of the liquid is below the saturation temperature  $T_{\text{sat}}$  and *saturated* (or *bulk*) when the temperature of the liquid is equal to  $T_{\text{sat}}$ . Boiling exhibits different regimes depending on the value of the excess temperature  $\Delta T_{\text{excess}}$ . Four different boiling regimes are observed: natural convection boiling, nucleate boiling, transition boiling, and film boiling. These regimes are illustrated on the *boiling curve*. The rate of evaporation and the rate of heat transfer in nucleate boiling increase with increasing  $\Delta T_{\text{excess}}$  and reach a maximum at some point. The heat flux at this point is called the *critical* (or *maximum*) *heat flux*,  $\dot{q}_{\text{max}}$ . The rate of heat transfer in nucleate pool boiling is determined from

$$\dot{q}_{\text{nucleate}} = \mu_l h_{fg} \left[ \frac{g(\rho_l - \rho_v)}{\sigma} \right]^{1/2} \left[ \frac{c_{pl}(T_s - T_{\text{sat}})}{C_{sf} h_{fg} \text{Pr}_l^n} \right]^3$$

The *maximum* (or *critical*) *heat flux* in nucleate pool boiling is determined from

$$\dot{q}_{\text{max}} = C_{cr} h_{fg} [\sigma g \rho_v^2 (\rho_l - \rho_v)]^{1/4}$$

where the value of the constant  $C_{cr}$  is about 0.15. The minimum heat flux is given by

$$\dot{q}_{\text{min}} = 0.09 \rho_v h_{fg} \left[ \frac{\sigma g(\rho_l - \rho_v)}{(\rho_l + \rho_v)^2} \right]^{1/4}$$

The heat flux for stable *film boiling* on the outside of a *horizontal cylinder* or *sphere* of diameter  $D$  is given by

$$\begin{aligned} \dot{q}_{\text{film}} &= C_{\text{film}} \left[ \frac{gk_v^3 \rho_v (\rho_l - \rho_v) h_{fg} + 0.4 c_{pv} (T_s - T_{\text{sat}})}{\mu_v D (T_s - T_{\text{sat}})} \right]^{1/4} \\ &\quad \times (T_s - T_{\text{sat}}) \end{aligned}$$

where the constant  $C_{\text{film}} = 0.62$  for horizontal cylinders and 0.67 for spheres. The *vapor* properties are to be evaluated at the *film temperature*  $T_f = (T_{\text{sat}} + T_s)/2$ , which is the *average temperature* of the vapor film. The liquid properties and  $h_{fg}$  are to be evaluated at the saturation temperature at the specified pressure.

Two distinct forms of condensation are observed in nature: *film condensation* and *dropwise condensation*. In *film condensation*, the condensate wets the surface and forms a liquid film on the surface that slides down under the influence of gravity. In *dropwise condensation*, the condensed vapor forms countless

droplets of varying diameters on the surface instead of a continuous film.

The Reynolds number for the condensate flow is defined as

$$\text{Re} = \frac{D_h \rho_l V_l}{\mu_l} = \frac{4 A_c \rho_l V_l}{p \mu_l} = \frac{4 \dot{m}}{p \mu_l}$$

and

$$\text{Re} = \frac{4 \dot{Q}_{\text{conden}}}{p \mu_l h_{fg}^*} = \frac{4 A_s h(T_{\text{sat}} - T_s)}{p \mu_l h_{fg}^*}$$

where  $h_{fg}^*$  is the *modified latent heat of vaporization*, defined as

$$h_{fg}^* = h_{fg} + 0.68 c_{pl} (T_{\text{sat}} - T_s)$$

and represents heat transfer during condensation per unit mass of condensate.

Using some simplifying assumptions, the *average heat transfer coefficient* for film condensation on a vertical plate of height  $L$  is determined to be

$$h_{\text{vert}} = 0.943 \left[ \frac{g \rho_l (\rho_l - \rho_v) h_{fg}^* k_l^3}{\mu_l (T_{\text{sat}} - T_s) L} \right]^{1/4}$$

All properties of the *liquid* are to be evaluated at the film temperature  $T_f = (T_{\text{sat}} + T_s)/2$ . The  $h_{fg}$  and  $\rho_v$  are to be evaluated at  $T_{\text{sat}}$ . Condensate flow is *smooth* and *wave-free laminar* for about  $\text{Re} \leq 30$ , *wavy-laminar* in the range of  $30 < \text{Re} < 1800$ , and *turbulent* for  $\text{Re} > 1800$ . Heat transfer coefficients in the wavy-laminar and turbulent flow regions are determined from

$$h_{\text{vert, wavy}} = \frac{\text{Re} k_l}{1.08 \text{Re}^{1.22} - 5.2} \left( \frac{g}{v_l^2} \right)^{1/3}, \quad 30 < \text{Re} < 1800 \quad \rho_v \ll \rho_l$$

$$h_{\text{vert, turbulent}} = \frac{\text{Re} k_l}{8750 + 58 \text{Pr}^{-0.5} (\text{Re}^{0.75} - 253)} \left( \frac{g}{v_l^2} \right)^{1/3},$$

$$\text{Re} > 1800$$

$$\rho_v \ll \rho_l$$

Equations for vertical plates can also be used for laminar film condensation on the upper surfaces of the plates that are inclined by an angle  $\theta$  from the vertical, by replacing  $g$  in that equation by  $g \cos \theta$ . Vertical plate equations can also be used to calculate the average heat transfer coefficient for laminar film condensation on the outer surfaces of vertical tubes provided that the tube diameter is large relative to the thickness of the liquid film.

The average heat transfer coefficient for film condensation on the outer surfaces of a *horizontal tube* is determined to be

$$h_{\text{horiz}} = 0.729 \left[ \frac{g \rho_l (\rho_l - \rho_v) h_{fg}^* k_l^3}{\mu_l (T_{\text{sat}} - T_s) D} \right]^{1/4}$$

where  $D$  is the diameter of the horizontal tube. This relation can easily be modified for a *sphere* by replacing the constant 0.729 by 0.815. It can also be used for  $N$  horizontal tubes stacked on top of each other by replacing  $D$  in the denominator by  $ND$ .

For low vapor velocities, film condensation heat transfer *inside horizontal tubes* can be determined from

$$h_{\text{internal}} = 0.555 \left[ \frac{g\rho_l(\rho_l - \rho_v)k_l^3}{\mu_l(T_{\text{sat}} - T_s)D} \left( h_{fg} + \frac{3}{8} c_{pl}(T_{\text{sat}} - T_s) \right) \right]^{1/4}$$

$$\text{Re}_{\text{vapor}} = \left( \frac{\rho_v V_v D}{\mu_v} \right)_{\text{inlet}} < 35,000$$

where the Reynolds number of the vapor is to be evaluated at the tube inlet conditions using the internal tube diameter as the characteristic length. Finally, the heat transfer coefficient for *dropwise condensation* of steam on copper surfaces is given by

$$h_{\text{dropwise}} = \begin{cases} 51,104 + 2044T_{\text{sat}}, & 22^\circ\text{C} < T_{\text{sat}} < 100^\circ\text{C} \\ 255,510, & T_{\text{sat}} > 100^\circ\text{C} \end{cases}$$

where  $T_{\text{sat}}$  is in  $^\circ\text{C}$  and the heat transfer coefficient  $h_{\text{dropwise}}$  is in  $\text{W/m}^2 \cdot ^\circ\text{C}$  or its equivalent  $\text{W/m}^2 \cdot \text{K}$ .

## PROBLEMS\*

## Boiling Heat Transfer

**10-1C** What is boiling? What mechanisms are responsible for the very high heat transfer coefficients in nucleate boiling?

**10-2C** Name the different boiling regimes in the order they occur in a vertical tube during flow boiling.

**10-3C** What is the difference between evaporation and boiling?

**10-4C** What is the difference between pool boiling and flow boiling?

**10-5C** Draw the boiling curve and identify the different boiling regimes. Also, explain the characteristics of each regime.

**10-6C** How does film boiling differ from nucleate boiling? Is the boiling heat flux necessarily higher in the stable film boiling regime than it is in the nucleate boiling regime?

**10-7C** Draw the boiling curve and identify the burnout point on the curve. Explain how burnout is caused. Why is the burnout point avoided in the design of boilers?

**10-8C** Discuss some methods of enhancing pool boiling heat transfer permanently.

**10-9C** Does the amount of heat absorbed as 1 kg of saturated liquid water boils at 100°C have to be equal to the amount of heat released as 1 kg of saturated water vapor condenses at 100°C?

**10-10** Water is boiled at 120°C in a mechanically polished stainless-steel pressure cooker placed on top of a heating unit. The inner surface of the bottom of the cooker is maintained at 130°C. Determine the heat flux on the surface.

*Answer:* 228.4 kW/m<sup>2</sup>

**10-11** A platinum-plated rod with a diameter of 10 mm is submerged horizontally in water at atmospheric pressure. If the surface of the rod is maintained at 10°C above the saturation temperature, determine the nucleate pool boiling heat transfer rate per unit length and the rate of evaporation per unit length (in kg/s·m).

$$P = 1 \text{ atm}$$

FIGURE P10-11

\*Problems designated by a "C" are concept questions, and students are encouraged to answer them all. Problems designated by an "E" are in English units, and the SI users can ignore them. Problems with the icon are solved using EES, and complete solutions together with parametric studies are included on the text website. Problems with the icon are comprehensive in nature, and are intended to be solved with an equation solver such as EES. Problems with the icon are Prevention through Design problems.

**10-12** A 65-cm-long, 2-cm-diameter brass heating element is to be used to boil water at 120°C. If the surface temperature of the heating element is not to exceed 125°C, determine the highest rate of steam production in the boiler, in kg/h. *Answer:* 19.4 kg/h

**10-13** Water is to be boiled at atmospheric pressure in a mechanically polished steel pan placed on top of a heating unit. The inner surface of the bottom of the pan is maintained at 110°C. If the diameter of the bottom of the pan is 30 cm, determine (a) the rate of heat transfer to the water and (b) the rate of evaporation.

FIGURE P10-13

**10-14** Water is boiled at atmospheric pressure by a horizontal platinum-plated rod with diameter of 10 mm. If the surface temperature of the rod is maintained at 110°C, determine the nucleate pool boiling heat transfer coefficient.

$$P = 1 \text{ atm}$$

FIGURE P10-14

**10-15** A 1-mm diameter-long electrical wire submerged in water at atmospheric pressure is dissipating 4100 W/m of heat, and the surface temperature reaches 128°C. If the experimental constant that depends on the fluid is  $n = 1$ , determine the nucleate boiling heat transfer coefficient and the value of the experimental constant  $C_{sf}$ .

FIGURE P10-15

**10-16** Water is boiled at sea level in a coffee maker equipped with a 20-cm-long 0.4-cm-diameter immersion-type electric heating element made of mechanically polished stainless steel. The coffee maker initially contains 1 L of water at 14°C. Once boiling starts, it is observed that half of the water in the coffee maker evaporates in 25 min. Determine the power rating of the electric heating element immersed in water and the surface temperature of the heating element. Also determine how long it will take for this heater to raise the temperature of 1 L of cold water from 14°C to the boiling temperature.

FIGURE P10-16

**10-17** Repeat Prob. 10-16 for a copper heating element.

**10-18** Water is boiled at 1 atm pressure in a 20-cm-internal-diameter Teflon®-pitted stainless-steel pan on an electric range. If it is observed that the water level in the pan drops by 10 cm in 15 min, determine the inner surface temperature of the pan. *Answer: 105.3°C*

**10-19** Repeat Prob. 10-18 for a polished copper pan.

**10-20** Water is boiled at 120°C in a mechanically polished stainless-steel pressure cooker placed on top of a heating unit. If the inner surface of the bottom of the cooker is maintained at 132°C, determine the boiling heat transfer coefficient.

**10-21E** Water is boiled at 250°F by a 2-ft-long and 0.5-in diameter nickel-plated electric heating element maintained at 280°F. Determine (a) the boiling heat transfer coefficient, (b) the electric power consumed by the heating element, and (c) the rate of evaporation of water.

**10-22E** Repeat Prob. 10-21E for a platinum-plated heating element.

**10-23E** Reconsider Prob. 10-21E. Using EES (or other) software, investigate the effect of surface temperature of the heating element on the boiling heat transfer coefficient, the electric power, and the rate of evaporation of water. Let the surface temperature vary from 260°F to 300°F. Plot the boiling heat transfer coefficient, the electric power consumption, and the rate of evaporation of water as a function of the surface temperature, and discuss the results.

**10-24** Mechanically polished, 5-cm-diameter, stainless steel ball bearings are heated to 125°C uniformly. The ball bearings are then submerged in water at 1 atm to be cooled. Determine the rate of heat that is removed from a ball bearing at the instant it is submerged in the water.

**10-25** A 15-m-long polished copper tube with an outer diameter of 5 cm is submerged in water at 270 kPa. The tube is heated with hot gases flowing through it to generate steam by boiling the water. In the interest of minimizing the excess temperature, determine the surface temperature of the tube that is necessary to achieve a rate of steam generation of 1.5 kg/s. What would be the boiling regime for the steam generation?

**10-26** A long hot mechanically polished stainless steel sheet ( $c_p = 450 \text{ J/kg}\cdot\text{K}$ ,  $\rho = 7900 \text{ kg/m}^3$ ) is being conveyed at 2 m/s through a water bath to be cooled. The 0.5-m-wide and 5-mm-thick stainless steel sheet has a temperature of 125°C as it enters the water bath. The length of the sheet submerged in water is 1 m as it is being conveyed through the water bath. As the hot sheet enters the water bath, boiling would occur at 1 atm. In order to prevent thermal burn on people handling the sheet, it must exit the water bath at a temperature below 45°C. Is the rate of heat that could be removed from the stainless steel sheet in the water bath sufficient to cool it to below 45°C as it leaves the water bath?

FIGURE P10-26

**10-27** Water is boiled at 90°C by a horizontal brass heating element of diameter 7 mm. Determine the maximum heat flux that can be attained in the nucleate boiling regime.

**10-28** A 1-mm-diameter nickel wire with electrical resistance of 0.129 Ω/m is submerged horizontally in water at atmospheric pressure. Determine the electrical current at which the wire would be in danger of burnout in nucleate boiling.

FIGURE P10-28

**10-29** In a boiler, water is boiled at 100°C by hot gases flowing through a 10-m-long tube with an outer diameter of 5 cm that is submerged in the water. Determine the maximum rate of water vaporization that can be produced by the tube in the nucleate boiling regime.

**10-30** Hot gasses flow inside an array of tubes that are embedded in a 3 m × 3 m horizontal flat heater. The heater is used for boiling water in a tank at 160°C. With the interest of avoiding burnout, determine the maximum rate of water vaporization that can be achieved by the heater.

FIGURE P10-30

**10-31** Water is boiled by two heaters of different geometries: a spherical heater and a horizontal flat heater. Both heaters are submerged in water that boils at 1 atm. The spherical heater has a diameter of 1 m, and the horizontal flat heater has the same surface area as the spherical heater. Determine the maximum rate of water vaporization that can be achieved by each heater without reaching burnout. Which heater geometry would produce higher maximum rate of vaporization?

**10-32** Hot gasses flow inside an array of tubes that are embedded in a 3 m × 3 m horizontal flat heater. The heater surface is nickel-plated and is used for generating steam by boiling water in the nucleate boiling regime at 180°C. Determine the surface temperature of the heater and the convection heat transfer coefficient that is necessary to achieve the maximum rate of steam generation.

**10-33** Water is to be boiled at atmospheric pressure on a 3-cm-diameter mechanically polished steel heater. Determine the maximum heat flux that can be attained in the nucleate boiling regime and the surface temperature of the heater surface in that case.

**10-34** Reconsider Prob. 10-33. Using EES (or other) software, investigate the effect of local atmospheric pressure on the maximum heat flux and the temperature difference  $T_s - T_{\text{sat}}$ . Let the atmospheric pressure vary from 70 kPa to 101.3 kPa. Plot the maximum heat flux and the temperature difference as a function of the atmospheric pressure, and discuss the results.

**10-35** A 10 cm × 10 cm horizontal flat heater is used for vaporizing refrigerant-134a at 350 kPa. The heater is supplied with 0.35 MW/m<sup>2</sup> of heat flux, and the surface temperature of the heater is 25°C. If the experimental constant in the Rohsenow correlation is  $n = 1.7$ , determine the value of the coefficient  $C_{sf}$ . Discuss whether or not the Rohsenow correlation is applicable in this analysis.

**10-36** In a gas-fired boiler, water is boiled at 150°C by hot gases flowing through 50-m-long, 5-cm-outer-diameter mechanically polished stainless-steel pipes submerged in water. If the outer surface temperature of the pipes is 165°C, determine (a) the rate of heat transfer from the hot gases to water, (b) the rate of evaporation, (c) the ratio of the critical heat flux to the present heat flux, and (d) the surface temperature of the pipe at which critical heat flux occurs.

FIGURE P10-36

**10-37** Repeat Prob. 10-36 for a boiling temperature of 155°C

**10-38** A 1 m × 1 m horizontal flat heater is used for generating steam by boiling water at 1 atm. The boiling occurs at an excess temperature above 300°C, but is maintained below the burnout point. Determine the range of the steam generation rate that can be achieved by the heater.

**10–39** Water is boiled at 90°C by a horizontal brass heating element of diameter 7 mm. Determine the surface temperature of the heater for the minimum heat flux case.

**10–40** A 2-mm-diameter cylindrical metal rod with emissivity of 0.5 is submerged horizontally in water under atmospheric pressure. When electric current is passed through the metal rod, the surface temperature reaches 500°C. Determine the power dissipation per unit length of the metal rod.

FIGURE P10–40

**10–41E** Water is boiled at atmospheric pressure by a horizontal polished copper heating element of diameter  $D = 0.5$  in and emissivity  $\epsilon = 0.05$  immersed in water. If the surface temperature of the heating element is 788°F, determine the rate of heat transfer to the water per unit length of the heating element.

**10–42E** Repeat Prob. 10–41E for a heating element temperature of 988°F.

**10–43** A 20-mm-diameter metal sphere has an emissivity of 0.75. The sphere was removed from a furnace when it reached a uniform temperature of 700°C and was suddenly submerged in a water bath at atmospheric pressure. Estimate the initial heat transfer rate from the submerged metal sphere.

**10–44** A 20-mm-diameter cylindrical steel rod with a length of 200 mm has an emissivity of 0.9. The steel rod was removed from a furnace when it reached a uniform temperature of 500°C and was suddenly submerged horizontally in a water bath at atmospheric pressure. Estimate the initial heat transfer rate from the submerged steel rod.

**10–45** Water is boiled at 100°C by a spherical platinum heating element of diameter 15 cm and emissivity 0.10 immersed in the water. If the surface temperature of the heating element is 350°C, determine the rate of heat transfer from the heating element to the water.

**10–46** Cylindrical stainless steel rods are heated to a uniform temperature of 700°C and then quenched in water at 1 atm. The rods are 25 cm in length, 25 mm in diameter, and their surface have an emissivity of 0.3. Determine the convection heat transfer coefficient and the total rate of heat removed from a rod at the instant it is submerged in the water during quenching.

**10–47** A long cylindrical stainless steel rod ( $c_p = 450 \text{ J/kg}\cdot\text{K}$ ,  $\rho = 7900 \text{ kg/m}^3$ ,  $\epsilon = 0.30$ ) with mechanically polished surface is being conveyed through a water bath to be quenched. The 25-mm-diameter stainless steel rod has a temperature of 700°C as it enters the water bath. A length of 3 m of the rod is submerged in water as it is conveyed through the water bath during the quenching process. As the stainless steel rod enters the water bath, boiling would occur at 1 atm. In order to prevent thermal burn on people handling the rod, it must exit the water bath at a temperature below 45°C. Determine the speed of the rod being conveyed through the water bath so that it leaves the water bath without the risk of thermal burn hazard.

FIGURE P10–47

**10–48** A cylindrical rod is used for boiling water at 1 atm. The rod has a diameter of 1 cm and its surface has an emissivity of 0.3. Determine the film boiling convection heat transfer coefficient at the burnout point. Evaluate the properties of vapor at 1150°C. Discuss whether 1150°C is a reasonable film temperature for the vapor properties.

**10–49** A 3-mm-diameter cylindrical heater is used for boiling water at 100°C. The heater surface is made of mechanically polished stainless steel with an emissivity of 0.3. Determine the boiling convection heat transfer coefficients at the maximum heat flux for (a) nucleate boiling and (b) film boiling. For film boiling, evaluate the properties of vapor at 1150°C.

**10–50** To understand the burnout phenomenon, boiling experiments are conducted in water at atmospheric pressure using an electrically heated 30-cm-long, 3-mm-diameter nickel-plated horizontal wire. Determine (a) the critical heat flux and (b) the increase in the temperature of the wire as the operating point jumps from the nucleate boiling to the film boiling regime at the critical heat flux. Take the emissivity of the wire to be 0.5.

**10–51** Reconsider Prob. 10–50. Using EES (or other) software, investigate the effects of the local atmospheric pressure and the emissivity of the wire on the critical heat flux and the temperature rise of wire. Let the atmospheric pressure vary from 70 kPa to 101.3 kPa and the emissivity from 0.1 to 1.0. Plot the critical heat flux and the temperature rise as functions of the atmospheric pressure and the emissivity, and discuss the results.

## Condensation Heat Transfer

**10–52C** What is condensation? How does it occur?

**10–53C** What is the difference between film and dropwise condensation? Which is a more effective mechanism of heat transfer?

**10–54C** How does the presence of a noncondensable gas in a vapor influence the condensation heat transfer?

**10–55C** What is the modified latent heat of vaporization? For what is it used? How does it differ from the ordinary latent heat of vaporization?

**10–56C** Consider film condensation on a vertical plate. Will the heat flux be higher at the top or at the bottom of the plate? Why?

**10–57C** Consider film condensation on the outer surfaces of four long tubes. For which orientation of the tubes will the condensation heat transfer coefficient be the highest: (a) vertical, (b) horizontal side by side, (c) horizontal but in a vertical tier (directly on top of each other), or (d) a horizontal stack of two tubes high and two tubes wide?

**10–58C** In condensate flow, how is the wetted perimeter defined? How does wetted perimeter differ from ordinary perimeter?

**10–59** The Reynolds number for condensate flow is defined as  $Re = 4\dot{m}/p \mu_l$ , where  $p$  is the wetted perimeter. Obtain simplified relations for the Reynolds number by expressing  $p$  and  $\dot{m}$  by their equivalence for the following geometries: (a) a vertical plate of height  $L$  and width  $w$ , (b) a tilted plate of height  $L$  and width  $W$  inclined at an angle  $\theta$  from the vertical, (c) a vertical cylinder of length  $L$  and diameter  $D$ , (d) a horizontal cylinder of length  $L$  and diameter  $D$ , and (e) a sphere of diameter  $D$ .

**10–60** A vertical  $0.2 \text{ m} \times 0.2 \text{ m}$  square plate is exposed to saturated water vapor at atmospheric pressure. If the surface temperature is  $80^\circ\text{C}$  and the flow is laminar, estimate the local heat transfer coefficients at the middle and at the bottom of the plate.

**10–61** A vertical  $0.5 \text{ m} \times 0.5 \text{ m}$  square plate is used in a process to condensate saturated water vapor. If the desired rate of condensation is  $0.016 \text{ kg/s}$ , determine the necessary surface temperature of the plate at atmospheric pressure. For this problem, as a first approximation, assume a film temperature of  $90^\circ\text{C}$  for the evaluation of the liquid properties and a surface temperature of  $80^\circ\text{C}$  for the evaluation of modified latent heat of vaporization. Are these good assumptions?

**10–62** Saturated ammonia vapor at  $30^\circ\text{C}$  is passed over 30 vertical flat plates, each of which is  $10 \text{ cm}$  high and  $25 \text{ cm}$  wide. The average surface temperature of the plates is  $10^\circ\text{C}$ . Estimate the average heat transfer coefficient and the rate of ammonia condensation. Assume wavy-laminar flow. Is this a good assumption?

**10–63** Saturated steam at  $1 \text{ atm}$  condenses on a  $3\text{-m}$ -high and  $8\text{-m}$ -wide vertical plate that is maintained at  $90^\circ\text{C}$  by circulating cooling water through the other side. Determine (a) the rate of heat transfer by condensation to the plate, and (b) the rate at which the condensate drips off the plate at the bottom. Assume wavy-laminar flow. Is this a good assumption?

FIGURE P10–63

**10–64** Repeat Prob. 10–63 for the case of the plate being tilted  $60^\circ$  from the vertical.

**10–65** Saturated steam at  $100^\circ\text{C}$  condenses on a  $2\text{-m} \times 2\text{-m}$  plate that is tilted  $40^\circ$  from the vertical. The plate is maintained at  $80^\circ\text{C}$  by cooling it from the other side. Determine (a) the average heat transfer coefficient over the entire plate and (b) the rate at which the condensate drips off the plate at the bottom. Assume wavy-laminar flow. Is this a good assumption?

**10–66**  Reconsider Prob. 10–65. Using EES (or other) software, investigate the effects of plate temperature and the angle of the plate from the vertical on the average heat transfer coefficient and the rate at which the condensate drips off. Let the plate temperature vary from  $40^\circ\text{C}$  to  $90^\circ\text{C}$  and the plate angle from  $0^\circ$  to  $60^\circ$ . Plot the heat transfer coefficient and the rate at which the condensate drips off as functions of the plate temperature and the tilt angle, and discuss the results.

**10–67** Saturated steam at  $30^\circ\text{C}$  condenses on the outside of a  $4\text{-cm}$ -outer-diameter,  $2\text{-m}$ -long vertical tube. The temperature of the tube is maintained at  $20^\circ\text{C}$  by the cooling water. Determine (a) the rate of heat transfer from the steam to the cooling water, (b) the rate of condensation of steam, and (c) the approximate thickness of the liquid film at the bottom of the tube. Assume wavy-laminar flow and that the tube diameter is large, relative to the thickness of the liquid film at the bottom of the tube. Are these good assumptions?

FIGURE P10-67

**10-68** Saturated water vapor at atmospheric pressure condenses on the outer surface of a 0.1-m-diameter vertical pipe. The pipe is 1 m long and has a uniform surface temperature of 80°C. Determine the rate of condensation and the heat transfer rate by condensation. Discuss whether the pipe can be treated as a vertical plate. Assume wavy-laminar flow and that the tube diameter is large relative to the thickness of the liquid film at the bottom of the tube. Are these good assumptions?

**10-69** Saturated steam at 55°C is to be condensed at a rate of 10 kg/h on the outside of a 3-cm-outer-diameter vertical tube whose surface is maintained at 45°C by the cooling water. Determine the required tube length. Assume wavy-laminar flow, and that the tube diameter is large, relative to the thickness of the liquid film at the bottom of the tube. Are these good assumptions?

**10-70** Repeat Prob. 10-69 for a horizontal tube. *Answer: 0.70 m*

**10-71** A 1.5-m-long vertical tube is used for condensing saturated steam at 60°C. The surface temperature of the tube is maintained at a uniform temperature of 40°C by flowing coolant inside the tube. Determine the heat transfer rate to the tube and the required tube diameter to condense 12 kg/h of steam during the condensation process. Assume wavy-laminar flow and that the tube diameter is large relative to the thickness of the liquid film at the bottom of the tube. Are these good assumptions?

**10-72** Repeat Prob. 10-71 for a horizontal tube. Compare the required diameters between a vertical tube and a horizontal tube to condense 12 kg/h of steam during the condensation process.

**10-73** Saturated ammonia vapor at 10°C condenses on the outside of a 4-cm-outer-diameter, 15-m-long horizontal tube whose outer surface is maintained at -10°C. Determine (a) the rate of heat transfer from the ammonia and (b) the rate of condensation of ammonia.

**10-74** A 3-m spherical tank storing cold fluid has a uniform surface temperature of 5°C. The lower temperature of the tank surface is causing condensation of moisture in the air at 25°C. The tank is situated in the vicinity of high voltage devices, and water from the condensation on

the tank surface can cause electrical hazard. To prevent such incident, a system is to be implemented to remove 0.5 kg/s of condensate from coming in contact with the high voltage devices. Determine whether or not the preventive system is capable of handling the rate of condensation from the tank surface.

**10-75** Consider film condensation on the outer surfaces of  $N$  horizontal tubes arranged in a vertical tier. For what value of  $N$  will the average heat transfer coefficient for the entire stack of tubes be equal to half of what it is for a single horizontal tube?

**10-76** A large heat exchanger has several columns of tubes, with 33 tubes in each column. The outer diameter of the tubes is 1.5 cm. Saturated steam at 50°C condenses on the outer surfaces of the tubes, which are maintained at 20°C. Determine (a) the average heat transfer coefficient and (b) the rate of condensation of steam per m length of a column.

**10-77** The condenser of a steam power plant operates at a pressure of 4.25 kPa. The condenser consists of 100 horizontal tubes arranged in a  $10 \times 10$  square array. The tubes are 8 m long and have an outer diameter of 3 cm. If the tube surfaces are at 20°C, determine (a) the rate of heat transfer from the steam to the cooling water and (b) the rate of condensation of steam in the condenser. *Answers: (a) 3678 kW, (b) 1.496 kg/s*

FIGURE P10-77

**10-78** Reconsider Prob. 10-77. Using EES (or other) software, investigate the effect of the condenser pressure on the rate of heat transfer and the rate of condensation of the steam. Let the condenser pressure vary from 3 kPa to 15 kPa. Plot the rate of heat transfer and the rate of condensation of the steam as a function of the condenser pressure, and discuss the results.

**10-79E** Saturated steam at 95°F is condensed on the outer surfaces of an array of horizontal pipes through which cooling water circulates. The outer diameter of the pipes is 1 in and the outer surfaces of the pipes are maintained at 65°F. Determine (a) the rate of heat transfer to the cooling water circulating in the pipes and (b) the rate of condensation of steam per unit length of a single horizontal pipe.

**10-80E** Repeat Prob. 10-79E for the case of 32 horizontal pipes arranged in a rectangular array of 4 pipes high and 8 pipes wide.

**10-81** A horizontal condenser uses a  $4 \times 4$  array of tubes that have an outer diameter of 5.0 cm and length 2.0 m. Saturated steam at 101.3 kPa condenses on the outside tube surface held at a temperature of 80°C. Calculate the steady rate of steam condensation in kg/h.

**10-82** Saturated water vapor at a pressure of 12.4 kPa is condensed over 100 horizontal tubes in a rectangular array of 5 tubes high and 20 tubes wide, each with a diameter of 8 mm. If the tube surfaces are maintained with a uniform temperature of 30°C, determine the condensation rate per unit length (in kg/s·m) of the tubes.

**10-83** Saturated water vapor at a pressure of 12.4 kPa is condensed over an array of 100 horizontal tubes, each with a diameter of 8 mm and a length of 1 m. The tube surfaces are maintained with a uniform temperature of 30°C. Determine the condensation rates of the tubes for (a) a rectangular array of 5 tubes high and 20 tubes wide and (b) a square array of 10 tubes high and 10 tubes wide. Compare and discuss the results of (a) and (b).

**10-84** Saturated refrigerant-134a vapor at a pressure of 888 kPa is condensed as it is flowing through a 0.25-m-long tube with a diameter of 12 mm. The tube wall temperature is maintained uniform at 15°C. If the vapor enters the tube at a flow rate of 0.003 kg/s, determine the flow rate of the vapor at the exit.

**10-85** Saturated ammonia vapor at a pressure of 1003 kPa is condensed as it flows through a 25-mm tube. The tube length is 0.5 m and the wall temperature is maintained uniform at 5°C. If the vapor exits the tube at a flow rate of 0.002 kg/s, determine the flow rate of the vapor at the inlet. Assume the Reynolds number of the vapor at the tube inlet is less than 35,000. Is this a good assumption?

**10-86** A 10-m-long copper tube with a diameter of 25 mm is used for transporting cold coolant. The coolant flow inside the tube maintains the tube surface temperature at 5°C and causes moist air to condense on the outer surface. Determine the dropwise condensation rate of the moisture in the air, if the saturation temperature is 25°C.

**10-87**  A 10-m-long copper tube with a diameter of 25 mm is used for transporting cold fluid. The cold fluid flow inside the tube causes the tube surface temperature at 3°C to be colder than the ambient temperature. As a

result, moist air condenses at 27°C on the tube outer surface. The tube is situated in the vicinity of high voltage devices, and water from the condensation can cause electrical hazard. It has been determined that both film condensation and dropwise condensation can occur on the tube surface. To prevent electrical hazard, a system is to be implemented to remove the condensate and prevent it from coming in contact with the high voltage devices. Size the system so that it is capable of handling the condensation rate from the tube surface.

FIGURE P10-87

**10-88** Steam is being condensed at 60°C by a 15-m-long horizontal copper tube with a diameter of 25 mm. The tube surface temperature is maintained at 40°C. Determine the condensation rate of the steam during (a) film condensation, and (b) dropwise condensation. Compare and discuss the results.

#### Special Topic: Non-Boiling Two-Phase Flow Heat Transfer

**10-89** Consider a non-boiling gas-liquid two-phase flow in a tube, where the ratio of the mass flow rate is  $\dot{m}_l/\dot{m}_g = 300$ . Determine the flow quality ( $x$ ) of this non-boiling two-phase flow.

**10-90** Consider a non-boiling gas-liquid two-phase flow in a 102-mm diameter tube, where the superficial gas velocity is one-third that of the liquid. If the densities of the gas and liquid are  $\rho_g = 8.5 \text{ kg/m}^3$  and  $\rho_l = 855 \text{ kg/m}^3$ , respectively, determine the flow quality and the mass flow rates of the gas and the liquid when the gas superficial velocity is 0.8 m/s.

**10-91** A non-boiling two-phase flow of air and engine oil in a 25-mm diameter tube has a bulk mean temperature of 140°C. If the flow quality is  $2.1 \times 10^{-3}$  and the mass flow rate of the engine oil is 0.9 kg/s, determine the mass flow rate of air and the superficial velocities of air and engine oil.

**10-92** Consider a mixture of air-water flow in a tube. Suddenly the air flow is shut off, so that only water is flowing in the tube. Starting with the two-phase non-boiling heat transfer correlation, find the expression that is appropriate for this situation.

**10-93** Air water slug flows through a 25.4-mm diameter horizontal tube in microgravity condition (less than 1% of earth's normal gravity). The liquid phase consists of water with dynamic viscosity of  $\mu_l = 85.5 \times 10^{-5} \text{ kg/m}\cdot\text{s}$ , density of  $\rho_l = 997 \text{ kg/m}^3$ , thermal conductivity of  $k_l = 0.613 \text{ W/m}\cdot\text{K}$ , and Prandtl number of  $\text{Pr}_l = 5.0$ . The gas phase consists of air with dynamic viscosity of  $\mu_g = 18.5 \times 10^{-6} \text{ kg/m}\cdot\text{s}$ , density  $\rho_g = 1.16 \text{ kg/m}^3$ , and Prandtl number  $\text{Pr}_g = 0.71$ . At superficial gas velocity of  $V_{sg} = 0.3 \text{ m/s}$ , superficial liq-

uid velocity  $V_{sl} = 0.544 \text{ m/s}$ , and void fraction of  $\alpha = 0.27$ , estimate the two-phase heat transfer coefficient  $h_{tp}$ . Assume the dynamic viscosity of water evaluated at the tube surface temperature to be  $73.9 \times 10^{-5} \text{ kg/m}\cdot\text{s}$ .

**10–94** A two-phase flow mixture of air and silicone (Dow Corning 200® Fluid, 5 cs) is being transported in an 11.7-mm-diameter thin-walled horizontal tube. The liquid phase consists of liquid silicone with surface tension ( $\sigma$ ) of  $19.7 \times 10^{-3} \text{ N/m}$ , dynamic viscosity ( $\mu_l$ ) of  $45.7 \times 10^{-4} \text{ kg/m}\cdot\text{s}$ , density ( $\rho_l$ ) of  $913 \text{ kg/m}^3$ , thermal conductivity ( $k_l$ ) of  $0.117 \text{ W/m}\cdot\text{K}$ , and Prandtl number ( $Pr_l$ ) of 64. The dynamic viscosity of the liquid silicone evaluated at the tube surface temperature ( $\mu_s$ ) is  $39.8 \times 10^{-4} \text{ kg/m}\cdot\text{s}$ . The gas phase consists of air with dynamic viscosity ( $\mu_g$ ) of  $18.4 \times 10^{-6} \text{ kg/m}\cdot\text{s}$ , density ( $\rho_g$ ) of  $1.19 \text{ kg/m}^3$ , and Prandtl number ( $Pr_g$ ) of 0.71. The two-phase flow has flow quality ( $x$ ) of  $2.08 \times 10^{-5}$ , void fraction ( $\alpha$ ) of 0.011, gas velocity ( $V_g$ ) of  $13.5 \text{ m/s}$ , liquid velocity ( $V_l$ ) of  $9.34 \text{ m/s}$ , and liquid mass flow rate ( $\dot{m}_l$ ) of  $0.907 \text{ kg/s}$ . Moist air at a saturation temperature of  $40^\circ\text{C}$  condenses on the outer surface of the tube. The tube has a uniform surface temperature of  $20^\circ\text{C}$ . Determine the overall convection heat transfer coefficient (inside and outside) of the tube.

FIGURE P10–94

**10–95** An air-water mixture is flowing in a  $5^\circ$  inclined tube that has a diameter of 25.4 mm. The two-phase mixture enters the tube at  $25^\circ\text{C}$  and exits at  $65^\circ\text{C}$ , while the tube surface temperature is maintained at  $80^\circ\text{C}$ . If the superficial gas and liquid velocities are 1 m/s and 2 m/s, respectively, determine the two-phase heat transfer coefficient  $h_{tp}$ . Assume the surface tension is  $\sigma = 0.068 \text{ N/m}$  and the void fraction is  $\alpha = 0.33$ .

**10–96** A mixture of petroleum and natural gas is being transported in a pipeline with a diameter of 102 mm. The pipeline is located in a terrain that caused it to have an average inclination angle of  $\theta = 10^\circ$ . The liquid phase consists of petroleum with dynamic viscosity of  $\mu_l = 297.5 \times 10^{-4} \text{ kg/m}\cdot\text{s}$ , density of  $\rho_l = 853 \text{ kg/m}^3$ , thermal conductivity of  $k_l = 0.163 \text{ W/m}\cdot\text{K}$ , surface tension of  $\sigma = 0.020 \text{ N/m}$ , and Prandtl number of  $Pr_l = 405$ . The gas phase consists of natural gas with dynamic viscosity of  $\mu_g = 9.225 \times 10^{-6} \text{ kg/m}\cdot\text{s}$ , density of  $\rho_g = 9.0 \text{ kg/m}^3$ , and Prandtl number of  $Pr_g = 0.80$ . The liquid is flowing at a flow rate of 16 kg/s, while the gas is flowing at 0.055 kg/s. If the void fraction is  $\alpha = 0.22$ , determine the two-phase heat transfer coefficient  $h_{tp}$ . Assume the dynamic viscosity of liquid petroleum evaluated at the tube surface temperature to be  $238 \times 10^{-4} \text{ kg/m}\cdot\text{s}$ .

**10–97** An air-water mixture is flowing in a tube with a diameter of 25.4 mm. The two-phase mixture enters the tube at  $15^\circ\text{C}$  and exits at  $75^\circ\text{C}$ , while the tube surface temperature is maintained at  $80^\circ\text{C}$ . If the superficial gas and liquid velocities are 1 m/s and 2 m/s, respectively, determine the two-phase heat transfer coefficient  $h_{tp}$  for (a) the horizontal tube ( $\theta = 0^\circ$ ) and (b) the vertical tube ( $\theta = 90^\circ$ ), and compare the two results. Assume the surface tension is  $\sigma = 0.068 \text{ N/m}$  and the void fraction is  $\alpha = 0.33$ .

**10–98** Consider a two phase flow of air-water in a vertical upward stainless steel pipe with an inside diameter of 0.0254 m. The two phase mixture enters the pipe at  $25^\circ\text{C}$  at a system pressure of 201 kPa. The superficial velocities of the water and air are 0.3 m/s and 23 m/s, respectively. The differential pressure transducer connected across the pressure taps set 1 m apart records a pressure drop of 2700 Pa and the measured value of void fraction is 0.86. Using the concept of Reynolds analogy determine the two phase convective heat transfer coefficient. Hint: Use EES to calculate the properties of water and air at the given temperature and pressure.

### Review Problems

**10–99** Water is boiled at  $120^\circ\text{C}$  in a mechanically polished stainless-steel pressure cooker placed on top of a heating unit. The inner surface of the bottom of the cooker is maintained at  $130^\circ\text{C}$ . The cooker that has a diameter of 20 cm and a height of 30 cm is half filled with water. Determine the time it will take for the tank to empty. *Answer: 22.8 min*

**10–100** Water is to be boiled at sea level in a 30-cm-diameter mechanically polished AISI 304 stainless steel pan placed on top of a 3-kW electric burner. If 60 percent of the heat generated by the burner is transferred to the water during boiling, determine the temperature of the inner surface of the bottom of the pan. Also, determine the temperature difference between the inner and outer surfaces of the bottom of the pan if it is 6-mm thick. Assume the boiling regime is nucleate boiling. Is this a good assumption?

FIGURE P10–100

**10–101** Repeat Prob. 10–100 for a location at an elevation of 1500 m where the atmospheric pressure is 84.5 kPa and thus the boiling temperature of water is  $95^\circ\text{C}$ .

**10–102** A resistance heater made of 2-mm-diameter nickel wire is used to heat water at 1 atm pressure. Determine the highest temperature at which this heater can operate safely without the danger of burning out.

**10–103** Water is boiled at 100°C electrically by an 80-cm-long, 2-mm-diameter horizontal resistance wire made of chemically etched stainless steel. Determine (a) the rate of heat transfer to the water and the rate of evaporation of water if the temperature of the wire is 115°C and (b) the maximum rate of evaporation in the nucleate boiling regime.

Answers: (a) 2387 W, 3.81 kg/h, (b) 1280 kW/m<sup>2</sup>

FIGURE P10–103

**10–104** During a heat treatment process, a 20-mm diameter cylindrical steel rod with a length of 200 mm was removed from a furnace when it reached a uniform temperature of 500°C and was suddenly submerged horizontally in a water bath at atmospheric pressure. If the steel rod has an emissivity of 0.9, determine the boiling heat transfer coefficient and the total heat transfer coefficient when it was initially submerged in the water bath.

**10–105** Electric current is passed through a 2-mm diameter cylindrical metal rod with emissivity of 0.5. The rod is submerged horizontally in water under atmospheric pressure and the rod surface temperature reaches 500°C. Determine the boiling heat transfer coefficient and the total heat transfer coefficient.

FIGURE P10–105

**10–106** Water is boiled at 100°C by a spherical platinum heating element of diameter 15 cm and emissivity 0.10 immersed in the water. If the surface temperature of the heating element is 350°C, determine the convective boiling heat transfer coefficient.

**10–107** In a heat treatment process, 20-mm-diameter steel ball bearings are being heated to a uniform temperature of 700°C. The ball bearings are then being removed and immediately submerged in a water bath at atmospheric pressure. If the steel ball bearings have an emissivity of 0.75, determine the boiling heat transfer coefficient and the total heat transfer coefficient when they were initially submerged in the water bath.

**10–108E** Saturated steam at 100°F is condensed on a 4-ft-high vertical plate that is maintained at 80°F. Determine the rate of heat transfer from the steam to the plate and the rate of condensation per foot width of the plate. Assume wavy-laminar flow. Is this a good assumption?

**10–109** Saturated ammonia vapor at 25°C condenses on the outside of a 2-m-long, 3.2-cm-outer-diameter vertical tube maintained at 15°C. Determine (a) the average heat transfer coefficient, (b) the rate of heat transfer, and (c) the rate of condensation of ammonia. Assume turbulent flow and that the tube diameter is large, relative to the thickness of the liquid film at the bottom of the tube. Are these good assumptions?

**10–110** Saturated refrigerant-134a vapor at 35°C is to be condensed on the outer surface of a 7-m-long, 1.5-cm-diameter horizontal tube that is maintained at a temperature of 25°C. Determine the rate at which the refrigerant will condense, in kg/min.

**10–111** Repeat Prob. 10–110 for a tube diameter of 3 cm.

**10–112** Steam at 40°C condenses on the outside of a 3-cm-diameter thin horizontal copper tube by cooling water that enters the tube at 25°C at an average velocity of 2 m/s and leaves at 35°C. Determine the rate of condensation of steam, the average overall heat transfer coefficient between the steam, and the cooling water, and the tube length.

FIGURE P10–112

**10–113** A 1.2-cm-diameter silver sphere initially at 25°C is suspended in a room filled with saturated steam at 100°C. Using the lumped system analysis, determine how long it will take for the temperature of the ball to rise to 50°C. Also, determine the amount of steam that condenses during this process and verify that the lumped system analysis is applicable.

**10–114** Repeat Prob. 10–113 for a 3-cm-diameter copper ball.

**10–115** Saturated isobutane vapor in a binary geothermal power plant is to be condensed outside an array of eight horizontal tubes. Determine the ratio of the condensation rate for the cases of the tubes being arranged in a horizontal tier versus in a vertical tier of horizontal tubes.

**10–116E** The condenser of a steam power plant operates at a pressure of 0.95 psia. The condenser consists of 144 horizontal tubes arranged in a  $12 \times 12$  square array. The tubes are 15 ft long and have an outer diameter of 1.2 in. If the outer surfaces of the tubes are maintained at 80°F, determine (a) the rate of heat transfer from the steam to the cooling water and (b) the rate of condensation of steam in the condenser.

**10–117E** Repeat Prob. 10–116E for a tube diameter of 2 in.

**10–118** Shown in Fig. P10–118 is the tube layout for a horizontal condenser that is used for liquefying 900 kg/h of saturated ammonia vapor at 37°C. There are 14 copper tubes, each with inner diameter  $D_i = 3.0$  cm and outer diameter  $D_o = 3.8$  cm. A coolant flows through the tubes at an average temperature of 20°C such that it yields a heat transfer coefficient of 4.0 kW/m<sup>2</sup>·K. For this condenser, estimate (a) the average value of the overall heat transfer coefficient and (b) the tube length. Assume a tube outer surface temperature of 31°C. Is this a good assumption?

**FIGURE P10–118**

**10–119** Saturated ammonia vapor at 25°C condenses on the outside surface of 16 thin-walled tubes, 2.5 cm in diameter, arranged horizontally in a  $4 \times 4$  square array. Cooling water enters the tubes at 14°C at an average velocity of 2 m/s and exits at 17°C. Calculate (a) the rate of NH<sub>3</sub> condensation, (b) the overall heat transfer coefficient, and (c) the tube length.

**10–120** Saturated steam at 270.1 kPa condenses inside a horizontal, 10-m-long, 2.5-cm-internal-diameter pipe whose surface is maintained at 110°C. Assuming low vapor velocity, determine the average heat transfer coefficient and the rate of condensation of the steam inside the pipe. *Answers: 8413 W/m<sup>2</sup>·K, 0.0608 kg/s*

### Fundamentals of Engineering (FE) Exam Problems

**10–121** When boiling a saturated liquid, one must be careful while increasing the heat flux to avoid burnout. Burnout occurs when the boiling transitions from \_\_\_\_ boiling.

- (a) convection to nucleate      (b) convection to film
- (c) film to nucleate      (d) nucleate to film
- (e) none of them

**10–122** Heat transfer coefficients for a vapor condensing on a surface can be increased by promoting

- (a) film condensation      (b) dropwise condensation
- (c) rolling action      (d) none of them

**10–123** At a distance  $x$  down a vertical, isothermal flat plate on which a saturated vapor is condensing in a continuous film, the thickness of the liquid condensate layer is  $\delta$ . The heat transfer coefficient at this location on the plate is given by

- (a)  $k_f/\delta$       (b)  $\delta h_f$
- (c)  $\delta h_{fg}$       (d)  $\delta h_g$
- (e) none of them

**10–124** When a saturated vapor condenses on a vertical, isothermal flat plate in a continuous film, the rate of heat transfer is proportional to

- |                                    |                                    |
|------------------------------------|------------------------------------|
| (a) $(T_s - T_{\text{sat}})^{1/4}$ | (b) $(T_s - T_{\text{sat}})^{1/2}$ |
| (c) $(T_s - T_{\text{sat}})^{3/4}$ | (d) $(T_s - T_{\text{sat}})$       |
| (e) $(T_s - T_{\text{sat}})^{2/3}$ |                                    |

**10–125** Saturated water vapor is condensing on a 0.5 m<sup>2</sup> vertical flat plate in a continuous film with an average heat transfer coefficient of 7 kW/m<sup>2</sup>·K. The temperature of the water is 80°C ( $h_{fg} = 2309$  kJ/kg) and the temperature of the plate is 60°C. The rate at which condensate is being formed is

- |                 |               |               |
|-----------------|---------------|---------------|
| (a) 0.0303 kg/s | (b) 0.07 kg/s | (c) 0.15 kg/s |
| (d) 0.24 kg/s   | (e) 0.28 kg/s |               |

**10–126** Steam condenses at 50°C on a 0.8-m-high and 2.4-m-wide vertical plate that is maintained at 30°C. The condensation heat transfer coefficient is

- |                                |                                |
|--------------------------------|--------------------------------|

### Design and Essay Problems

**10–131** Design the condenser of a steam power plant that has a thermal efficiency of 40 percent and generates 10 MW of net electric power. Steam enters the condenser as saturated vapor at 10 kPa, and it is to be condensed outside horizontal tubes through which cooling water from a nearby river flows. The temperature rise of the cooling water is limited to 8°C, and the velocity of the cooling water in the pipes is limited to 6 m/s to keep the pressure drop at an acceptable level. Specify the pipe diameter, total pipe length, and the arrangement of the pipes to minimize the condenser volume.

**10–132** The refrigerant in a household refrigerator is condensed as it flows through the coil that is typically placed behind the refrigerator. Heat transfer from the outer surface of the coil to the surroundings is by natural convection and radiation. Obtaining information about the operating conditions of the refrigerator, including the pressures and temperatures of the refrigerant at the inlet and the exit of the coil, show that the coil is selected properly, and determine the safety margin in the selection.

**10–133** Water-cooled steam condensers are commonly used in steam power plants. Obtain information about water-cooled steam condensers by doing a literature search on the topic and also by contacting some condenser manufacturers. In a report, describe the various types, the way they are designed, the limitation on each type, and the selection criteria.

**10–134** A manufacturing facility requires saturated steam at 120°C at a rate of 1.2 kg/min. Design an electric steam boiler for this purpose under these constraints:

- The boiler will be in cylindrical shape with a height-to-diameter ratio of 1.5. The boiler can be horizontal or vertical.
- The boiler will operate in the nucleate boiling regime, and the design heat flux will not exceed 60 percent of the critical heat flux to provide an adequate safety margin.

FIGURE P10–134

- A commercially available plug-in type electrical heating element made of mechanically polished stainless steel will be used. The diameter of the heater cannot be between 0.5 cm and 3 cm.
- Half of the volume of the boiler should be occupied by steam, and the boiler should be large enough to hold enough water for 2 h supply of steam. Also, the boiler will be well insulated.

You are to specify the following: (a) The height and inner diameter of the tank, (b) the length, diameter, power rating, and surface temperature of the electric heating element, (c) the maximum rate of steam production during short periods of overload conditions, and how it can be accomplished.

**10–135** Repeat Prob. 10–134 for a boiler that produces steam at 150°C at a rate of 2.5 kg/min.

**10–136** Conduct this experiment to determine the boiling heat transfer coefficient. You will need a portable immersion-type electric heating element, an indoor-outdoor thermometer, and metal glue (all can be purchased for about \$15 in a hardware store). You will also need a piece of string and a ruler to calculate the surface area of the heater. First, boil water in a pan using the heating element and measure the temperature of the boiling water away from the heating element. Based on your reading, estimate the elevation of your location, and compare it to the actual value. Then glue the tip of the thermocouple wire of the thermometer to the midsection of the heater surface. The temperature reading in this case will give the surface temperature of the heater. Assuming the rated power of the heater to be the actual power consumption during heating (you can check this by measuring the electric current and voltage), calculate the heat transfer coefficients from Newton's law of cooling.

FIGURE P10–136

# HEAT EXCHANGERS

**H**eat exchangers are devices that facilitate the *exchange of heat* between two fluids that are at different temperatures while keeping them from mixing with each other. Heat exchangers are commonly used in practice in a wide range of applications, from heating and air-conditioning systems in a household, to chemical processing and power production in large plants. Heat exchangers differ from mixing chambers in that they do not allow the two fluids involved to mix.

Heat transfer in a heat exchanger usually involves *convection* in each fluid and *conduction* through the wall separating the two fluids. In the analysis of heat exchangers, it is convenient to work with an *overall heat transfer coefficient U* that accounts for the contribution of all these effects on heat transfer. The rate of heat transfer between the two fluids at a location in a heat exchanger depends on the magnitude of the temperature difference at that location, which varies along the heat exchanger.

Heat exchangers are manufactured in a variety of types, and thus we start this chapter with the *classification* of heat exchangers. We then discuss the determination of the overall heat transfer coefficient in heat exchangers, and the *log mean temperature difference* (LMTD) for some configurations. We then introduce the *correction factor F* to account for the deviation of the mean temperature difference from the LMTD in complex configurations. Next we discuss the effectiveness–NTU method, which enables us to analyze heat exchangers when the outlet temperatures of the fluids are not known. Finally, we discuss the selection of heat exchangers.

## OBJECTIVES

When you finish studying this chapter, you should be able to:

- Recognize numerous types of heat exchangers, and classify them,
- Develop an awareness of fouling on surfaces, and determine the overall heat transfer coefficient for a heat exchanger,
- Perform a general energy analysis on heat exchangers,
- Obtain a relation for the logarithmic mean temperature difference for use in the LMTD method, and modify it for different types of heat exchangers using the correction factor,
- Develop relations for effectiveness, and analyze heat exchangers when outlet temperatures are not known using the effectiveness-NTU method,
- Know the primary considerations in the selection of heat exchangers.

## 11–1 • TYPES OF HEAT EXCHANGERS

Different heat transfer applications require different types of hardware and different configurations of heat transfer equipment. The attempt to match the heat transfer hardware to the heat transfer requirements within the specified constraints has resulted in numerous types of innovative heat exchanger designs.

The simplest type of heat exchanger consists of two concentric pipes of different diameters, as shown in Fig. 11–1, called the **double-pipe** heat exchanger. One fluid in a double-pipe heat exchanger flows through the smaller pipe while the other fluid flows through the annular space between the two pipes. Two types of flow arrangement are possible in a double-pipe heat exchanger: in **parallel flow**, both the hot and cold fluids enter the heat exchanger at the same end and move in the *same* direction. In **counter flow**, on the other hand, the hot and cold fluids enter the heat exchanger at opposite ends and flow in *opposite* directions.

Another type of heat exchanger, which is specifically designed to realize a large heat transfer surface area per unit volume, is the **compact** heat exchanger. The ratio of the heat transfer surface area of a heat exchanger to its volume is called the *area density*  $\beta$ . A heat exchanger with  $\beta > 700 \text{ m}^2/\text{m}^3$  (or  $200 \text{ ft}^2/\text{ft}^3$ ) is classified as being compact. Examples of compact heat exchangers are car radiators ( $\beta \approx 1000 \text{ m}^2/\text{m}^3$ ), glass-ceramic gas turbine heat exchangers ( $\beta \approx 6000 \text{ m}^2/\text{m}^3$ ), the regenerator of a Stirling engine ( $\beta \approx 15,000 \text{ m}^2/\text{m}^3$ ), and the human lung ( $\beta \approx 20,000 \text{ m}^2/\text{m}^3$ ). The flow passages in these compact heat exchangers are usually small and the flow can be considered to be laminar.

**FIGURE 11–1**

Different flow regimes and associated temperature profiles in a double-pipe heat exchanger.

Compact heat exchangers enable us to achieve high heat transfer rates between two fluids in a small volume, and they are commonly used in applications with strict limitations on the weight and volume of heat exchangers (Fig. 11–2).

The large surface area in compact heat exchangers is obtained by attaching closely spaced *thin plate* or *corrugated fins* to the walls separating the two fluids. Compact heat exchangers are commonly used in gas-to-gas and gas-to-liquid (or liquid-to-gas) heat exchangers to counteract the low heat transfer coefficient associated with gas flow with increased surface area. In a car radiator, which is a water-to-air compact heat exchanger, for example, it is no surprise that fins are attached to the air side of the tube surface.

Another example of compact heat exchangers widely used today in industrial applications such as chemical processing, fuel processing, waste heat recovery, and refrigeration is the **printed circuit heat exchanger** referred to as PCHE (Fig. 11–3). PCHE derives its name from the manufacturing process in which the flat metal plates that form the core of this heat exchanger are chemically etched to a depth of 1 to 3 mm. The chemically etched plates are then stacked together and joined by diffusion bonding. There may be different etching patterns on the plates to make the heat exchanger as a parallel, counter or cross flow heat exchanger. Furthermore, Li et al. (2011) reported that unlike conventional heat exchangers with straight flow channels, the flow channels in PCHE can be made in zigzag, S-shape or aero foil shape in order to induce flow turbulence and hence enhance the heat transfer coefficient. PCHEs have high surface density typically greater than  $2500 \text{ m}^2/\text{m}^3$ . The PCHEs are usually made from stainless steel, titanium, copper, nickel and nickel alloys and can withstand operating pressures up to 500 bar. The major advantages of printed circuit heat exchangers are their wide operating temperature range, which is from  $-250^\circ\text{C}$  to  $900^\circ\text{C}$ , very high heat transfer coefficients, and their size, which is about four to six times smaller and lighter than conventional heat exchangers. One of the major disadvantages of using PCHEs is very high pressure drop and that they require very clean fluid to be passed through them otherwise blockages can occur easily in the fine channel spacing (0.5 to 2 mm).

In compact heat exchangers, the two fluids usually move *perpendicular* to each other, and such flow configuration is called **cross-flow**. The cross-flow is further classified as *unmixed* and *mixed* flow, depending on the flow configuration, as shown in Fig. 11–4. In (a) the cross-flow is said to be *unmixed*

since the plate fins force the fluid to flow through a particular interfin spacing and prevent it from moving in the transverse direction (i.e., parallel to the tubes). The cross-flow in (b) is said to be *mixed* since the fluid now is free to move in the transverse direction. Both fluids are unmixed in a car radiator. The presence of mixing in the fluid can have a significant effect on the heat transfer characteristics of the heat exchanger.

Perhaps the most common type of heat exchanger in industrial applications is the **shell-and-tube** heat exchanger, shown in Fig. 11–5. Shell-and-tube heat exchangers contain a large number of tubes (sometimes several hundred) packed in a shell with their axes parallel to that of the shell. Heat transfer takes place as one fluid flows inside the tubes while the other fluid flows outside the tubes through the shell. **Baffles** are commonly placed in the shell to force the shell-side fluid to flow across the shell to enhance heat transfer and to maintain uniform spacing between the tubes. Despite their widespread use, shell-and-tube heat exchangers are not suitable for use in automotive and aircraft applications because of their relatively large size and weight. Note that the tubes in a shell-and-tube heat exchanger open to some large flow areas called *headers* at both ends of the shell, where the tube-side fluid accumulates before entering the tubes and after leaving them.

Shell-and-tube heat exchangers are further classified according to the number of shell and tube passes involved. Heat exchangers in which all the tubes make one U-turn in the shell, for example, are called *one-shell-pass and two-tube-passes* heat exchangers. Likewise, a heat exchanger that involves two passes in the shell and four passes in the tubes is called a *two-shell-passes and four-tube-passes* heat exchanger (Fig. 11–6).

An innovative type of heat exchanger that has found widespread use is the **plate and frame** (or just plate) heat exchanger, which consists of a series of plates with corrugated flat flow passages (Fig. 11–7). The hot and cold fluids flow in alternate passages, and thus each cold fluid stream is surrounded by two hot fluid streams, resulting in very effective heat transfer. Also, plate heat exchangers can grow with increasing demand for heat transfer by simply mounting more plates. They are well suited for liquid-to-liquid heat exchange applications, provided that the hot and cold fluid streams are at about the same pressure.

Another type of heat exchanger that involves the alternate passage of the hot and cold fluid streams through the same flow area is the **regenerative**

**FIGURE 11–6**

Multipass flow arrangements in shell-and-tube heat exchangers.

**FIGURE 11-7**

A plate-and-frame liquid-to-liquid heat exchanger.

heat exchanger. The *static*-type regenerative heat exchanger is basically a porous mass that has a large heat storage capacity, such as a ceramic wire mesh. Hot and cold fluids flow through this porous mass alternatively. Heat is transferred from the hot fluid to the matrix of the regenerator during the flow of the hot fluid, and from the matrix to the cold fluid during the flow of the cold fluid. Thus, the matrix serves as a temporary heat storage medium.

The *dynamic*-type regenerator involves a rotating drum and continuous flow of the hot and cold fluid through different portions of the drum so that any portion of the drum passes periodically through the hot stream, storing heat, and then through the cold stream, rejecting this stored heat. Again the drum serves as the medium to transport the heat from the hot to the cold fluid stream.

Heat exchangers are often given specific names to reflect the specific application for which they are used. For example, a *condenser* is a heat exchanger in which one of the fluids is cooled and condenses as it flows through the heat exchanger. A *boiler* is another heat exchanger in which one of the fluids absorbs heat and vaporizes. A *space radiator* is a heat exchanger that transfers heat from the hot fluid to the surrounding space by radiation.

## 11-2 • THE OVERALL HEAT TRANSFER COEFFICIENT

A heat exchanger typically involves two flowing fluids separated by a solid wall. Heat is first transferred from the hot fluid to the wall by *convection*, through the wall by *conduction*, and from the wall to the cold fluid again by *convection*. Any radiation effects are usually included in the convection heat transfer coefficients.

FIGURE 11-8

Thermal resistance network associated with heat transfer in a double-pipe heat exchanger.

FIGURE 11-9

The two heat transfer surface areas associated with a double-pipe heat exchanger (for thin tubes,  $D_i \approx D_o$  and thus  $A_i \approx A_o$ ).

The thermal resistance network associated with this heat transfer process involves two convection and one conduction resistances, as shown in Fig. 11-8. The analysis is very similar to the material presented in Chapter 3. Here the subscripts  $i$  and  $o$  represent the inner and outer surfaces of the inner tube. For a double-pipe heat exchanger, the *thermal resistance* of the tube wall is (also see Eq. 3-39)

$$R_{\text{wall}} = \frac{\ln(D_o/D_i)}{2\pi kL} \quad (11-1)$$

where  $k$  is the thermal conductivity of the wall material and  $L$  is the length of the tube. Then the *total thermal resistance* becomes (also see Eq. 3-43)

$$R = R_{\text{total}} = R_i + R_{\text{wall}} + R_o = \frac{1}{h_i A_i} + \frac{\ln(D_o/D_i)}{2\pi kL} + \frac{1}{h_o A_o} \quad (11-2)$$

The  $A_i$  is the area of the inner surface of the wall that separates the two fluids, and  $A_o$  is the area of the outer surface of the wall. In other words,  $A_i$  and  $A_o$  are surface areas of the separating wall wetted by the inner and the outer fluids, respectively. When one fluid flows inside a circular tube and the other outside of it, we have  $A_i = \pi D_i L$  and  $A_o = \pi D_o L$  (Fig. 11-9).

In the analysis of heat exchangers, it is convenient to combine all the thermal resistances in the path of heat flow from the hot fluid to the cold one into a single resistance  $R$ , and to express the rate of heat transfer between the two fluids as

$$\dot{Q} = \frac{\Delta T}{R} = UA_s \Delta T = U_i A_i \Delta T = U_o A_o \Delta T \quad (11-3)$$

where  $A_s$  is the surface area and  $U$  is the **overall heat transfer coefficient**, whose unit is  $\text{W/m}^2\cdot\text{K}$ , which is identical to the unit of the ordinary convection coefficient  $h$ . Canceling  $\Delta T$ , Eq. 11-3 reduces to

$$\frac{1}{UA_s} = \frac{1}{U_i A_i} = \frac{1}{U_o A_o} = R = \frac{1}{h_i A_i} + R_{\text{wall}} + \frac{1}{h_o A_o} \quad (11-4)$$

Perhaps you are wondering why we have two overall heat transfer coefficients  $U_i$  and  $U_o$  for a heat exchanger. The reason is that every heat exchanger has two heat transfer surface areas  $A_i$  and  $A_o$ , which, in general, are not equal to each other.

Note that  $U_i A_i = U_o A_o$ , but  $U_i \neq U_o$  unless  $A_i = A_o$ . Therefore, the overall heat transfer coefficient  $U$  of a heat exchanger is meaningless unless the area on which it is based is specified. This is especially the case when one side of the tube wall is finned and the other side is not, since the surface area of the finned side is several times that of the unfinned side.

When the wall thickness of the tube is small and the thermal conductivity of the tube material is high, as is usually the case, the thermal resistance of the tube is negligible ( $R_{\text{wall}} \approx 0$ ) and the inner and outer surfaces of the tube are almost identical ( $A_i \approx A_o \approx A_s$ ). Then Eq. 11-4 for the overall heat transfer coefficient simplifies to

$$\frac{1}{U} \approx \frac{1}{h_i} + \frac{1}{h_o} \quad (11-5)$$

where  $U \approx U_i \approx U_o$ . The individual convection heat transfer coefficients inside and outside the tube,  $h_i$  and  $h_o$ , are determined using the convection relations discussed in Chapters 8 and 7 for internal and external forced convection flows, respectively.

The overall heat transfer coefficient  $U$  in Eq. 11–5 is dominated by the *smaller* convection coefficient, since the inverse of a large number is small. When one of the convection coefficients is *much smaller* than the other (say,  $h_i \ll h_o$ ), we have  $1/h_i \gg 1/h_o$ , and thus  $U \approx h_i$ . Therefore, the smaller heat transfer coefficient creates a *bottleneck* on the path of heat transfer and seriously impedes heat transfer. This situation arises frequently when one of the fluids is a gas and the other is a liquid. In such cases, fins are commonly used on the gas side to enhance the product  $UA$  and thus the heat transfer on that side.

Representative values of the overall heat transfer coefficient  $U$  are given in Table 11–1. Note that the overall heat transfer coefficient ranges from about 10 W/m<sup>2</sup>·K for gas-to-gas heat exchangers to about 10,000 W/m<sup>2</sup>·K for heat exchangers that involve phase changes. This is not surprising, since gases have very low thermal conductivities, and phase-change processes involve very high heat transfer coefficients.

When the tube is *finned* on one side to enhance heat transfer, the total heat transfer surface area on the finned side becomes

$$A_s = A_{\text{total}} = A_{\text{fin}} + A_{\text{unfinned}} \quad (11-6)$$

**TABLE 11–1**

Representative values of the overall heat transfer coefficients in heat exchangers

| Type of heat exchanger                        | $U$ , W/m <sup>2</sup> ·K* |
|---|----------------------------|
| Water-to-water                                | 850–1700                   |
| Water-to-oil                                  | 100–350                    |

<sup>‡</sup>Based on water- or steam-side surface area.

where  $A_{\text{fin}}$  is the surface area of the fins and  $A_{\text{unfinned}}$  is the area of the unfinned portion of the tube surface. For short fins of high thermal conductivity, we can use this total area in the convection resistance relation  $R_{\text{conv}} = 1/hA_s$  since the fins in this case will be very nearly isothermal. Otherwise, we should determine the effective surface area from

$$A_s = A_{\text{unfinned}} + \eta_{\text{fin}} A_{\text{fin}} \quad (11-7)$$

where  $\eta_{\text{fin}}$  is the fin efficiency which can be obtained from the relationships discussed in Chapter 3. This way, the temperature drop along the fins is accounted for. Note that  $\eta_{\text{fin}} = 1$  for isothermal fins, and thus Eq. 11-7 reduces to Eq. 11-6 in that case. Note that for the finned surface, the relevant area ( $A_i$  or  $A_o$ ) in Eq. 11-4 should be calculated from Eq. 11-7.

## Fouling Factor

The performance of heat exchangers usually deteriorates with time as a result of accumulation of *deposits* on heat transfer surfaces. The layer of deposits represents *additional resistance* to heat transfer and causes the rate of heat transfer in a heat exchanger to decrease. The net effect of these accumulations on heat transfer is represented by a **fouling factor**  $R_f$ , which is a measure of the *thermal resistance* introduced by fouling.

The most common type of fouling is the *precipitation* of solid deposits in a fluid on the heat transfer surfaces. You can observe this type of fouling even in your house. If you check the inner surfaces of your teapot after prolonged use, you will probably notice a layer of calcium-based deposits on the surfaces at which boiling occurs. This is especially the case in areas where the water is hard. The scales of such deposits come off by scratching, and the surfaces can be cleaned of such deposits by chemical treatment. Now imagine those mineral deposits forming on the inner surfaces of fine tubes in a heat exchanger (Fig. 11-10) and the detrimental effect it may have on the flow passage area and the heat transfer. To avoid this potential problem, water in power and process plants is extensively treated and its solid contents are removed before it is allowed to circulate through the system. The solid ash particles in the flue gases accumulating on the surfaces of air preheaters create similar problems.

Another form of fouling, which is common in the chemical process industry, is *corrosion* and other *chemical fouling*. In this case, the surfaces are fouled by the accumulation of the products of chemical reactions on the surfaces. This form of fouling can be avoided by coating metal pipes with glass or using plastic pipes instead of metal ones. Heat exchangers may also be fouled by the growth of algae in warm fluids. This type of fouling is called *biological fouling* and can be prevented by chemical treatment.

In applications where it is likely to occur, fouling should be considered in the design and selection of heat exchangers. In such applications, it may be necessary to select a larger and thus more expensive heat exchanger to ensure that it meets the design heat transfer requirements even after fouling occurs. The periodic cleaning of heat exchangers and the resulting down time are additional penalties associated with fouling.

**FIGURE 11-10**

Precipitation fouling of ash particles on superheater tubes.

*From Steam: Its Generation, and Use, Babcock and Wilcox Co., 1978. Reprinted by permission.*

The fouling factor is obviously zero for a new heat exchanger and increases with time as the solid deposits build up on the heat exchanger surface. The fouling factor depends on the *operating temperature* and the *velocity* of the fluids, as well as the length of service. Fouling increases with *increasing temperature* and *decreasing velocity*.

The overall heat transfer coefficient relation Eq. 11–4 or 11–5, for an unfinned double-pipe heat exchanger is valid for clean surfaces and needs to be modified to account for the effects of fouling on both the inner and the outer surfaces of the tube. For an unfinned double-pipe heat exchanger, it can be expressed as

$$\frac{1}{UA_s} = \frac{1}{U_i A_i} = \frac{1}{U_o A_o} = R = \frac{1}{h_i A_i} + \frac{R_{f,i}}{A_i} + \frac{\ln(D_o/D_i)}{2\pi k L} + \frac{R_{f,o}}{A_o} + \frac{1}{h_o A_o} \quad (11-8)$$

where  $R_{f,i}$  and  $R_{f,o}$  are the fouling factors at those surfaces.

Representative values of fouling factors are given in Table 11–2. More comprehensive tables of fouling factors are available in handbooks. As you would expect, considerable uncertainty exists in these values, and they should be used as a guide in the selection and evaluation of heat exchangers to account for the effects of anticipated fouling on heat transfer. Note that most fouling factors in the table are of the order of  $10^{-4} \text{ m}^2 \cdot \text{K/W}$ , which is equivalent to the thermal resistance of a 0.2-mm-thick limestone layer ( $k = 2.9 \text{ W/m} \cdot \text{K}$ ) per unit surface area. Therefore, in the absence of specific data, we can assume the surfaces to be coated with 0.2 mm of limestone as a starting point to account for the effects of fouling.

### EXAMPLE 11–1 Overall Heat Transfer Coefficient of a Heat Exchanger

Hot oil is to be cooled in a double-tube counter-flow heat exchanger. The copper inner tubes have a diameter of 2 cm and negligible thickness. The inner diameter of the outer tube (the shell) is 3 cm. Water flows through the tube at a rate of 0.5 kg/s, and the oil through the shell at a rate of 0.8 kg/s. Taking the average temperatures of the water and the oil to be 45°C and 80°C, respectively, determine the overall heat transfer coefficient of this heat exchanger.

**SOLUTION** Hot oil is cooled by water in a double-tube counter-flow heat exchanger. The overall heat transfer coefficient is to be determined.

**Assumptions** 1 The thermal resistance of the inner tube is negligible since the tube material is highly conductive and its thickness is negligible. 2 Both the oil and water flow are fully developed. 3 Properties of the oil and water are constant.

**Properties** The properties of water at 45°C are (Table A–9)

$$\rho = 990.1 \text{ kg/m}^3 \quad \text{Pr} = 3.91$$

$$k = 0.637 \text{ W/m} \cdot \text{K} \quad \nu = \mu/\rho = 0.602 \times 10^{-6} \text{ m}^2/\text{s}$$

FIGURE 11-11

Schematic for Example 11-1.

The properties of oil at 80°C are (Table A-13)

$$\rho = 852 \text{ kg/m}^3 \quad \text{Pr} = 499.3$$

$$k = 0.138 \text{ W/m}\cdot\text{K} \quad \nu = 3.794 \times 10^{-5} \text{ m}^2/\text{s}$$

**Analysis** The schematic of the heat exchanger is given in Fig. 11-11. The overall heat transfer coefficient  $U$  can be determined from Eq. 11-5:

$$\frac{1}{U} \approx \frac{1}{h_i} + \frac{1}{h_o}$$

where  $h_i$  and  $h_o$  are the convection heat transfer coefficients inside and outside the tube, respectively, which are to be determined using the forced convection relations.

The hydraulic diameter for a circular tube is the diameter of the tube itself,  $D_h = D = 0.02 \text{ m}$ . The average velocity of water in the tube and the Reynolds number are

$$V = \frac{\dot{m}}{\rho A_c} = \frac{\dot{m}}{\rho (\frac{1}{4}\pi D^2)} = \frac{0.5 \text{ kg/s}}{(990.1 \text{ kg/m}^3)[\frac{1}{4}\pi(0.02 \text{ m})^2]} = 1.61 \text{ m/s}$$

and

$$\text{Re} = \frac{VD}{\nu} = \frac{(1.61 \text{ m/s})(0.02 \text{ m})}{0.602 \times 10^{-6} \text{ m}^2/\text{s}} = 53,490$$

which is greater than 10,000. Therefore, the flow of water is turbulent. Assuming the flow to be fully developed, the Nusselt number can be determined from

$$\text{Nu} = \frac{hD}{k} = 0.023 \text{ Re}^{0.8} \text{ Pr}^{0.4} = 0.023(53,490)^{0.8}(3.91)^{0.4} = 240.6$$

Then,

$$h = \frac{k}{D} \text{ Nu} = \frac{0.637 \text{ W/m}\cdot\text{K}}{0.02 \text{ m}} (240.6) = 7663 \text{ W/m}^2\cdot\text{K}$$

Now we repeat the analysis above for oil. The properties of oil at 80°C are

$$\rho = 852 \text{ kg/m}^3 \quad \nu = 37.5 \times 10^{-6} \text{ m}^2/\text{s}$$

$$k = 0.138 \text{ W/m}\cdot\text{K} \quad \text{Pr} = 490$$

The hydraulic diameter for the annular space is

$$D_h = D_o - D_i = 0.03 - 0.02 = 0.01 \text{ m}$$

The average velocity and the Reynolds number in this case are

$$V = \frac{\dot{m}}{\rho A_c} = \frac{\dot{m}}{\rho [\frac{1}{4}\pi(D_o^2 - D_i^2)]} = \frac{0.8 \text{ kg/s}}{(852 \text{ kg/m}^3)[\frac{1}{4}\pi(0.03^2 - 0.02^2)] \text{ m}^2} = 2.39 \text{ m/s}$$

and

$$\text{Re} = \frac{VD}{\nu} = \frac{(2.39 \text{ m/s})(0.01 \text{ m})}{3.794 \times 10^{-5} \text{ m}^2/\text{s}} = 630$$

which is less than 2300. Therefore, the flow of oil is laminar. Assuming fully developed flow, the Nusselt number on the tube side of the annular space

$Nu_i$  corresponding to  $D/D_o = 0.02/0.03 = 0.667$  can be determined from Table 11–3 by interpolation to be

$$Nu = 5.45$$

and

$$h_o = \frac{k}{D_h} Nu = \frac{0.138 \text{ W/m}\cdot\text{K}}{0.01 \text{ m}} (5.45) = 75.2 \text{ W/m}^2\cdot\text{K}$$

Then the overall heat transfer coefficient for this heat exchanger becomes

$$U = \frac{1}{\frac{1}{h_i} + \frac{1}{h_o}} = \frac{1}{\frac{1}{7663 \text{ W/m}^2\cdot\text{K}} + \frac{1}{75.2 \text{ W/m}^2\cdot\text{K}}} = 74.5 \text{ W/m}^2\cdot\text{K}$$

**Discussion** Note that  $U \approx h_o$  in this case, since  $h_i \gg h_o$ . This confirms our earlier statement that the overall heat transfer coefficient in a heat exchanger is dominated by the smaller heat transfer coefficient when the difference between the two values is large.

To improve the overall heat transfer coefficient and thus the heat transfer in this heat exchanger, we must use some enhancement techniques on the oil side, such as a finned surface.

TABLE 11–3

Nusselt number for fully developed laminar flow in a circular annulus with one surface insulated and the other isothermal (Kays and Perkins, 1972)

| $D_i/D_o$ | $Nu_i$ | $Nu_o$ |

| 0.00      | —      | 3.66   |
| 0.05      | 17.46  | 4.06   |
| 0.10      | 11.56  | 4.11   |
| 0.25      | 7.37   | 4.23   |
| 0.50      | 5.74   | 4.43   |
| 1.00      | 4.86   | 4.86   |

### EXAMPLE 11–2 Effect of Fouling on the Overall Heat Transfer Coefficient

A double-pipe (shell-and-tube) heat exchanger is constructed of a stainless steel ( $k = 15.1 \text{ W/m}\cdot\text{K}$ ) inner tube of inner diameter  $D_i = 1.5 \text{ cm}$  and outer diameter  $D_o = 1.9 \text{ cm}$  and an outer shell of inner diameter  $3.2 \text{ cm}$ . The convection heat transfer coefficient is given to be  $h_i = 800 \text{ W/m}^2\cdot\text{K}$  on the inner surface of the tube and  $h_o = 1200 \text{ W/m}^2\cdot\text{K}$  on the outer surface. For a fouling factor of  $R_{f,i} = 0.0004 \text{ m}^2\cdot\text{K/W}$  on the tube side and  $R_{f,o} = 0.0001 \text{ m}^2\cdot\text{K/W}$  on the shell side, determine (a) the thermal resistance of the heat exchanger per unit length and (b) the overall heat transfer coefficients,  $U_i$  and  $U_o$  based on the inner and outer surface areas of the tube, respectively.

**SOLUTION** The heat transfer coefficients and the fouling factors on the tube and shell sides of a heat exchanger are given. The thermal resistance and the overall heat transfer coefficients based on the inner and outer areas are to be determined.

**Assumptions** The heat transfer coefficients and the fouling factors are constant and uniform.

**Analysis** (a) The schematic of the heat exchanger is given in Fig. 11–12. The thermal resistance for an unfinned shell-and-tube heat exchanger with fouling on both heat transfer surfaces is given by Eq. 11–8 as

$$R = \frac{1}{UA_s} = \frac{1}{U_i A_i} = \frac{1}{U_o A_o} = \frac{1}{h_i A_i} + \frac{R_{f,i}}{A_i} + \frac{\ln(D_o/D_i)}{2\pi k L} + \frac{R_{f,o}}{A_o} + \frac{1}{h_o A_o}$$

FIGURE 11–12  
Schematic for Example 11–2.

where

$$A_i = \pi D_i L = \pi(0.015 \text{ m})(1 \text{ m}) = 0.0471 \text{ m}^2$$

$$A_o = \pi D_o L = \pi(0.019 \text{ m})(1 \text{ m}) = 0.0597 \text{ m}^2$$

Substituting, the total thermal resistance is determined to be

$$\begin{aligned} R &= \frac{1}{(800 \text{ W/m}^2\text{-K})(0.0471 \text{ m}^2)} + \frac{0.0004 \text{ m}^2\text{-K/W}}{0.0471 \text{ m}^2} \\ &\quad + \frac{\ln(0.019/0.015)}{2\pi(15.1 \text{ W/m}\cdot\text{K})(1 \text{ m})} \\ &\quad + \frac{0.0001 \text{ m}^2\text{-K/W}}{0.0597 \text{ m}^2} + \frac{1}{(1200 \text{ W/m}^2\cdot\text{K})(0.0597 \text{ m}^2)} \\ &= (0.02654 + 0.00849 + 0.0025 + 0.00168 + 0.01396)\text{K/W} \\ &= \mathbf{0.0532^\circ\text{C/W}} \end{aligned}$$

Note that about 19 percent of the total thermal resistance in this case is due to fouling and about 5 percent of it is due to the steel tube separating the two fluids. The rest (76 percent) is due to the convection resistances.

(b) Knowing the total thermal resistance and the heat transfer surface areas, the overall heat transfer coefficients based on the inner and outer surfaces of the tube are

$$U_i = \frac{1}{RA_i} = \frac{1}{(0.0532 \text{ K/W})(0.0471 \text{ m}^2)} = \mathbf{399 \text{ W/m}^2\text{-K}}$$

and

$$U_o = \frac{1}{RA_o} = \frac{1}{(0.0532 \text{ K/W})(0.0597 \text{ m}^2)} = \mathbf{315 \text{ W/m}^2\text{-K}}$$

**DISCUSSION** Note that the two overall heat transfer coefficients differ significantly (by 27 percent) in this case because of the considerable difference between the heat transfer surface areas on the inner and the outer sides of the tube. For tubes of negligible thickness, the difference between the two overall heat transfer coefficients would be negligible.

## 11–3 ■ ANALYSIS OF HEAT EXCHANGERS

Heat exchangers are commonly used in practice, and an engineer often finds himself or herself in a position to *select a heat exchanger* that will achieve a *specified temperature change* in a fluid stream of known mass flow rate, or to *predict the outlet temperatures* of the hot and cold fluid streams in a *specified heat exchanger*.

In upcoming sections, we discuss the two methods used in the analysis of heat exchangers. Of these, the *log mean temperature difference* (or LMTD) method is best suited for the first task and the *effectiveness–NTU* (the number of transfer units) method for the second task. But first we present some general considerations.

Heat exchangers usually operate for long periods of time with no change in their operating conditions. Therefore, they can be modeled as *steady-flow* devices. As such, the mass flow rate of each fluid remains constant, and the fluid properties such as temperature and velocity at any inlet or outlet remain the same. Also, the fluid streams experience little or no change in their velocities and elevations, and thus the kinetic and potential energy changes are negligible. The specific heat of a fluid, in general, changes with temperature. But, in a specified temperature range, it can be treated as a constant at some average value with little loss in accuracy. Axial heat conduction along the tube is usually insignificant and can be considered negligible. Finally, the outer surface of the heat exchanger is assumed to be *perfectly insulated*, so that there is no heat loss to the surrounding medium, and any heat transfer occurs between the two fluids only.

The idealizations stated above are closely approximated in practice, and they greatly simplify the analysis of a heat exchanger with little sacrifice from accuracy. Therefore, they are commonly used. Under these assumptions, the *first law of thermodynamics* requires that the rate of heat transfer from the hot fluid be equal to the rate of heat transfer to the cold one. That is,

$$\dot{Q} = \dot{m}_c c_{pc} (T_{c,\text{out}} - T_{c,\text{in}}) \quad (11-9)$$

and

$$\dot{Q} = \dot{m}_h c_{ph} (T_{h,\text{in}} - T_{h,\text{out}}) \quad (11-10)$$

where the subscripts *c* and *h* stand for *cold* and *hot* fluids, respectively, and

$\dot{m}_c, \dot{m}_h$  = mass flow rates

$c_{pc}, c_{ph}$  = specific heats

$T_{c,\text{out}}, T_{h,\text{out}}$  = outlet temperatures

$T_{c,\text{in}}, T_{h,\text{in}}$  = inlet temperatures

Note that the heat transfer rate  $\dot{Q}$  is taken to be a positive quantity, and its direction is understood to be from the hot fluid to the cold one in accordance with the second law of thermodynamics.

In heat exchanger analysis, it is often convenient to combine the product of the mass flow rate and the specific heat of a fluid into a single quantity. This quantity is called the **heat capacity rate** and is defined for the hot and cold fluid streams as

$$C_h = \dot{m}_h c_{ph} \text{ and } C_c = \dot{m}_c c_{pc} \quad (11-11)$$

The heat capacity rate of a fluid stream represents the rate of heat transfer needed to change the temperature of the fluid stream by  $1^\circ\text{C}$  as it flows through a heat exchanger. Note that in a heat exchanger, the fluid with a *large* heat capacity rate experiences a *small* temperature change, and the fluid with a *small* heat capacity rate experiences a *large* temperature change. Therefore, *doubling* the mass flow rate of a fluid while leaving everything else unchanged will *halve* the temperature change of that fluid.

With the definition of the heat capacity rate above, Eqs. 11–9 and 11–10 can also be expressed as

$$\dot{Q} = C_c (T_{c,\text{out}} - T_{c,\text{in}}) \quad (11-12)$$

FIGURE 11-13

Two fluid streams that have the same capacity rates experience the same temperature change in a well-insulated heat exchanger.

(a) Condenser ( $C_h \rightarrow \infty$ )(b) Boiler ( $C_c \rightarrow \infty$ )

FIGURE 11-14

Variation of fluid temperatures in a heat exchanger when one of the fluids condenses or boils.

and

$$\dot{Q} = C_h(T_{h, \text{in}} - T_{h, \text{out}}) \quad (11-13)$$

That is, the heat transfer rate in a heat exchanger is equal to the heat capacity rate of either fluid multiplied by the temperature change of that fluid. Note that *the only time the temperature rise of a cold fluid is equal to the temperature drop of the hot fluid is when the heat capacity rates of the two fluids are equal to each other* (Fig. 11-13).

Two special types of heat exchangers commonly used in practice are *condensers* and *boilers*. One of the fluids in a condenser or a boiler undergoes a phase-change process, and the rate of heat transfer is expressed as

$$\dot{Q} = \dot{m}h_{fg} \quad (11-14)$$

where  $\dot{m}$  is the rate of evaporation or condensation of the fluid and  $h_{fg}$  is the enthalpy of vaporization of the fluid at the specified temperature or pressure.

An ordinary fluid absorbs or releases a large amount of heat essentially at constant temperature during a phase-change process, as shown in Fig. 11-14. The heat capacity rate of a fluid during a phase-change process must approach infinity since the temperature change is practically zero. That is,  $C = \dot{m}c_p \rightarrow \infty$  when  $\Delta T \rightarrow 0$ , so that the heat transfer rate  $\dot{Q} = \dot{m}c_p \Delta T$  is a finite quantity. Therefore, in heat exchanger analysis, a condensing or boiling fluid is conveniently modeled as a fluid whose heat capacity rate is *infinity*.

The rate of heat transfer in a heat exchanger can also be expressed in an analogous manner to Newton's law of cooling as

$$\dot{Q} = UA_s \Delta T_m \quad (11-15)$$

where  $U$  is the overall heat transfer coefficient,  $A_s$  is the heat transfer surface area, and  $\Delta T_m$  is an appropriate mean temperature difference between the two fluids. Here the surface area  $A_s$  can be determined precisely using the dimensions of the heat exchanger. However, the overall heat transfer coefficient  $U$  and the temperature difference  $\Delta T$  between the hot and cold fluids, in general, may vary along the heat exchanger.

The average value of the overall heat transfer coefficient can be determined as described in the preceding section by using the average convection coefficients for each fluid. It turns out that the appropriate form of the average temperature difference between the two fluids is *logarithmic* in nature, and its determination is presented in Section 11-4. It should be noted that the average temperature difference  $\Delta T_m$  is dependent on the heat exchanger flow arrangement and its type of construction.

## 11-4 • THE LOG MEAN TEMPERATURE DIFFERENCE METHOD

Earlier, we mentioned that the temperature difference between the hot and cold fluids varies along the heat exchanger, and it is convenient to have a *mean temperature difference*  $\Delta T_m$  for use in the relation  $\dot{Q} = UA_s \Delta T_m$ .

In order to develop a relation for the equivalent average temperature difference between the two fluids, consider the *parallel-flow double-pipe* heat exchanger

shown in Fig. 11–15. Note that the temperature difference  $\Delta T$  between the hot and cold fluids is large at the inlet of the heat exchanger but decreases exponentially toward the outlet. As you would expect, the temperature of the hot fluid decreases and the temperature of the cold fluid increases along the heat exchanger, but the temperature of the cold fluid can never exceed that of the hot fluid no matter how long the heat exchanger is.

Assuming the outer surface of the heat exchanger to be well insulated so that any heat transfer occurs between the two fluids, and disregarding any changes in kinetic and potential energy, an energy balance on each fluid in a differential section of the heat exchanger can be expressed as

$$\delta \dot{Q} = -\dot{m}_h c_{ph} dT_h \quad (11-16)$$

and

$$\delta \dot{Q} = \dot{m}_c c_{pc} dT_c \quad (11-17)$$

That is, the rate of heat loss from the hot fluid at any section of a heat exchanger is equal to the rate of heat gain by the cold fluid in that section. The temperature change of the hot fluid is a *negative* quantity, and so a *negative sign* is added to Eq. 11–16 to make the heat transfer rate  $\dot{Q}$  a positive quantity. Solving the equations above for  $dT_h$  and  $dT_c$  gives

$$dT_h = -\frac{\delta \dot{Q}}{\dot{m}_h c_{ph}} \quad (11-18)$$

and

$$dT_c = \frac{\delta \dot{Q}}{\dot{m}_c c_{pc}} \quad (11-19)$$

Taking their difference, we get

$$dT_h - dT_c = d(T_h - T_c) = -\delta \dot{Q} \left( \frac{1}{\dot{m}_h c_{ph}} + \frac{1}{\dot{m}_c c_{pc}} \right) \quad (11-20)$$

The rate of heat transfer in the differential section of the heat exchanger can also be expressed as

$$\delta \dot{Q} = U(T_h - T_c) dA_s \quad (11-21)$$

Substituting this equation into Eq. 11–20 and rearranging give

$$\frac{d(T_h - T_c)}{T_h - T_c} = -U dA_s \left( \frac{1}{\dot{m}_h c_{ph}} + \frac{1}{\dot{m}_c c_{pc}} \right) \quad (11-22)$$

Integrating from the inlet of the heat exchanger to its outlet, we obtain

$$\ln \frac{T_{h,out} - T_{c,out}}{T_{h,in} - T_{c,in}} = -UA_s \left( \frac{1}{\dot{m}_h c_{ph}} + \frac{1}{\dot{m}_c c_{pc}} \right) \quad (11-23)$$

Finally, solving Eqs. 11–9 and 11–10 for  $\dot{m}_c c_{pc}$  and  $\dot{m}_h c_{ph}$  and substituting into Eq. 11–23 give, after some rearrangement,

$$\dot{Q} = UA_s \Delta T_{lm} \quad (11-24)$$

**FIGURE 11-15**

Variation of the fluid temperatures in a parallel-flow double-pipe heat exchanger.

(a) Parallel-flow heat exchangers

(b) Counter-flow heat exchangers

**FIGURE 11-16**

The  $\Delta T_1$  and  $\Delta T_2$  expressions in parallel-flow and counter-flow heat exchangers.

where

$$\Delta T_{lm} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)} \quad (11-25)$$

is the **log mean temperature difference**, which is the suitable form of the average temperature difference for use in the analysis of heat exchangers. Here  $\Delta T_1$  and  $\Delta T_2$  represent the temperature difference between the two fluids at the two ends (inlet and outlet) of the heat exchanger. It makes no difference which end of the heat exchanger is designated as the inlet or the outlet (Fig. 11-16). It should be noted that Eqs. 11-24 and 11-25 are good for any heat exchanger provided that the end point temperature differences are defined properly. For multipass and cross-flow heat exchangers, as will be shown later, the log mean temperature difference should be corrected through a correction factor.

The temperature difference between the two fluids decreases from  $\Delta T_1$  at the inlet to  $\Delta T_2$  at the outlet. Thus, it is tempting to use the arithmetic mean temperature  $\Delta T_{am} = \frac{1}{2}(\Delta T_1 + \Delta T_2)$  as the average temperature difference. The logarithmic mean temperature difference  $\Delta T_{lm}$  is obtained by tracing the actual temperature profile of the fluids along the heat exchanger and is an *exact* representation of the *average temperature difference* between the hot and cold fluids. It truly reflects the exponential decay of the local temperature difference.

Note that  $\Delta T_{lm}$  is always less than  $\Delta T_{am}$ . Therefore, using  $\Delta T_{am}$  in calculations instead of  $\Delta T_{lm}$  will overestimate the rate of heat transfer in a heat exchanger between the two fluids. When  $\Delta T_1$  differs from  $\Delta T_2$  by no more than 40 percent, the error in using the arithmetic mean temperature difference is less than 1 percent. But the error increases to undesirable levels when  $\Delta T_1$  differs from  $\Delta T_2$  by greater amounts. Therefore, we should always use the *logarithmic mean temperature difference* when determining the rate of heat transfer in a heat exchanger.

## Counter-Flow Heat Exchangers

The variation of temperatures of hot and cold fluids in a counter-flow heat exchanger is given in Fig. 11-17. Note that the hot and cold fluids enter the heat exchanger from opposite ends, and the outlet temperature of the *cold fluid* in this case may exceed the outlet temperature of the *hot fluid*. In the limiting case, the cold fluid will be heated to the inlet temperature of the hot fluid. However, the outlet temperature of the cold fluid can *never* exceed the inlet temperature of the hot fluid, since this would be a violation of the second law of thermodynamics.

The relation already given for the log mean temperature difference is developed using a parallel-flow heat exchanger, but we can show by repeating the analysis for a counter-flow heat exchanger that is also applicable to counter-flow heat exchangers. But this time,  $\Delta T_1$  and  $\Delta T_2$  are expressed as shown in Fig. 11-16.

For specified inlet and outlet temperatures, the log mean temperature difference for a counter-flow heat exchanger is always greater than that for a parallel-flow heat exchanger. That is,  $\Delta T_{lm, CF} > \Delta T_{lm, PF}$ , and thus a smaller surface area (and thus a smaller heat exchanger) is needed to achieve

a specified heat transfer rate in a counter-flow heat exchanger, assuming the same value of the overall heat transfer coefficient. Therefore, it is common practice to use counter-flow arrangements in heat exchangers.

In a counter-flow heat exchanger, the temperature difference between the hot and the cold fluids remains constant along the heat exchanger when the *heat capacity rates* of the two fluids are *equal* (that is,  $\Delta T = \text{constant}$  when  $C_h = C_c$  or  $\dot{m}_h c_{ph} = \dot{m}_c c_{pc}$ ). Then we have  $\Delta T_1 = \Delta T_2$ , and the log mean temperature difference relation gives  $\Delta T_{lm} = \frac{0}{0}$ , which is indeterminate. It can be shown by the application of l'Hôpital's rule that in this case we have  $\Delta T_{lm} = \Delta T_1 = \Delta T_2$ , as expected.

A *condenser* or a *boiler* can be considered to be either a parallel- or counter-flow heat exchanger since both approaches give the same result.

## Multipass and Cross-Flow Heat Exchangers: Use of a Correction Factor

The log mean temperature difference  $\Delta T_{lm}$  relation developed earlier is limited to parallel-flow and counter-flow heat exchangers only. Similar relations are also developed for *cross-flow* and *multipass shell-and-tube* heat exchangers, but the resulting expressions are too complicated because of the complex flow conditions.

In such cases, it is convenient to relate the equivalent temperature difference to the log mean temperature difference relation for the counter-flow case as

$$\Delta T_{lm} = F \Delta T_{lm, CF} \quad (11-26)$$

where  $F$  is the **correction factor**, which depends on the *geometry* of the heat exchanger and the inlet and outlet temperatures of the hot and cold fluid streams. The  $\Delta T_{lm, CF}$  is the log mean temperature difference for the case of a *counter-flow* heat exchanger with the same inlet and outlet temperatures and is determined from Eq. 11-25 by taking  $\Delta T_1 = T_{h,in} - T_{c,out}$  and  $\Delta T_2 = T_{h,out} - T_{c,in}$  (Fig. 11-18).

The correction factor is less than unity for a cross-flow and multipass shell-and-tube heat exchanger. That is,  $F \leq 1$ . The limiting value of  $F = 1$  corresponds to the counter-flow heat exchanger. Thus, the correction factor  $F$  for a heat exchanger is a measure of deviation of the  $\Delta T_{lm}$  from the corresponding values for the counter-flow case.

The correction factor  $F$  for common cross-flow and shell-and-tube heat exchanger configurations is given in Fig. 11-19 versus two temperature ratios  $P$  and  $R$  defined as

$$P = \frac{t_2 - t_1}{T_1 - t_1} \quad (11-27)$$

and

$$R = \frac{T_1 - T_2}{t_2 - t_1} = \frac{(\dot{m}c_p)_{\text{tube side}}}{(\dot{m}c_p)_{\text{shell side}}} \quad (11-28)$$

where the subscripts 1 and 2 represent the *inlet* and *outlet*, respectively. Note that for a shell-and-tube heat exchanger,  $T$  and  $t$  represent the *shell-* and *tube-side* temperatures, respectively, as shown in the correction factor charts.

**FIGURE 11-17**

The variation of the fluid temperatures in a counter-flow double-pipe heat exchanger.

Heat transfer rate:

$$\dot{Q} = UA_s F \Delta T_{lm, CF}$$

$$\text{where } \Delta T_{lm, CF} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1 / \Delta T_2)}$$

$$\Delta T_1 = T_{h,in} - T_{c,out}$$

$$\Delta T_2 = T_{h,out} - T_{c,in}$$

and

$$F = \dots \text{ (Fig. 11-19)}$$

**FIGURE 11-18**

The determination of the heat transfer rate for cross-flow and multipass shell-and-tube heat exchangers using the correction factor.

**FIGURE 11-19**

Correction factor  $F$  charts for common shell-and-tube and cross-flow heat exchangers.

From Bowman, Mueller, and Nagle, 1940.

It makes no difference whether the hot or the cold fluid flows through the shell or the tube. The determination of the correction factor  $F$  requires the availability of the inlet and the outlet temperatures for both the cold and hot fluids.

Note that the value of  $P$  ranges from 0 to 1. The value of  $R$ , on the other hand, ranges from 0 to infinity, with  $R = 0$  corresponding to the phase-change (condensation or boiling) on the shell-side and  $R \rightarrow \infty$  to phase-change on the tube side. The correction factor is  $F = 1$  for both of these limiting cases. Therefore, the correction factor for a condenser or boiler is  $F = 1$ , regardless of the configuration of the heat exchanger.

### EXAMPLE 11–3 The Condensation of Steam in a Condenser

Steam in the condenser of a power plant is to be condensed at a temperature of  $30^\circ\text{C}$  with cooling water from a nearby lake, which enters the tubes of the condenser at  $14^\circ\text{C}$  and leaves at  $22^\circ\text{C}$ . The surface area of the tubes is  $45 \text{ m}^2$ , and the overall heat transfer coefficient is  $2100 \text{ W/m}^2\cdot\text{K}$ . Determine the mass flow rate of the cooling water needed and the rate of condensation of the steam in the condenser.

**SOLUTION** Steam is condensed by cooling water in the condenser of a power plant. The mass flow rate of the cooling water and the rate of condensation are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The heat exchanger is well insulated so that heat loss to the surroundings is negligible. 3 Changes in the kinetic and potential energies of fluid streams are negligible. 4 There is no fouling. 5 Fluid properties are constant.

**Properties** The heat of vaporization of water at  $30^\circ\text{C}$  is  $h_{fg} = 2431 \text{ kJ/kg}$  and the specific heat of cold water at the average temperature of  $18^\circ\text{C}$  is  $c_p = 4184 \text{ J/kg}\cdot\text{K}$  (Table A–9).

**Analysis** The schematic of the condenser is given in Fig. 11–20. The condenser can be treated as a counter-flow heat exchanger since the temperature of one of the fluids (the steam) remains constant.

The temperature difference between the steam and the cooling water at the two ends of the condenser is

$$\Delta T_1 = T_{h,\text{in}} - T_{c,\text{out}} = (30 - 22)^\circ\text{C} = 8^\circ\text{C}$$

$$\Delta T_2 = T_{h,\text{out}} - T_{c,\text{in}} = (30 - 14)^\circ\text{C} = 16^\circ\text{C}$$

That is, the temperature difference between the two fluids varies from  $8^\circ\text{C}$  at one end to  $16^\circ\text{C}$  at the other. The proper average temperature difference between the two fluids is the *log mean temperature difference* (not the arithmetic), which is determined from

$$\Delta T_{\text{lm}} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)} = \frac{8 - 16}{\ln(8/16)} = 11.5^\circ\text{C}$$

This is a little less than the arithmetic mean temperature difference of  $\frac{1}{2}(8 + 16) = 12^\circ\text{C}$ . Then the heat transfer rate in the condenser is determined from

$$\dot{Q} = UA_s \Delta T_{\text{lm}} = (2100 \text{ W/m}^2\cdot\text{K})(45 \text{ m}^2)(11.5^\circ\text{C}) = 1.087 \times 10^6 \text{ W} = 1087 \text{ kW}$$

**FIGURE 11–20**  
Schematic for Example 11–3.

Therefore, steam will lose heat at a rate of 1087 kW as it flows through the condenser, and the cooling water will gain practically all of it, since the condenser is well insulated.

The mass flow rate of the cooling water and the rate of the condensation of the steam are determined from  $\dot{Q} = [\dot{m}c_p(T_{\text{out}} - T_{\text{in}})]_{\text{cooling water}} = (\dot{m}h_{fg})_{\text{steam}}$  to be

$$\dot{m}_{\text{cooling water}} = \frac{\dot{Q}}{c_p(T_{\text{out}} - T_{\text{in}})} = \frac{1087 \text{ kJ/s}}{(4.184 \text{ kJ/kg}\cdot\text{K})(22 - 14)^\circ\text{C}} = 32.5 \text{ kg/s}$$

and

$$\dot{m}_{\text{steam}} = \frac{\dot{Q}}{h_{fg}} = \frac{1087 \text{ kJ/s}}{2431 \text{ kJ/kg}} = 0.45 \text{ kg/s}$$

Therefore, we need to circulate about 72 kg of cooling water for each 1 kg of steam condensing to remove the heat released during the condensation process.

#### EXAMPLE 11–4 Heating Water in a Counter-Flow Heat Exchanger

A counter-flow double-pipe heat exchanger is to heat water from 20°C to 80°C at a rate of 1.2 kg/s. The heating is to be accomplished by geothermal water available at 160°C at a mass flow rate of 2 kg/s. The inner tube is thin-walled and has a diameter of 1.5 cm. If the overall heat transfer coefficient of the heat exchanger is 640 W/m<sup>2</sup>·K, determine the length of the heat exchanger required to achieve the desired heating.

**SOLUTION** Water is heated in a counter-flow double-pipe heat exchanger by geothermal water. The required length of the heat exchanger is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The heat exchanger is well insulated so that heat loss to the surroundings is negligible. 3 Changes in the kinetic and potential energies of fluid streams are negligible. 4 There is no fouling. 5 Fluid properties are constant.

**Properties** We take the specific heats of water and geothermal fluid to be 4.18 and 4.31 kJ/kg·K, respectively.

**Analysis** The schematic of the heat exchanger is given in Fig. 11–21. The rate of heat transfer in the heat exchanger can be determined from

$$\dot{Q} = [\dot{m}c_p(T_{\text{out}} - T_{\text{in}})]_{\text{water}} = (1.2 \text{ kg/s})(4.18 \text{ kJ/kg}\cdot\text{K})(80 - 20)^\circ\text{C} = 301 \text{ kW}$$

Noting that all of this heat is supplied by the geothermal water, the outlet temperature of the geothermal water is determined to be

$$\begin{aligned} \dot{Q} &= [\dot{m}c_p(T_{\text{in}} - T_{\text{out}})]_{\text{geothermal}} \longrightarrow T_{\text{out}} = T_{\text{in}} - \frac{\dot{Q}}{\dot{m}c_p} \\ &= 160^\circ\text{C} - \frac{301 \text{ kW}}{(2 \text{ kg/s})(4.31 \text{ kJ/kg}\cdot\text{K})} \\ &= 125^\circ\text{C} \end{aligned}$$

FIGURE 11–21

Schematic for Example 11–4.

Knowing the inlet and outlet temperatures of both fluids, the logarithmic mean temperature difference for this counter-flow heat exchanger becomes

$$\Delta T_1 = T_{h,\text{in}} - T_{c,\text{out}} = (160 - 80)^\circ\text{C} = 80^\circ\text{C}$$

$$\Delta T_2 = T_{h,\text{out}} - T_{c,\text{in}} = (125 - 20)^\circ\text{C} = 105^\circ\text{C}$$

and

$$\Delta T_{\text{lm}} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)} = \frac{80 - 105}{\ln(80/105)} = 91.9^\circ\text{C}$$

Then the surface area of the heat exchanger is determined to be

$$\dot{Q} = UA_s \Delta T_{\text{lm}} \longrightarrow A_s = \frac{\dot{Q}}{U \Delta T_{\text{lm}}} = \frac{301,000 \text{ W}}{(640 \text{ W/m}^2 \cdot \text{K})(91.9^\circ\text{C})} = 5.12 \text{ m}^2$$

To provide this much heat transfer surface area, the length of the tube must be

$$A_s = \pi D L \longrightarrow L = \frac{A_s}{\pi D} = \frac{5.12 \text{ m}^2}{\pi(0.015 \text{ m})} = 109 \text{ m}$$

**Discussion** The inner tube of this counter-flow heat exchanger (and thus the heat exchanger itself) needs to be over 100 m long to achieve the desired heat transfer, which is impractical. In cases like this, we need to use a plate heat exchanger or a multipass shell-and-tube heat exchanger with multiple passes of tube bundles.

### EXAMPLE 11–5 Heating of Glycerin in a Multipass Heat Exchanger

A 2-shell passes and 4-tube passes heat exchanger is used to heat glycerin from 20°C to 50°C by hot water, which enters the thin-walled 2-cm-diameter tubes at 80°C and leaves at 40°C (Fig. 11–22). The total length of the tubes in the heat exchanger is 60 m. The convection heat transfer coefficient is 25 W/m<sup>2</sup>·K on the glycerin (shell) side and 160 W/m<sup>2</sup>·K on the water (tube) side. Determine the rate of heat transfer in the heat exchanger (a) before any fouling and (b) after fouling with a fouling factor of 0.0006 m<sup>2</sup>·K/W occurs on the outer surfaces of the tubes.

**SOLUTION** Glycerin is heated in a 2-shell passes and 4-tube passes heat exchanger by hot water. The rate of heat transfer for the cases of fouling and no fouling are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The heat exchanger is well insulated so that heat loss to the surroundings is negligible. 3 Changes in the kinetic and potential energies of fluid streams are negligible. 4 Heat transfer coefficients and fouling factors are constant and uniform. 5 The thermal resistance of the inner tube is negligible since the tube is thin-walled and highly conductive.

**FIGURE 11–22**  
Schematic for Example 11–5.

**Analysis** The tubes are said to be thin-walled, and thus it is reasonable to assume the inner and outer surface areas of the tubes to be equal. Then the heat transfer surface area becomes

$$A_s = \pi DL = \pi(0.02 \text{ m})(60 \text{ m}) = 3.77 \text{ m}^2$$

The rate of heat transfer in this heat exchanger can be determined from

$$\dot{Q} = UA_s F \Delta T_{\text{lm, CF}}$$

where  $F$  is the correction factor and  $\Delta T_{\text{lm, CF}}$  is the log mean temperature difference for the counter-flow arrangement. These two quantities are determined from

$$\Delta T_1 = T_{h, \text{in}} - T_{c, \text{out}} = (80 - 50)^\circ\text{C} = 30^\circ\text{C}$$

$$\Delta T_2 = T_{h, \text{out}} - T_{c, \text{in}} = (40 - 20)^\circ\text{C} = 20^\circ\text{C}$$

$$\Delta T_{\text{lm, CF}} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)} = \frac{30 - 20}{\ln(30/20)} = 24.7^\circ\text{C}$$

and

$$\left. \begin{aligned} P &= \frac{t_2 - t_1}{T_1 - t_1} = \frac{40 - 80}{20 - 80} = 0.67 \\ R &= \frac{T_1 - T_2}{t_2 - t_1} = \frac{20 - 50}{40 - 80} = 0.75 \end{aligned} \right\} F = 0.91 \quad (\text{Fig. 11-19b})$$

(a) In the case of no fouling, the overall heat transfer coefficient  $U$  is

$$U = \frac{1}{\frac{1}{h_i} + \frac{1}{h_o}} = \frac{1}{\frac{1}{160 \text{ W/m}^2\cdot\text{K}} + \frac{1}{25 \text{ W/m}^2\cdot\text{K}}} = 21.6 \text{ W/m}^2\cdot\text{K}$$

Then the rate of heat transfer becomes

$$\dot{Q} = UA_s F \Delta T_{\text{lm, CF}} = (21.6 \text{ W/m}^2\cdot\text{K})(3.77 \text{ m}^2)(0.91)(24.7^\circ\text{C}) = 1830 \text{ W}$$

(b) When there is fouling on one of the surfaces, we have

$$\begin{aligned} U &= \frac{1}{\frac{1}{h_i} + \frac{1}{h_o} + R_f} = \frac{1}{\frac{1}{160 \text{ W/m}^2\cdot\text{K}} + \frac{1}{25 \text{ W/m}^2\cdot\text{K}} + 0.0006 \text{ m}^2\cdot\text{K/W}} \\ &= 21.3 \text{ W/m}^2\cdot\text{K} \end{aligned}$$

and

$$\dot{Q} = UA_s F \Delta T_{\text{lm, CF}} = (21.3 \text{ W/m}^2\cdot\text{K})(3.77 \text{ m}^2)(0.91)(24.7^\circ\text{C}) = 1805 \text{ W}$$

**Discussion** Note that the rate of heat transfer decreases as a result of fouling, as expected. The decrease is not dramatic, however, because of the relatively low convection heat transfer coefficients involved.

**EXAMPLE 11–6 Cooling of Water in an Automotive Radiator**

A test is conducted to determine the overall heat transfer coefficient in an automotive radiator that is a compact cross-flow water-to-air heat exchanger with both fluids (air and water) unmixed (Fig. 11–23). The radiator has 40 tubes of internal diameter 0.5 cm and length 65 cm in a closely spaced plate-finned matrix. Hot water enters the tubes at 90°C at a rate of 0.6 kg/s and leaves at 65°C. Air flows across the radiator through the interfin spaces and is heated from 20°C to 40°C. Determine the overall heat transfer coefficient  $U_i$  of this radiator based on the inner surface area of the tubes.

**SOLUTION** During an experiment involving an automotive radiator, the inlet and exit temperatures of water and air and the mass flow rate of water are measured. The overall heat transfer coefficient based on the inner surface area is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Changes in the kinetic and potential energies of fluid streams are negligible. 3 Fluid properties are constant.

**Properties** The specific heat of water at the average temperature of  $(90 + 65)/2 = 77.5^\circ\text{C}$  is 4.195 kJ/kg·K (Table A–9).

**Analysis** The rate of heat transfer in this radiator from the hot water to the air is determined from an energy balance on water flow,

$$\begin{aligned}\dot{Q} &= [\dot{m}c_p(T_{\text{in}} - T_{\text{out}})]_{\text{water}} = (0.6 \text{ kg/s})(4.195 \text{ kJ/kg}\cdot\text{K})(90 - 65)^\circ\text{C} \\ &= 62.93 \text{ kW}\end{aligned}$$

The tube-side heat transfer area is the total surface area of the tubes, and is determined from

$$A_i = n\pi D_i L = (40)\pi(0.005 \text{ m})(0.65 \text{ m}) = 0.408 \text{ m}^2$$

Knowing the rate of heat transfer and the surface area, the overall heat transfer coefficient can be determined from

$$\dot{Q} = U_i A_i F \Delta T_{\text{lm, CF}} \longrightarrow U_i = \frac{\dot{Q}}{A_i F \Delta T_{\text{lm, CF}}}$$

where  $F$  is the correction factor and  $\Delta T_{\text{lm, CF}}$  is the log mean temperature difference for the counter-flow arrangement. These two quantities are found to be

$$\Delta T_1 = T_{h, \text{in}} - T_{c, \text{out}} = (90 - 40)^\circ\text{C} = 50^\circ\text{C}$$

$$\Delta T_2 = T_{h, \text{out}} - T_{c, \text{in}} = (65 - 20)^\circ\text{C} = 45^\circ\text{C}$$

$$\Delta T_{\text{lm, CF}} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)} = \frac{50 - 45}{\ln(50/45)} = 47.5^\circ\text{C}$$

and

$$\left. \begin{aligned} P &= \frac{t_2 - t_1}{T_1 - t_1} = \frac{65 - 90}{20 - 90} = 0.36 \\ R &= \frac{T_1 - T_2}{t_2 - t_1} = \frac{20 - 40}{65 - 90} = 0.80 \end{aligned} \right\} F = 0.97 \quad (\text{Fig. 11-19c})$$

**FIGURE 11–23**

Schematic for Example 11–6.

Substituting, the overall heat transfer coefficient  $U_i$  is determined to be

$$U_i = \frac{\dot{Q}}{A_i F \Delta T_{lm, CF}} = \frac{62,930 \text{ W}}{(0.408 \text{ m}^2)(0.97)(47.5^\circ\text{C})} = 3347 \text{ W/m}^2 \cdot \text{K}$$

**Discussion** Note that the overall heat transfer coefficient on the air side will be much lower because of the large surface area involved on that side.

## 11–5 • THE EFFECTIVENESS–NTU METHOD

The log mean temperature difference (LMTD) method discussed in Section 11–4 is easy to use in heat exchanger analysis when the inlet and the outlet temperatures of the hot and cold fluids are known or can be determined from an energy balance. Once  $\Delta T_{lm}$ , the mass flow rates, and the overall heat transfer coefficient are available, the heat transfer surface area of the heat exchanger can be determined from

$$\dot{Q} = UA_s \Delta T_{lm}$$

Therefore, the LMTD method is very suitable for determining the *size* of a heat exchanger to realize prescribed outlet temperatures when the mass flow rates and the inlet and outlet temperatures of the hot and cold fluids are specified.

With the LMTD method, the task is to *select* a heat exchanger that will meet the prescribed heat transfer requirements. The procedure to be followed by the selection process is:

1. Select the type of heat exchanger suitable for the application.
2. Determine any unknown inlet or outlet temperature and the heat transfer rate using an energy balance.
3. Calculate the log mean temperature difference  $\Delta T_{lm}$  and the correction factor  $F$ , if necessary.
4. Obtain (select or calculate) the value of the overall heat transfer coefficient  $U$ .
5. Calculate the heat transfer surface area  $A_s$ .

The task is completed by selecting a heat exchanger that has a heat transfer surface area equal to or larger than  $A_s$ .

A second kind of problem encountered in heat exchanger analysis is the determination of the *heat transfer rate* and the *outlet temperatures* of the hot and cold fluids for prescribed fluid mass flow rates and inlet temperatures when the *type* and *size* of the heat exchanger are specified. The heat transfer surface area of the heat exchanger in this case is known, but the *outlet temperatures* are not. Here the task is to determine the heat transfer performance of a specified heat exchanger or to determine if a heat exchanger available in storage will do the job.

The LMTD method could still be used for this alternative problem, but the procedure would require tedious iterations, and thus it is not practical. In an attempt to eliminate the iterations from the solution of such problems,

Kays and London came up with a method in 1955 called the **effectiveness-NTU method**, which greatly simplified heat exchanger analysis.

This method is based on a dimensionless parameter called the **heat transfer effectiveness**  $\varepsilon$ , defined as

$$\varepsilon = \frac{\dot{Q}}{\dot{Q}_{\max}} = \frac{\text{Actual heat transfer rate}}{\text{Maximum possible heat transfer rate}} \quad (11-29)$$

The *actual* heat transfer rate in a heat exchanger can be determined from an energy balance on the hot or cold fluids and can be expressed as

$$\dot{Q} = C_c(T_{c,\text{out}} - T_{c,\text{in}}) = C_h(T_{h,\text{in}} - T_{h,\text{out}}) \quad (11-30)$$

where  $C_c = \dot{m}_c c_{pc}$  and  $C_h = \dot{m}_h c_{ph}$  are the heat capacity rates of the cold and hot fluids, respectively.

To determine the maximum possible heat transfer rate in a heat exchanger, we first recognize that the *maximum temperature difference* in a heat exchanger is the difference between the *inlet* temperatures of the hot and cold fluids. That is,

$$\Delta T_{\max} = T_{h,\text{in}} - T_{c,\text{in}} \quad (11-31)$$

The heat transfer in a heat exchanger will reach its maximum value when (1) the cold fluid is heated to the inlet temperature of the hot fluid or (2) the hot fluid is cooled to the inlet temperature of the cold fluid. These two limiting conditions will not be reached simultaneously unless the heat capacity rates of the hot and cold fluids are identical (i.e.,  $C_c = C_h$ ). When  $C_c \neq C_h$ , which is usually the case, the fluid with the *smaller* heat capacity rate will experience a larger temperature change, and thus it will be the first to experience the maximum temperature, at which point the heat transfer will come to a halt. Therefore, the maximum possible heat transfer rate in a heat exchanger is (Fig. 11-24)

$$\dot{Q}_{\max} = C_{\min}(T_{h,\text{in}} - T_{c,\text{in}}) \quad (11-32)$$

where  $C_{\min}$  is the smaller of  $C_h$  and  $C_c$ . This is further clarified by Example 11-7.

**FIGURE 11-24**

The determination of the maximum rate of heat transfer in a heat exchanger.

### EXAMPLE 11-7 Upper Limit for Heat Transfer in a Heat Exchanger

Cold water enters a counter-flow heat exchanger at 10°C at a rate of 8 kg/s, where it is heated by a hot-water stream that enters the heat exchanger at 70°C at a rate of 2 kg/s. Assuming the specific heat of water to remain constant at  $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ , determine the maximum heat transfer rate and the outlet temperatures of the cold- and the hot-water streams for this limiting case.

**SOLUTION** Cold- and hot-water streams enter a heat exchanger at specified temperatures and flow rates. The maximum rate of heat transfer in the heat exchanger and the outlet temperatures are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The heat exchanger is well insulated so that heat loss to the surroundings is negligible. 3 Changes

FIGURE 11–25

Schematic for Example 11–7.

in the kinetic and potential energies of fluid streams are negligible. **4** Fluid properties are constant.

**Properties** The specific heat of water is given to be  $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ .

**Analysis** A schematic of the heat exchanger is given in Fig. 11–25. The heat capacity rates of the hot and cold fluids are

$$C_h = \dot{m}_h c_{ph} = (2 \text{ kg/s})(4.18 \text{ kJ/kg}\cdot\text{K}) = 8.36 \text{ kW/K}$$

and

$$C_c = \dot{m}_c c_{pc} = (8 \text{ kg/s})(4.18 \text{ kJ/kg}\cdot\text{K}) = 33.4 \text{ kW/K}$$

Therefore,

$$C_{\min} = C_h = 8.36 \text{ kW/K}$$

which is the smaller of the two heat capacity rates. Then the maximum heat transfer rate is determined from Eq. 11–32 to be

$$\begin{aligned}\dot{Q}_{\max} &= C_{\min}(T_{h, \text{in}} - T_{c, \text{in}}) \\ &= (8.36 \text{ kW/K})(70 - 10)^\circ\text{C} \\ &= \mathbf{502 \text{ kW}}\end{aligned}$$

That is, the maximum possible heat transfer rate in this heat exchanger is 502 kW. This value would be approached in a counter-flow heat exchanger with a *very large* heat transfer surface area.

The maximum temperature difference in this heat exchanger is  $\Delta T_{\max} = T_{h, \text{in}} - T_{c, \text{in}} = (70 - 10)^\circ\text{C} = 60^\circ\text{C}$ . Therefore, the hot water cannot be cooled by more than 60°C (to 10°C) in this heat exchanger, and the cold water cannot be heated by more than 60°C (to 70°C), no matter what we do. The outlet temperatures of the cold and the hot streams in this limiting case are determined to be

$$\dot{Q} = C_c(T_{c, \text{out}} - T_{c, \text{in}}) \longrightarrow T_{c, \text{out}} = T_{c, \text{in}} + \frac{\dot{Q}}{C_c} = 10^\circ\text{C} + \frac{502 \text{ kW}}{33.4 \text{ kW/K}} = \mathbf{25^\circ\text{C}}$$

$$\dot{Q} = C_h(T_{h, \text{in}} - T_{h, \text{out}}) \longrightarrow T_{h, \text{out}} = T_{h, \text{in}} - \frac{\dot{Q}}{C_h} = 70^\circ\text{C} - \frac{502 \text{ kW}}{8.38 \text{ kW/K}} = \mathbf{10^\circ\text{C}}$$

**Discussion** Note that the hot water is cooled to the limit of 10°C (the inlet temperature of the cold-water stream), but the cold water is heated to 25°C only when maximum heat transfer occurs in the heat exchanger. This is not surprising, since the mass flow rate of the hot water is only one-fourth that of the cold water, and, as a result, the temperature of the cold water increases by 0.25°C for each 1°C drop in the temperature of the hot water.

You may be tempted to think that the cold water should be heated to 70°C in the limiting case of maximum heat transfer. But this will require the temperature of the hot water to drop to  $-170^\circ\text{C}$  (below 10°C), which is impossible. Therefore, heat transfer in a heat exchanger reaches its maximum value when the fluid with the smaller heat capacity rate (or the smaller mass flow rate when both fluids have the same specific heat value) experiences the maximum

temperature change. This example explains why we use  $C_{\min}$  in the evaluation of  $\dot{Q}_{\max}$  instead of  $C_{\max}$ .

We can show that the hot water will leave at the inlet temperature of the cold water and vice versa in the limiting case of maximum heat transfer when the mass flow rates of the hot- and cold-water streams are identical (Fig. 11–26). We can also show that the outlet temperature of the cold water will reach the 70°C limit when the mass flow rate of the hot water is greater than that of the cold water.

The determination of  $\dot{Q}_{\max}$  requires the availability of the *inlet temperature* of the hot and cold fluids and their *mass flow rates*, which are usually specified. Then, once the effectiveness of the heat exchanger is known, the actual heat transfer rate  $\dot{Q}$  can be determined from

$$\dot{Q} = \varepsilon \dot{Q}_{\max} = \varepsilon C_{\min} (T_{h,\text{in}} - T_{c,\text{in}}) \quad (11-33)$$

where

$$\text{if } C_c = C_{\min}: \quad \varepsilon = \frac{\dot{Q}}{\dot{Q}_{\max}} = \frac{C_c(T_{c,\text{out}} - T_{c,\text{in}})}{C_c(T_{h,\text{in}} - T_{c,\text{in}})} = \frac{T_{c,\text{out}} - T_{c,\text{in}}}{T_{h,\text{in}} - T_{c,\text{in}}}$$

$$\text{if } C_h = C_{\min}: \quad \varepsilon = \frac{\dot{Q}}{\dot{Q}_{\max}} = \frac{C_h(T_{h,\text{in}} - T_{h,\text{out}})}{C_h(T_{h,\text{in}} - T_{c,\text{in}})} = \frac{T_{h,\text{in}} - T_{h,\text{out}}}{T_{h,\text{in}} - T_{c,\text{in}}}$$

Therefore, the effectiveness of a heat exchanger enables us to determine the heat transfer rate without knowing the *outlet temperatures* of the fluids.

The effectiveness of a heat exchanger depends on the *geometry* of the heat exchanger as well as the *flow arrangement*. Therefore, different types of heat exchangers have different effectiveness relations. Below we illustrate the development of the effectiveness  $\varepsilon$  relation for the double-pipe *parallel-flow* heat exchanger.

Equation 11–23 developed in Section 11–4 for a parallel-flow heat exchanger can be rearranged as

$$\ln \frac{T_{h,\text{out}} - T_{c,\text{out}}}{T_{h,\text{in}} - T_{c,\text{in}}} = - \frac{UA_s}{C_c} \left( 1 + \frac{C_c}{C_h} \right) \quad (11-34)$$

Also, solving Eq. 11–30 for  $T_{h,\text{out}}$  gives

$$T_{h,\text{out}} = T_{h,\text{in}} - \frac{C_c}{C_h} (T_{c,\text{out}} - T_{c,\text{in}}) \quad (11-35)$$

Substituting this relation into Eq. 11–34 after adding and subtracting  $T_{c,\text{in}}$  gives

$$\ln \frac{T_{h,\text{in}} - T_{c,\text{in}} + T_{c,\text{in}} - T_{c,\text{out}} - \frac{C_c}{C_h} (T_{c,\text{out}} - T_{c,\text{in}})}{T_{h,\text{in}} - T_{c,\text{in}}} = - \frac{UA_s}{C_c} \left( 1 + \frac{C_c}{C_h} \right)$$

$$\begin{aligned} \dot{Q} &= \dot{m}_h c_{ph} \Delta T_h \\ &= \dot{m}_c c_{pc} \Delta T_c \end{aligned}$$

$$\text{If } \dot{m}_c c_{pc} = \dot{m}_h c_{ph}$$

$$\text{then } \Delta T_h = \Delta T_c$$

**FIGURE 11–26**

The temperature rise of the cold fluid in a heat exchanger will be equal to the temperature drop of the hot fluid when the heat capacity rates of the hot and cold fluids are identical.

which simplifies to

$$\ln \left[ 1 - \left( 1 + \frac{C_c}{C_h} \right) \frac{T_{c,\text{out}} - T_{c,\text{in}}}{T_{h,\text{in}} - T_{c,\text{in}}} \right] = -\frac{UA_s}{C_c} \left( 1 + \frac{C_c}{C_h} \right) \quad (11-36)$$

We now manipulate the definition of effectiveness to obtain

$$\varepsilon = \frac{\dot{Q}}{\dot{Q}_{\max}} = \frac{C_c(T_{c,\text{out}} - T_{c,\text{in}})}{C_{\min}(T_{h,\text{in}} - T_{c,\text{in}})} \longrightarrow \frac{T_{c,\text{out}} - T_{c,\text{in}}}{T_{h,\text{in}} - T_{c,\text{in}}} = \varepsilon \frac{C_{\min}}{C_c}$$

Substituting this result into Eq. 11-36 and solving for  $\varepsilon$  gives the following relation for the effectiveness of a *parallel-flow* heat exchanger:

$$\varepsilon_{\text{parallel flow}} = \frac{1 - \exp \left[ -\frac{UA_s}{C_c} \left( 1 + \frac{C_c}{C_h} \right) \right]}{\left( 1 + \frac{C_c}{C_h} \right) \frac{C_{\min}}{C_c}} \quad (11-37)$$

Taking either  $C_c$  or  $C_h$  to be  $C_{\min}$  (both approaches give the same result), the relation above can be expressed more conveniently as

$$\varepsilon_{\text{parallel flow}} = \frac{1 - \exp \left[ -\frac{UA_s}{C_{\min}} \left( 1 + \frac{C_{\min}}{C_{\max}} \right) \right]}{1 + \frac{C_{\min}}{C_{\max}}} \quad (11-38)$$

Again  $C_{\min}$  is the *smaller* heat capacity rate and  $C_{\max}$  is the larger one, and it makes no difference whether  $C_{\min}$  belongs to the hot or cold fluid.

Effectiveness relations of the heat exchangers typically involve the *dimensionless* group  $UA_s/C_{\min}$ . This quantity is called the **number of transfer units NTU** and is expressed as

$$\text{NTU} = \frac{UA_s}{C_{\min}} = \frac{UA_s}{(mc_p)_{\min}} \quad (11-39)$$

where  $U$  is the overall heat transfer coefficient and  $A_s$  is the heat transfer surface area of the heat exchanger. Note that NTU is proportional to  $A_s$ . Therefore, for specified values of  $U$  and  $C_{\min}$ , the value of NTU is a measure of the heat transfer surface area  $A_s$ . Thus, the larger the NTU, the larger the heat exchanger.

In heat exchanger analysis, it is also convenient to define another dimensionless quantity called the **capacity ratio  $c$**  as

$$c = \frac{C_{\min}}{C_{\max}} \quad (11-40)$$

It can be shown that the effectiveness of a heat exchanger is a function of the number of transfer units NTU and the capacity ratio  $c$ . That is,

$$\varepsilon = \text{function } (UA_s/C_{\min}, C_{\min}/C_{\max}) = \text{function } (\text{NTU}, c)$$

**TABLE 11-4**

Effectiveness relations for heat exchangers:  $NTU = UA_s/C_{min}$  and  $c = C_{min}/C_{max} = (\dot{m}c_p)_{min}/(\dot{m}c_p)_{max}$

| Heat exchanger type                   | Effectiveness relation   |
|---------------------------------------|--|
| 1 Double pipe:                        |  |
| Parallel-flow                         | $\varepsilon = \frac{1 - \exp[-NTU(1 + c)]}{1 + c}$  |
| Counter-flow                          | $\varepsilon = \frac{1 - \exp[-NTU(1 - c)]}{1 - c \exp[-NTU(1 - c)]}$ (for $c < 1$ )   |
|                                       | $\varepsilon = \frac{NTU}{1 + NTU}$ (for $c = 1$ )   |
| 2 Shell-and-tube:                     |  |
| One-shell pass                        |  |
| 2, 4,...tube passes                   | $\varepsilon_1 = 2 \left\{ 1 + c + \sqrt{1 + c^2} \frac{1 + \exp[-NTU_1 \sqrt{1 + c^2}]}{1 - \exp[-NTU_1 \sqrt{1 + c^2}]} \right\}^{-1}$   |
| $n$ -shell passes                     |  |
| $2n, 4n, \dots$ tube passes           | $\varepsilon_n = \left[ \left( \frac{1 - \varepsilon_1 c}{1 - \varepsilon_1} \right)^n - 1 \right] \left[ \left( \frac{1 - \varepsilon_1 c}{1 - \varepsilon_1} \right)^n - c \right]^{-1}$ |
| 3 Cross-flow<br>(single-pass)         |  |
| Both fluids unmixed                   | $\varepsilon = 1 - \exp \left\{ \frac{NTU^{0.22}}{c} [\exp(-cNTU^{0.78}) - 1] \right\}$  |
| $C_{max}$ mixed,<br>$C_{min}$ unmixed | $\varepsilon = \frac{1}{c} (1 - \exp \{-c[1 - \exp(-NTU)]\})$  |
| $C_{min}$ mixed,<br>$C_{max}$ unmixed | $\varepsilon = 1 - \exp \left\{ -\frac{1}{c} [1 - \exp(-c NTU)] \right\}$  |
| 4 All heat exchangers                 | $\varepsilon = 1 - \exp(-NTU)$   |
| with $c = 0$                          |  |

From W. M. Kays and A. L. London. *Compact Heat Exchangers*, 3/e. McGraw-Hill, 1984. Reprinted by permission of William M. Kays.

Effectiveness relations have been developed for a large number of heat exchangers, and the results are given in Table 11-4. The effectivenesses of some common types of heat exchangers are also plotted in Fig. 11-27 on the next page.

More extensive effectiveness charts and relations are available in the literature. The dashed lines in Fig. 11-27f are for the case of  $C_{min}$  unmixed and  $C_{max}$  mixed and the solid lines are for the opposite case. The analytic relations for the effectiveness give more accurate results than the charts, since reading errors in charts are unavoidable, and the relations are very suitable for computerized analysis of heat exchangers.

We make these observations from the effectiveness relations and charts already given:

1. The value of the effectiveness ranges from 0 to 1. It increases rapidly with NTU for small values (up to about  $NTU = 1.5$ ) but rather slowly

(a) Parallel-flow

(b) Counter-flow

(c) One-shell pass and 2, 4, 6, ... tube passes

(d) Two-shell passes and 4, 8, 12, ... tube passes

(e) Cross-flow with both fluids unmixed

(f) Cross-flow with one fluid mixed and the other unmixed

**FIGURE 11-27**

Effectiveness for heat exchangers.

From Kays and London, 1984.

for larger values. Therefore, the use of a heat exchanger with a large NTU (usually larger than 3) and thus a large size cannot be justified economically, since a large increase in NTU in this case corresponds to a small increase in effectiveness. Thus, a heat exchanger with a very high effectiveness may be desirable from a heat transfer point of view but undesirable from an economical point of view.

2. For a given NTU and capacity ratio  $c = C_{\min}/C_{\max}$ , the *counter-flow* heat exchanger has the *highest* effectiveness, followed closely by the cross-flow heat exchangers with both fluids unmixed. As you might expect, the lowest effectiveness values are encountered in parallel-flow heat exchangers (Fig. 11–28).
3. The effectiveness of a heat exchanger is independent of the capacity ratio  $c$  for NTU values of less than about 0.3.
4. The value of the capacity ratio  $c$  ranges between 0 and 1. For a given NTU, the effectiveness becomes a *maximum* for  $c = 0$  and a *minimum* for  $c = 1$ . The case  $c = C_{\min}/C_{\max} \rightarrow 0$  corresponds to  $C_{\max} \rightarrow \infty$ , which is realized during a phase-change process in a *condenser* or *boiler*. All effectiveness relations in this case reduce to

$$\varepsilon = \varepsilon_{\max} = 1 - \exp(-\text{NTU}) \quad (11-41)$$

regardless of the type of heat exchanger (Fig. 11–29). Note that the temperature of the condensing or boiling fluid remains constant in this case. The effectiveness is the *lowest* in the other limiting case of  $c = C_{\min}/C_{\max} = 1$ , which is realized when the heat capacity rates of the two fluids are equal. In industrial applications such as hot water cooling or chilled water heating pertaining to heating, ventilating, and air conditioning (HVAC) industry, the hot or cold fluid is channeled from one location to another with the pipe immersed in ambient environment. Typical examples of this flow situation are the fluid carrying heat exchanger pipe exposed to ambient air or submerged in large liquid mediums such as a lake. In such cases, since the effective change in reference temperature of the ambient environment is virtually zero and the relative mass of the ambient environment is infinitely large, the maximum heat capacity rate  $C_{\max}$  is a very large number. Thus the capacity ratio,  $c = C_{\min}/C_{\max} \rightarrow 0$  and hence Eq. 11-41 is applicable in cases when the heat exchanger is in contact with the ambient environment.

Once the quantities  $c = C_{\min}/C_{\max}$  and  $\text{NTU} = UA_s/C_{\min}$  have been evaluated, the effectiveness  $\varepsilon$  can be determined from either the charts or the effectiveness relation for the specified type of heat exchanger. Then the rate of heat transfer  $\dot{Q}$  and the outlet temperatures  $T_{h,\text{out}}$  and  $T_{c,\text{out}}$  can be determined from Eqs. 11-33 and 11-30, respectively. Note that the analysis of heat exchangers with unknown outlet temperatures is a straightforward matter with the effectiveness–NTU method but requires rather tedious iterations with the LMTD method.

We mentioned earlier that when all the inlet and outlet temperatures are specified, the *size* of the heat exchanger can easily be determined using the LMTD method. Alternatively, it can also be determined from the effectiveness–NTU method by first evaluating the effectiveness  $\varepsilon$  from its definition (Eq. 11-29) and then the NTU from the appropriate NTU relation in Table 11-5.

**FIGURE 11-28**  
For a specified NTU and capacity ratio  $c$ , the counter-flow heat exchanger has the highest effectiveness and the parallel-flow the lowest.

**FIGURE 11-29**  
The effectiveness relation reduces to  $\varepsilon = \varepsilon_{\max} = 1 - \exp(-\text{NTU})$  for all heat exchangers when the capacity ratio  $c = 0$ .

TABLE 11-5

NTU relations for heat exchangers:  $NTU = UA_s/C_{min}$  and  $c = C_{min}/C_{max} = (\dot{m}c_p)_{min}/(\dot{m}c_p)_{max}$

| Heat exchanger type                   | NTU relation   |
|---------------------------------------|--|
| 1 Double-pipe:                        |  |
| Parallel-flow                         | $NTU = -\frac{\ln[1 - \varepsilon(1 + c)]}{1 + c}$   |
| Counter-flow                          | $NTU = \frac{1}{c - 1} \ln \left( \frac{\varepsilon - 1}{\varepsilon c - 1} \right)$ (for $c < 1$ )  |
|                                       | $NTU = \frac{\varepsilon}{1 - \varepsilon}$ (for $c = 1$ )   |
| 2 Shell and tube:                     |  |
| One-shell pass                        |  |
| 2, 4,...tube passes                   | $NTU_1 = -\frac{1}{\sqrt{1 + c^2}} \ln \left( \frac{2/\varepsilon_1 - 1 - c - \sqrt{1 + c^2}}{2/\varepsilon_1 - 1 - c + \sqrt{1 + c^2}} \right)$ |
| $n$ -shell passes                     |  |
| 2n, 4n,...tube passes                 | $NTU_n = n(NTU)_1$   |
|                                       | To find effectiveness of the heat exchanger with one-shell pass use, $\varepsilon_1 = \frac{F - 1}{F - c}$                                       |
|                                       | where $F = \left( \frac{\varepsilon_n c - 1}{\varepsilon_n - 1} \right)^{1/n}$   |
| 3 Cross-flow (single-pass):           |  |
| $C_{max}$ mixed,<br>$C_{min}$ unmixed | $NTU = -\ln \left[ 1 + \frac{\ln(1 - \varepsilon c)}{c} \right]$   |
| $C_{min}$ mixed,<br>$C_{max}$ unmixed | $NTU = -\frac{\ln [c \ln(1 - \varepsilon) + 1]}{c}$  |
| 4 All heat exchangers<br>with $c = 0$ | $NTU = -\ln(1 - \varepsilon)$  |

Note that the relations in Table 11-5 are equivalent to those in Table 11-4. Both sets of relations are given for convenience. The relations in Table 11-4 give the effectiveness directly when NTU is known, and the relations in Table 11-5 give the NTU directly when the effectiveness  $\varepsilon$  is known.

FIGURE 11-30

Schematic for Example 11-8.

#### EXAMPLE 11-8 The Effectiveness-NTU Method

A counter-flow double-pipe heat exchanger is to heat water from 20°C to 80°C at a rate of 1.2 kg/s (Fig. 11-30). The heating is to be accomplished by geothermal water available at 160°C at a mass flow rate of 2 kg/s. The inner tube is thin-walled and has a diameter of 1.5 cm. The overall heat transfer coefficient of the heat exchanger is 640 W/m<sup>2</sup>·K. Using the effectiveness-NTU method determine the length of the heat exchanger required to achieve the desired heating.

**SOLUTION** Water is heated in a counter-flow double-pipe heat exchanger by geothermal water. Using the  $\varepsilon$ -NTU method, the required length of the heat exchanger is to be determined.

**Analysis** In the effectiveness-NTU method, we first determine the heat capacity rates of the hot and cold fluids and identify the smaller one.

$$C_h = \dot{m}_h c_{ph} = (2 \text{ kg/s})(4.31 \text{ kJ/kg}\cdot\text{K}) = 8.62 \text{ kW/K}$$

$$C_c = \dot{m}_c c_{pc} = (1.2 \text{ kg/s})(4.18 \text{ kJ/kg}\cdot\text{K}) = 5.02 \text{ kW/K}$$

Therefore,

$$C_{\min} = C_c = 5.02 \text{ kW/K}$$

and

$$c = C_{\min}/C_{\max} = 5.02/8.62 = 0.582$$

Then the maximum heat transfer rate is determined from Eq. 11-32 to be

$$\begin{aligned}\dot{Q}_{\max} &= C_{\min}(T_{h,\text{in}} - T_{c,\text{in}}) \\ &= (5.02 \text{ kW/K})(160 - 20)^\circ\text{C} \\ &= 702.8 \text{ kW}\end{aligned}$$

That is, the maximum possible heat transfer rate in this heat exchanger is 702.8 kW. The actual rate of heat transfer is

$$\begin{aligned}\dot{Q} &= [\dot{m}_c(T_{\text{out}} - T_{\text{in}})]_{\text{water}} = (1.2 \text{ kg/s})(4.18 \text{ kJ/kg}\cdot\text{K})(80 - 20)^\circ\text{C} \\ &= 301.0 \text{ kW}\end{aligned}$$

Thus, the effectiveness of the heat exchanger is

$$\varepsilon = \frac{\dot{Q}}{\dot{Q}_{\max}} = \frac{301.0 \text{ kW}}{702.8 \text{ kW}} = 0.428$$

Knowing the effectiveness, the NTU of this counter-flow heat exchanger can be determined from Fig. 11-27b or the appropriate relation from Table 11-5 for  $c < 1$ . We choose the latter approach for greater accuracy:

$$\text{NTU} = \frac{1}{c - 1} \ln\left(\frac{\varepsilon - 1}{\varepsilon c - 1}\right) = \frac{1}{0.582 - 1} \ln\left(\frac{0.428 - 1}{0.428 \times 0.582 - 1}\right) = 0.651$$

Then the heat transfer surface area becomes

$$\text{NTU} = \frac{UA_s}{C_{\min}} \longrightarrow A_s = \frac{\text{NTU} C_{\min}}{U} = \frac{(0.651)(5020 \text{ W/K})}{640 \text{ W/m}^2\cdot\text{K}} = 5.11 \text{ m}^2$$

To provide this much heat transfer surface area, the length of the tube must be

$$A_s = \pi D L \longrightarrow L = \frac{A_s}{\pi D} = \frac{5.11 \text{ m}^2}{\pi(0.015 \text{ m})} = 108 \text{ m}$$

**Discussion** This problem was solved in Example 11-4 using the LMTD method. Note that we obtained practically the same result in a systematic and straightforward manner using the effectiveness-NTU method.

**EXAMPLE 11–9 Cooling Hot Oil by Water in a Multipass Heat Exchanger**

Hot oil is to be cooled by water in a 1-shell-pass and 8-tube-passes heat exchanger. The tubes are thin-walled and are made of copper with an internal diameter of 1.4 cm. The length of each tube pass in the heat exchanger is 5 m, and the overall heat transfer coefficient is 310 W/m<sup>2</sup>·K. Water flows through the tubes at a rate of 0.2 kg/s, and the oil through the shell at a rate of 0.3 kg/s. The water and the oil enter at temperatures of 20°C and 150°C, respectively. Determine the rate of heat transfer in the heat exchanger and the outlet temperatures of the water and the oil.

**SOLUTION** Hot oil is to be cooled by water in a heat exchanger. The mass flow rates and the inlet temperatures are given. The rate of heat transfer and the outlet temperatures are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The heat exchanger is well insulated so that heat loss to the surroundings is negligible. 3 The thickness of the tube is negligible since it is thin-walled. 4 Changes in the kinetic and potential energies of fluid streams are negligible. 5 The overall heat transfer coefficient is constant and uniform.

**Properties** We take the specific heats of water and oil to be 4.18 and 2.13 kJ/kg·°C, respectively.

**Analysis** The schematic of the heat exchanger is given in Fig. 11–31. The outlet temperatures are not specified, and they cannot be determined from an energy balance. The use of the LMTD method in this case will involve tedious iterations, and thus the  $\varepsilon$ -NTU method is indicated. The first step in the  $\varepsilon$ -NTU method is to determine the heat capacity rates of the hot and cold fluids and identify the smaller one:

$$C_h = \dot{m}_h c_{ph} = (0.3 \text{ kg/s})(2.13 \text{ kJ/kg} \cdot ^\circ\text{C}) = 0.639 \text{ kW/K}$$

$$C_c = \dot{m}_c c_{pc} = (0.2 \text{ kg/s})(4.18 \text{ kJ/kg} \cdot ^\circ\text{C}) = 0.836 \text{ kW/K}$$

Therefore,

$$C_{\min} = C_h = 0.639 \text{ kW/K} \text{ and } c = \frac{C_{\min}}{C_{\max}} = \frac{0.639}{0.836} = 0.764$$

Then the maximum heat transfer rate is determined from Eq. 11–32 to be

$$\dot{Q}_{\max} = C_{\min}(T_{h, \text{in}} - T_{c, \text{in}}) = (0.639 \text{ kW/K})(150 - 20)^\circ\text{C} = 83.1 \text{ kW}$$

That is, the maximum possible heat transfer rate in this heat exchanger is 83.1 kW. The heat transfer surface area is

$$A_s = n(\pi D L) = 8\pi(0.014 \text{ m})(5 \text{ m}) = 1.76 \text{ m}^2$$

Then the NTU of this heat exchanger becomes

$$\text{NTU} = \frac{UA_s}{C_{\min}} = \frac{(310 \text{ W/m}^2 \cdot \text{K})(1.76 \text{ m}^2)}{639 \text{ W/K}} = 0.854$$

The effectiveness of this heat exchanger corresponding to  $c = 0.764$  and  $\text{NTU} = 0.854$  is determined from Fig. 11–27c to be

$$\varepsilon = 0.47$$

**FIGURE 11–31**

Schematic for Example 11–9.

We could also determine the effectiveness from the third relation in Table 11–4 more accurately but with more labor. Then the actual rate of heat transfer becomes

$$\dot{Q} = \varepsilon \dot{Q}_{\max} = (0.47)(83.1 \text{ kW}) = \mathbf{39.1 \text{ kW}}$$

Finally, the outlet temperatures of the cold and the hot fluid streams are determined to be

$$\begin{aligned}\dot{Q} &= C_c(T_{c,\text{out}} - T_{c,\text{in}}) \longrightarrow T_{c,\text{out}} = T_{c,\text{in}} + \frac{\dot{Q}}{C_c} \\ &= 20^\circ\text{C} + \frac{39.1 \text{ kW}}{0.836 \text{ kW/K}} = \mathbf{66.8^\circ\text{C}}\end{aligned}$$

$$\begin{aligned}\dot{Q} &= C_h(T_{h,\text{in}} - T_{h,\text{out}}) \longrightarrow T_{h,\text{out}} = T_{h,\text{in}} - \frac{\dot{Q}}{C_h} \\ &= 150^\circ\text{C} - \frac{39.1 \text{ kW}}{0.639 \text{ kW/K}} = \mathbf{88.8^\circ\text{C}}\end{aligned}$$

Therefore, the temperature of the cooling water will rise from 20°C to 66.8°C as it cools the hot oil from 150°C to 88.8°C in this heat exchanger.

### PtD EXAMPLE 11-10 Prevention of Fire Hazard by Cooling Ethanol to below its Flash Point

Ethanol is classified by the National Fire Protection Association (NFPA) as a flammable fluid because of its low flash point of 17°C. This means that at 17°C or higher, ethanol can vaporize and become a mixture in air that would ignite when an ignition source is present. Thus, in an environment that ignition sources are present, keeping ethanol at a temperature below its flash point can help to prevent fire hazard. Consider a process where ethanol is cooled by water in a 1-shell-pass heat exchanger that can accommodate a maximum of 14-tube-passes (Fig. 11-32). The tubes are made of copper and thin-walled with an inner diameter of 1.5 cm. The length of each tube pass that can be fitted inside the heat exchanger is 3 m, and the overall heat transfer coefficient is 700 W/m<sup>2</sup>·K. Ethanol ( $c_p = 2630 \text{ J/kg}\cdot\text{K}$ ) enters the heat exchanger at 55°C and flows through the shell at a rate of 0.28 kg/s. Water enters the heat exchanger at 2°C and flows through the tubes at a rate of 1.3 kg/s. To prevent fire hazard, the ethanol is to be cooled to 15°C, which is below its flash point. Determine the number of tube passes that is necessary inside the shell-and-tube heat exchanger to cool the ethanol to the prescribed temperature. Discuss whether or not this heat exchanger is suitable for this application. Evaluate any required property of water at 5°C. Is this a good assumption?

**SOLUTION** In this example, the concepts of Prevention through Design (PtD) are applied in conjunction with the concept of effectiveness–NTU method for heat exchanger analysis.

**FIGURE 11-32**  
Schematic for Example 11–10.

**Assumptions** 1 Steady operating conditions exist. 2 The heat exchanger is well insulated so that heat loss to the surroundings is negligible. 3 Changes in the kinetic and potential energies of fluid streams are negligible. 4 Fluid properties are constant. 5 Thermal resistance of tube wall is negligible.

**Properties** The specific heat of ethanol is given to be  $c_{ph} = 2630 \text{ J/kg}\cdot\text{K}$ . The specific heat of water at 5°C is  $c_{pc} = 4205 \text{ J/kg}\cdot\text{K}$  (Table A-9).

**Analysis** In the effectiveness-NTU method, we first determine the heat capacity rates of the hot and cold fluids and identify the smaller one:

$$C_h = \dot{m}_h c_{ph} = (0.28 \text{ kg/s})(2630 \text{ J/kg}\cdot\text{K}) = 736.4 \text{ W/K}$$

$$C_c = \dot{m}_c c_{pc} = (1.3 \text{ kg/s})(4205 \text{ J/kg}\cdot\text{K}) = 5466.5 \text{ W/K}$$

Therefore,

$$C_{\min} = C_h = 736.4 \text{ W/K}$$

and

$$c = C_{\min}/C_{\max} = 736.4/5466.5 = 0.1347$$

Then the maximum heat transfer rate is determined from Eq. 11-32 to be

$$\dot{Q}_{\max} = C_{\min}(T_{h,\text{in}} - T_{c,\text{in}}) = (736.4 \text{ W/K})(55 - 2) \text{ K} = 39,029 \text{ W}$$

The actual rate of heat transfer is

$$\dot{Q} = C_h(T_{h,\text{in}} - T_{h,\text{out}}) = (736.4 \text{ W/K})(55 - 15) \text{ K} = 29,456 \text{ W}$$

Thus, the effectiveness of the heat exchanger is

$$\varepsilon = \frac{\dot{Q}}{\dot{Q}_{\max}} = \frac{29,456}{39,029} = 0.7547$$

For this one-shell pass heat exchanger, knowing the effectiveness ( $\varepsilon$ ), the NTU of this heat exchanger can be determined from the appropriate relation from Table 11-5:

$$\begin{aligned} \text{NTU}_1 &= -\frac{1}{\sqrt{1 + c^2}} \ln \left( \frac{2/\varepsilon_1 - 1 - c - \sqrt{1 + c^2}}{2/\varepsilon_1 - 1 - c + \sqrt{1 + c^2}} \right) \\ &= -\frac{1}{\sqrt{1 + 0.1347^2}} \ln \left( \frac{2/0.7547 - 1 - 0.1347 - \sqrt{1 + 0.1347^2}}{2/0.7547 - 1 - 0.1347 + \sqrt{1 + 0.1347^2}} \right) \\ &= 1.592 \end{aligned}$$

Note that for this one-shell pass heat exchanger  $\varepsilon_1 = \varepsilon$  and  $\text{NTU}_1 = \text{NTU}$

Then the number of tube passes can be determined using

$$\text{NTU} = \frac{UA_s}{C_{\min}} = \frac{U(\pi DL)n}{C_{\min}} = 1.592$$

Thus,

$$n = \frac{C_{\min} \text{NTU}}{U\pi DL} = \frac{(736.4 \text{ W/K})(1.592)}{(700 \text{ W/m}^2\text{-K})\pi(0.015 \text{ m})(3 \text{ m})} = 11.85 \rightarrow \text{12-tube-passes}$$

**Discussion** To reduce the ethanol temperature from 55°C to 15°C, the 1-shell pass heat exchanger requires at least 12-tube-passes of 1.5-cm-diameter and 3-m-long tubes. At 15°C, the temperature is below the flash point of ethanol, and the risk of fire hazard is alleviated.

The heat exchanger can accommodate up to 14-tube-passes, therefore it is suitable for this application.

Note that the outlet temperature of water can be determined from

$$\dot{Q} = C_c(T_{c,\text{out}} - T_{c,\text{in}}) \rightarrow T_{c,\text{out}} = \frac{\dot{Q}}{C_c} + T_{c,\text{in}} = \frac{29,456 \text{ W}}{5466.5 \text{ W/}^\circ\text{C}} + 2^\circ\text{C} = 7.4^\circ\text{C}$$

Then the bulk mean temperature for the water is  $T_{c,b} = (T_{c,\text{out}} + T_{c,\text{in}})/2 = 4.7^\circ\text{C}$ . Thus, 5°C is an appropriate temperature for evaluating the specific heat of water.

## 11–6 • SELECTION OF HEAT EXCHANGERS

Heat exchangers are complicated devices, and the results obtained with the simplified approaches presented above should be used with care. For example, we assumed that the overall heat transfer coefficient  $U$  is constant throughout the heat exchanger and that the convection heat transfer coefficients can be predicted using the convection correlations. However, it should be kept in mind that the uncertainty in the predicted value of  $U$  can exceed 30 percent. Thus, it is natural to tend to overdesign the heat exchangers in order to avoid unpleasant surprises.

Heat transfer enhancement in heat exchangers is usually accompanied by *increased pressure drop*, and thus *higher pumping power*. Therefore, any gain from the enhancement in heat transfer should be weighed against the cost of the accompanying pressure drop. Also, some thought should be given to which fluid should pass through the tube side and which through the shell side. Usually, the *more viscous fluid is more suitable for the shell side* (larger passage area and thus lower pressure drop) and the *fluid with the higher pressure for the tube side*.

Engineers in industry often find themselves in a position to select heat exchangers to accomplish certain heat transfer tasks. Usually, the goal is to heat or cool a certain fluid at a known mass flow rate and temperature to a desired temperature. Thus, the *rate of heat transfer* in the prospective heat exchanger is

$$\dot{Q} = \dot{m}c_p(T_{\text{in}} - T_{\text{out}})$$

which gives the heat transfer requirement of the heat exchanger before having any idea about the heat exchanger itself.

An engineer going through catalogs of heat exchanger manufacturers will be overwhelmed by the type and number of readily available off-the-shelf heat exchangers. The proper selection depends on several factors.

## Heat Transfer Rate

This is the most important quantity in the selection of a heat exchanger. A heat exchanger should be capable of transferring heat at the specified rate in order to achieve the desired temperature change of the fluid at the specified mass flow rate.

## Cost

Budgetary limitations usually play an important role in the selection of heat exchangers, except for some specialized cases where “money is no object.” An off-the-shelf heat exchanger has a definite cost advantage over those made to order. However, in some cases, none of the existing heat exchangers will do, and it may be necessary to undertake the expensive and time-consuming task of designing and manufacturing a heat exchanger from scratch to suit the needs. This is often the case when the heat exchanger is an integral part of the overall device to be manufactured.

The operation and maintenance costs of the heat exchanger are also important considerations in assessing the overall cost.

## Pumping Power

In a heat exchanger, both fluids are usually forced to flow by pumps or fans that consume electrical power. The annual cost of electricity associated with the operation of the pumps and fans can be determined from

$$\begin{aligned}\text{Operating cost} &= (\text{Pumping power, kW}) \times (\text{Hours of operation, h}) \\ &\quad \times (\text{Unit cost of electricity, \$/kWh})\end{aligned}$$

where the pumping power is the total electrical power consumed by the motors of the pumps and fans. For example, a heat exchanger that involves a 1-hp pump and a  $\frac{1}{3}$ -hp fan (1 hp = 0.746 kW) operating at full load 8 h a day and 5 days a week will consume 2069 kWh of electricity per year, which will cost \$166 at an electricity cost of 8 cents/kWh.

Minimizing the pressure drop and the mass flow rate of the fluids will minimize the operating cost of the heat exchanger, but it will maximize the size of the heat exchanger and thus the initial cost. As a rule of thumb, doubling the mass flow rate will reduce the initial cost by *half* but will increase the pumping power requirements by a factor of roughly *eight*.

Typically, fluid velocities encountered in heat exchangers range between 0.7 and 7 m/s for liquids and between 3 and 30 m/s for gases. Low velocities are helpful in avoiding erosion, tube vibrations, and noise as well as pressure drop.

## Size and Weight

Normally, the *smaller* and the *lighter* the heat exchanger, the better it is. This is especially the case in the *automotive* and *aerospace* industries, where size and weight requirements are most stringent. Also, a larger heat exchanger normally carries a higher price tag. The space available for the heat exchanger in some cases limits the length of the tubes that can be used.

## Type

The type of heat exchanger to be selected depends primarily on the type of *fluids* involved, the *size* and *weight* limitations, and the presence of any *phase-change* processes. For example, a heat exchanger is suitable to cool a liquid by a gas if the surface area on the gas side is many times that on the liquid side. On the other hand, a plate or shell-and-tube heat exchanger is very suitable for cooling a liquid by another liquid.

## Materials

The materials used in the construction of the heat exchanger may be an important consideration in the selection of heat exchangers. For example, the thermal and structural *stress effects* need not be considered at pressures below 15 atm or temperatures below 150°C. But these effects are major considerations above 70 atm or 550°C and seriously limit the acceptable materials of the heat exchanger.

A temperature difference of 50°C or more between the tubes and the shell will probably pose *differential thermal expansion* problems and needs to be considered. In the case of corrosive fluids, we may have to select expensive *corrosion-resistant* materials such as stainless steel or even titanium if we are not willing to replace low-cost heat exchangers frequently.

## Other Considerations

There are other considerations in the selection of heat exchangers that may or may not be important, depending on the application. For example, being *leak-tight* is an important consideration when *toxic* or *expensive* fluids are involved. Ease of servicing, low maintenance cost, and safety and reliability are some other important considerations in the selection process. Quietness is one of the primary considerations in the selection of liquid-to-air heat exchangers used in heating and air-conditioning applications.

### EXAMPLE 11–11 Installing a Heat Exchanger to Save Energy and Money

In a dairy plant, milk is pasteurized by hot water supplied by a natural gas furnace. The hot water is then discharged to an open floor drain at 80°C at a rate of 15 kg/min. The plant operates 24 h a day and 365 days a year. The furnace has an efficiency of 80 percent, and the cost of the natural gas is \$1.10 per therm (1 therm = 105,500 kJ). The average temperature of the cold water entering the furnace throughout the year is 15°C. The drained hot water cannot be returned to the furnace and recirculated, because it is contaminated during the process.

In order to save energy, installation of a water-to-water heat exchanger to preheat the incoming cold water by the drained hot water is proposed. Assuming that the heat exchanger will recover 75 percent of the available heat in the hot water, determine the heat transfer rating of the heat exchanger that needs to be purchased and suggest a suitable type. Also, determine the amount of money this heat exchanger will save the company per year from natural gas savings.

**FIGURE 11–33**

Schematic for Example 11–11.

**SOLUTION** A water-to-water heat exchanger is to be installed to transfer energy from drained hot water to the incoming cold water to preheat it. The rate of heat transfer in the heat exchanger and the amounts of energy and money saved per year are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The effectiveness of the heat exchanger remains constant.

**Properties** We use the specific heat of water at room temperature,  $c_p = 4.18 \text{ kJ/kg}\cdot\text{°C}$ , and treat it as a constant.

**Analysis** A schematic of the prospective heat exchanger is given in Fig. 11–33. The heat recovery from the hot water will be a maximum when it leaves the heat exchanger at the inlet temperature of the cold water. Therefore,

$$\begin{aligned}\dot{Q}_{\max} &= \dot{m}_h c_p (T_{h,\text{in}} - T_{c,\text{in}}) \\ &= \left(\frac{15}{60} \text{ kg/s}\right)(4.18 \text{ kJ/kg}\cdot\text{K})(80 - 15)\text{°C} \\ &= 67.9 \text{ kJ/s}\end{aligned}$$

That is, the existing hot-water stream has the potential to supply heat at a rate of 67.9 kJ/s to the incoming cold water. This value would be approached in a counter-flow heat exchanger with a *very large* heat transfer surface area. A heat exchanger of reasonable size and cost can capture 75 percent of this heat transfer potential. Thus, the heat transfer rating of the prospective heat exchanger must be

$$\dot{Q} = \varepsilon \dot{Q}_{\max} = (0.75)(67.9 \text{ kJ/s}) = \mathbf{50.9 \text{ kJ/s}}$$

That is, the heat exchanger should be able to deliver heat at a rate of 50.9 kJ/s from the hot to the cold water. An ordinary plate or *shell-and-tube* heat exchanger should be adequate for this purpose, since both sides of the heat exchanger involve the same fluid at comparable flow rates and thus comparable heat transfer coefficients. (Note that if we were heating air with hot water, we would have to specify a heat exchanger that has a large surface area on the air side.)

The heat exchanger will operate 24 h a day and 365 days a year. Therefore, the annual operating hours are

$$\text{Operating hours} = (24 \text{ h/day})(365 \text{ days/year}) = 8760 \text{ h/year}$$

Noting that this heat exchanger saves 50.9 kJ of energy per second, the energy saved during an entire year will be

$$\begin{aligned}\text{Energy saved} &= (\text{Heat transfer rate})(\text{Operation time}) \\ &= (50.9 \text{ kJ/s})(8760 \text{ h/year})(3600 \text{ s/h}) \\ &= 1.605 \times 10^9 \text{ kJ/year}\end{aligned}$$

The furnace is said to be 80 percent efficient. That is, for each 80 units of heat supplied by the furnace, natural gas with an energy content of 100 units must be supplied to the furnace. Therefore, the energy savings determined above result in fuel savings in the amount of

$$\begin{aligned}\text{Fuel saved} &= \frac{\text{Energy saved}}{\text{Furnace efficiency}} = \frac{1.605 \times 10^9 \text{ kJ/year}}{0.80} \left( \frac{1 \text{ therm}}{105,500 \text{ kJ}} \right) \\ &= 19,020 \text{ therms/year}\end{aligned}$$

Noting that the price of natural gas is \$1.10 per therm, the amount of money saved becomes

$$\begin{aligned}\text{Money saved} &= (\text{Fuel saved}) \times (\text{Price of fuel}) \\ &= (19,020 \text{ therms/year})(\$1.10/\text{therm}) \\ &= \$\mathbf{20,920/\text{year}}\end{aligned}$$

Therefore, the installation of the proposed heat exchanger will save the company \$20,920 a year, and the installation cost of the heat exchanger will probably be paid from the fuel savings in a short time.

## TOPIC OF SPECIAL INTEREST

### *The Human Cardiovascular System as a Counter-Current Heat Exchanger\**

The human body experiences many mechanisms by which it gains or loses heat; including conduction (e.g., feet to concrete), convection (wind blowing past exposed skin), radiation (e.g., solar) and evaporation (Figure 11–34), as described throughout Chapter 1. Additionally, the human body generates heat through metabolism; however, a significant amount of this heat can be lost to the surrounding environment through conduction and convection. In order to prevent the core body temperature from reducing significantly, the cardiovascular system is organized as a counter-current heat exchanger. This cardiovascular counter-current mechanism plays a major role in human thermoregulation (Section 3–7). In this design, one artery is always paired and adjacent to one vein. It has been suggested that the salient physiological factor in reducing the amount of heat loss by the body to the environment, as measured by a blood flow temperature drop, is this arrangement of the cardiovascular system as a counter-current heat exchanger. This organization has been observed in many species (including all warm-blooded animals) and significant quantifiable heat transfer has been seen to occur and has been measured between these two vessels.

How does the counter-current mechanism work in humans? Imagine a human that enters an environment colder than the body's core temperature (e.g., 37°C) from an environment that is approximately equal to the body's core temperature. Initially, the human's extremities (hands, fingers, toes, etc.) will be at a higher temperature than the environment. Thus, heat will flow from the extremities to the environment. This means that the temperature of the tissue in the extremity and importantly the blood in the veins will be lower than the temperature of blood in the arteries (Figure 11–35 on the next page). This is caused by the energy transfer to the environment if we remember that arteries feed tissue with blood and it is the veins that remove blood from the tissue. With significant heat transfer between the artery and vein, the arte-

**FIGURE 11–34**

Heat exchange between the human body and its environment by different mechanisms (conduction, convection, radiation and evaporation).

\*The section is contributed by Professor David A. Rubenstein, Department of Biomedical Engineering, Stony Brook University, Stony Brook, NY.

(a) Cold environment

(b) Hot environment

**FIGURE 11–35**

Blood temperature variation in the human arm for both a cold and hot environment.

rial blood temperature begins to reduce, but at the same time, the venous blood would begin to be re-warmed (remember that in warm-blooded animals, including humans, circulatory systems are closed). This results in the venous blood returning to the core at a higher temperature than it would have without the heat transfer between the artery and vein in a counter-current mechanism. Furthermore, this warmed venous blood may be closer to the body's core temperature generated by metabolism. Therefore, the net heat transfer to the environment is reduced through the actions of the cardiovascular counter-current heat exchanger. Recall that with excessive heat lost to the environment, the human body will reduce the skin temperature and increase the rate of metabolic heat generation, as described in Chapter 1's Topic of Special Interest on Thermal Comfort. This mechanism plays a primary role when the external environmental temperature diverges significantly from the core body temperature in all warm-blooded animals (Figure 11–35, shown for both a cold and hot environment).

A simplified model of the cardiovascular counter-current heat exchanger found in a limb can be depicted by Figure 11–36 on the next page. The heat transfer directions are denoted on this figure, but remember that temperature can increase or decrease (heat is gained or lost) primarily depending on the environmental temperature. Applying the conservation of energy to the system, we can see that energy is only transported by blood and the heat flux between the three systems (artery, vein and external environment). The energy that is carried by the blood can be denoted as

$$\dot{Q}_{\text{blood}} = \dot{m} \frac{dh}{dx} = \dot{m} c_p \frac{dT}{dx} \quad (11-42)$$

where  $\dot{m}$  is the mass flow rate of the blood and  $h$  is the blood enthalpy. Furthermore, the heat transfer that occurs between the three systems can be described by

$$\dot{Q} = UA_s \Delta T_m \quad (11-15)$$

which has been used previously to describe the total heat transfer rate in a heat exchanger. Here we include multiple heat transfer occurrences into one global parameter to simplify the analysis. Therefore the total heat transfer rate of this system can be defined as

$$\dot{Q}_{\text{blood}} + \dot{Q} = \dot{m} c_p \frac{dT}{dx} + UA_s \Delta T_m \quad (11-43)$$

The preceding equation can be expanded for the arterial (denoted with a subscript  $A$ ) and venous (denoted with a subscript  $V$ ) systems as

$$\begin{aligned} \dot{m} c_p \frac{dT_A}{dx} + (UA_s)_{AV}(T_A - T_V) + (UA_s)_A(T_A - T_\infty) &= 0 && \text{Artery} \\ \dot{m} c_p \frac{dT_V}{dx} + (UA_s)_{AV}(T_A - T_V) - (UA_s)_V(T_V - T_\infty) &= 0 && \text{Vein} \end{aligned} \quad (11-44)$$

Equation 11–44 is a system of linear ordinary differential equations, which can be solved with any method that you are familiar with from a previous

course in advanced mathematics. Before we continue, we want to point out that there are a few assumptions that have been incorporated in this model. The first assumption is that the temperature difference in the radial direction ( $r$ ) and angular direction ( $\phi$ ) are negligible (please refer to the coordinate system discussion in Section 2–1, Figure 2–3); the temperature is only a function of the flow direction ( $x$ ). We can also expand this analysis to a more complicated vascular system if we know how each of the artery-vein pairs is related to the analyzed artery-vein pair (i.e., if all heat transfer properties are the same, then we can simply multiply by the number of vascular beds in the entire system to get the total heat transfer rate). We also assume that the heat transfer coefficients and all other thermal properties do not change along the flow direction within one vascular bed (i.e., the heat transfer coefficient between the artery and the vein are the same along the entire blood vessel length). The flow rates within the arterial and venous circulation are the same (or very similar), will also be an underlying assumption of this model.

All methods that have been previously discussed in this section (the log mean temperature difference method or the effectiveness-NTU method) to analyze a counter-current heat exchanger can be applied to the flow through the cardiovascular system. However, there are a couple of key points to remember which makes these systems different than what we have discussed previously. First, the fluid is the same in both vessels and we may be able to assume that the fluid properties (except for temperature) are very similar in each vessel. Furthermore, the outflow of the warmer vessel is connected to the inflow of the colder vessel, so we should have a similar mass flow rate through each tube and  $T_{h,out}$  may be assumed to equal  $T_{c,in}$ . Therefore, there is some additional coupling that may need to be considered under these cases.

The system of linear ordinary differential equations may be quite complex to analyze in practice. Therefore, there has been significant work on simplifying this analysis. The most applicable simplification came from Weinbaum and Jiji (1985) and can be represented as

$$\rho c_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left( k_{\text{eff}} \frac{\partial T}{\partial x} \right) + \dot{e}_m \quad (11-45)$$

where  $\dot{e}_m$  is the metabolic heat source term. Equation 11–45 is only valid if we can assume one dimensional heat transfer. In fact, this equation can be derived from the bioheat transfer equation discussed in Chapter 3 (see Section 3–7). This model has been derived based on the temperature of the tissue only assuming that the average blood temperature and local tissue temperature will be similar. The difficulty with this analysis is the effective conductivity term becomes quite complicated because Weinbaum and Jiji (1985) tried to incorporate the imperfections within the cardiovascular counter-current heat exchanger design within this term. The effective conductivity can be represented as

$$k_{\text{eff}} = k + \frac{n\pi^2 r^4 \rho^2 c_p^2 V_{\text{avg}}^2}{S^2 k_b} \quad (11-46)$$

**FIGURE 11–36**

Simplified extremity model for a counter-current heat exchanger.

where  $S$  is the conduction shape factor of blood vessels,  $n$  is the number density of vessel pairs crossing the control volume,  $r$  is the artery radius,  $\rho$  is the blood density,  $V_{\text{avg}}$  is the average blood velocity,  $k$  is the thermal conductivity of the blood vessel, and  $k_b$  is the thermal conductivity of blood. The most critical finding from the Weinbaum and Jiji (1985) paper is that the design of the cardiovascular system in this manner effectively enhances the tissue conductivity. For the smallest vessels in the skin, the conductivity is approximately 5% larger than what would be anticipated without the counter-current design. For larger vessels in the skin region, this enhancement can go as high as 70%, suggesting that the counter-current cardiovascular mechanisms is a very efficient design to re-warm blood prior to entering the core of the body. The major assumptions in the Weinbaum and Jiji model are that the mean tissue temperature is equal to the average of the arterial blood temperature and the vein blood temperature at one particular cross-section. Secondly, most of the heat conduction occurs between the artery and the vein whereas minimal heat is lost to the surrounding tissue or the environment. There has been some computational and experimental work aimed at relieving the constraints of the models described above. For these methods, it was typical to take a volume averaging approach to derive the bioheat transfer equations and blood flow equations. These equations tend to ignore spatial inhomogeneities and the possibility of fluctuations with time. These models tend to be overly complicated without adding much accuracy.

### EXAMPLE 11-12 Counter-Current Heat Exchanger in the Human Body

Blood is flowing through an artery and vein pair near an extremity of the human body. The artery has a diameter of 1 cm and the vein has a diameter of 1.5 cm. The length of each blood vessel is 100 cm. Blood is flowing through the artery at a mass flow rate of 2 g/s and is flowing through the vein at a mass flow rate of 1.8 g/s. The average temperature of blood in the artery is 34°C and the average temperature of blood in the vein is 32°C. The inflow temperature of the artery is 36°C and the external environment temperature is 20°C. Determine the overall heat transfer coefficient for blood and the change in temperature with respect to distance for these blood flow conditions.

**SOLUTION** Blood in the artery is being cooled, while blood in the vein is being warmed. Blood flows in a counter-current manner and the overall heat transfer coefficient for blood and the change in temperature for these blood flow conditions are to be determined.

**Assumptions** 1 The flow through each blood vessel is fully developed. 2 Properties of blood are constant and equal in the artery and the vein. 3 Constant surface heat flux. 4 The conductances to the environment from the artery and the vein are equal.

**Properties** The properties of blood are as follows

$$k = 0.67 \frac{\text{W}}{\text{m}\cdot\text{K}} \quad c_p = 3.475 \frac{\text{kJ}}{\text{kg}\cdot\text{K}}$$

$$\rho = 1050 \frac{\text{kg}}{\text{m}^3} \quad \mu = 0.035 \frac{\text{g}}{\text{s}\cdot\text{cm}}$$

**Analysis** The schematic of the blood vessels are given in Figure 11–36. The overall heat transfer coefficient can be calculated from

$$\frac{1}{U} = \frac{1}{h_{\text{artery}}} + \frac{1}{h_{\text{vein}}}$$

which is a modification of Eq. 11–5. The convection heat transfer coefficients can be determined using the forced convection relationships. Using Eq. 8–5, the Reynolds number for blood in the artery is

$$\text{Re} = \frac{4\dot{m}}{\mu\pi D} = \frac{4(2 \frac{\text{g}}{\text{s}})}{\left(0.035 \frac{\text{g}}{\text{s}\cdot\text{cm}}\right)(\pi)(1 \text{ cm})} = 72.8$$

And the Reynolds number for blood in the vein is

$$\text{Re} = \frac{4\dot{m}}{\mu\pi D} = \frac{4(1.8 \frac{\text{g}}{\text{s}})}{\left(0.035 \frac{\text{g}}{\text{s}\cdot\text{cm}}\right)(\pi)(1.5 \text{ cm})} = 43.7$$

The flow is laminar ( $\text{Re} < 2300$ ) in both the artery and vein. Therefore, since the flow is fully-developed, laminar with constant surface heat flux boundary condition, the Nusselt number for each of these flow conditions is 4.36 as given by Eq. 8–60.

The convection heat transfer coefficients can be calculated from

$$h_{\text{artery}} = \frac{k}{D} \text{Nu} = \frac{0.67 \frac{\text{W}}{\text{m}\cdot\text{K}}}{1 \text{ cm}} (4.36) = 292 \frac{\text{W}}{\text{m}^2\cdot\text{K}}$$

$$h_{\text{vein}} = \frac{k}{D} \text{Nu} = \frac{0.67 \frac{\text{W}}{\text{m}\cdot\text{K}}}{1.5 \text{ cm}} (4.36) = 195 \frac{\text{W}}{\text{m}^2\cdot\text{K}}$$

Therefore, the overall heat transfer coefficient is equal to

$$U = \frac{1}{\frac{1}{h_{\text{artery}}} + \frac{1}{h_{\text{vein}}}} = \frac{1}{\frac{1}{292.12 \frac{\text{W}}{\text{m}^2\cdot\text{K}}} + \frac{1}{194.75 \frac{\text{W}}{\text{m}^2\cdot\text{K}}}} = 116.9 \frac{\text{W}}{\text{m}^2\cdot\text{K}}$$

If we solve Eq. 11–44, we get

$$\frac{T_A - T_\infty}{T_0 - T_\infty} = \frac{\sqrt{1 + 2\left(\frac{N_i}{N_o}\right)} \cosh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right) \left(1 - \frac{x}{L}\right) + \sinh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right) \left(1 - \frac{x}{L}\right)}{\sqrt{1 + 2\left(\frac{N_i}{N_o}\right)} \cosh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right) + \sinh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right)}$$

$$\frac{T_V - T_\infty}{T_0 - T_\infty} = \frac{\sqrt{1 + 2\left(\frac{N_i}{N_o}\right)} \cosh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right) \left(1 - \frac{x}{L}\right) - \sinh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right) \left(1 - \frac{x}{L}\right)}{\sqrt{1 + 2\left(\frac{N_i}{N_o}\right)} \cosh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right) + \sinh\left(N_0 \sqrt{1 + 2\left(\frac{N_i}{N_o}\right)}\right)}$$

where

$$N_o = \frac{(UA_s)_A L}{\dot{m} c_p} \cong \frac{(UA_s)_V L}{\dot{m} c_p} = 0.00132$$

$$N_i = \frac{(UA_s)_{AV} L}{\dot{m} c_p} = 1.06$$

where  $L$  is the total length of interest of the blood vessel and the subscripts either denote artery ( $A$ ) or vein ( $V$ ) or the combined vascular pair ( $AV$ ). The solution to Eq. 11–44 follows a similar form as that discussed for the fin equation in Chapter 3 (see Section 3–6) and is closely related to the solution for convection from the fin tip. Solving the two preceding equations for our conditions, we get

$$\frac{T_A - 20^\circ\text{C}}{36^\circ\text{C} - 20^\circ\text{C}} = \frac{\sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)} \cosh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right) \left(1 - \frac{x}{100 \text{ cm}}\right) + \sinh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right) \left(1 - \frac{x}{100 \text{ cm}}\right)}{\sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)} \cosh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right) + \sinh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right)}$$

$$\frac{T_V - 20^\circ\text{C}}{36^\circ\text{C} - 20^\circ\text{C}} = \frac{\sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)} \cosh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right) \left(1 - \frac{x}{100 \text{ cm}}\right) - \sinh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right) \left(1 - \frac{x}{100 \text{ cm}}\right)}{\sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)} \cosh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right) + \sinh\left(0.00132 \sqrt{1 + 2\left(\frac{1.06}{0.00132}\right)}\right)}$$

Carrying out the algebraic operations, we can find an expression for the variation in temperature along the blood vessel length.

$$T_A = 16^\circ\text{C} \left(1 - \frac{x}{100 \text{ cm}}\right) + 20^\circ\text{C}$$

$$T_V = 15.97^\circ\text{C} \left(1 - \frac{x}{100 \text{ cm}}\right) + 20^\circ\text{C}$$

**Discussion** The temperature variation along the length of the blood vessel varies linearly with distance. We have encountered similar solutions for internal fully developed flow under constant surface heat flux boundary conditions (Fig. 8–11) and for heat exchangers with two fluid streams that have the same heat capacity (Fig. 11–13). We made the assumption that the fluid properties were the same in the artery and the vein and would change significantly with temperature. From the two temperature variation equations we can calculate the temperature along the blood vessel length. When  $x = 0 \text{ cm}$  the temperatures in the artery and vein are  $36^\circ\text{C}$  and  $35.9^\circ\text{C}$ , respectively (remember that the length would be relative to the inlet of the artery). When  $x = 50 \text{ cm}$ , the temperatures in the artery and vein are  $28^\circ\text{C}$  and  $27.9^\circ\text{C}$ , respectively. Finally, when  $x = 100 \text{ cm}$ , the temperature in the artery and the vein are equal and are  $20^\circ\text{C}$ , which is the environmental temperature.

**SUMMARY**

Heat exchangers are devices that allow the exchange of heat between two fluids without allowing them to mix with each other. Heat exchangers are manufactured in a variety of types, the simplest being the *double-pipe* heat exchanger. In a *parallel-flow* type, both the hot and cold fluids enter the heat exchanger at the same end and move in the same direction, whereas in a *counter-flow* type, the hot and cold fluids enter the heat exchanger at opposite ends and flow in opposite directions. In *compact* heat exchangers, the two fluids move perpendicular to each other, and such a flow configuration is called *cross-flow*. Other common types of heat exchangers in industrial applications are the *plate* and the *shell-and-tube* heat exchangers.

Heat transfer in a heat exchanger usually involves convection in each fluid and conduction through the wall separating the two fluids. In the analysis of heat exchangers, it is convenient to work with an *overall heat transfer coefficient*  $U$  or a *total thermal resistance*  $R$ , expressed as

$$\frac{1}{UA_s} = \frac{1}{U_i A_i} = \frac{1}{U_o A_o} = R = \frac{1}{h_i A_i} + R_{\text{wall}} + \frac{1}{h_o A_o}$$

where the subscripts  $i$  and  $o$  stand for the inner and outer surfaces of the wall that separates the two fluids, respectively. When the wall thickness of the tube is small and the thermal conductivity of the tube material is high, the relation simplifies to

$$\frac{1}{U} \approx \frac{1}{h_i} + \frac{1}{h_o}$$

where  $U \approx U_i \approx U_o$ . The effects of fouling on both the inner and the outer surfaces of the tubes of a heat exchanger can be accounted for by

$$\begin{aligned} \frac{1}{UA_s} &= \frac{1}{U_i A_i} = \frac{1}{U_o A_o} = R \\ &= \frac{1}{h_i A_i} + \frac{R_{f,i}}{A_i} + \frac{\ln(D_o/D_i)}{2\pi kL} + \frac{R_{f,o}}{A_o} + \frac{1}{h_o A_o} \end{aligned}$$

where  $A_i = \pi D_i L$  and  $A_o = \pi D_o L$  are the areas of the inner and outer surfaces and  $R_{f,i}$  and  $R_{f,o}$  are the fouling factors at those surfaces.

In a well-insulated heat exchanger, the rate of heat transfer from the hot fluid is equal to the rate of heat transfer to the cold one. That is,

$$\dot{Q} = \dot{m}_c c_{pc} (T_{c,\text{out}} - T_{c,\text{in}}) = C_c (T_{c,\text{out}} - T_{c,\text{in}})$$

and

$$\dot{Q} = \dot{m}_h c_{ph} (T_{h,\text{in}} - T_{h,\text{out}}) = C_h (T_{h,\text{in}} - T_{h,\text{out}})$$

where the subscripts  $c$  and  $h$  stand for the cold and hot fluids, respectively, and the product of the mass flow rate and the specific heat of a fluid  $\dot{m}c_p$  is called the *heat capacity rate*.

Of the two methods used in the analysis of heat exchangers, the *log mean temperature difference* (or LMTD) method is best suited for determining the size of a heat exchanger when all the inlet and the outlet temperatures are known. The *effectiveness-NTU* method is best suited to predict the outlet temperatures of the hot and cold fluid streams in a specified heat exchanger. In the LMTD method, the rate of heat transfer is determined from

$$\dot{Q} = UA_s \Delta T_{\text{lm}}$$

where

$$\Delta T_{\text{lm}} = \frac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1 / \Delta T_2)}$$

is the *log mean temperature difference*, which is the suitable form of the average temperature difference for use in the analysis of heat exchangers. Here  $\Delta T_1$  and  $\Delta T_2$  represent the temperature differences between the two fluids at the two ends (inlet and outlet) of the heat exchanger. For cross-flow and multipass shell-and-tube heat exchangers, the logarithmic mean temperature difference is related to the counter-flow one  $\Delta T_{\text{lm, CF}}$  as

$$\Delta T_{\text{lm}} = F \Delta T_{\text{lm, CF}}$$

where  $F$  is the *correction factor*, which depends on the geometry of the heat exchanger and the inlet and outlet temperatures of the hot and cold fluid streams.

The *effectiveness* of a heat exchanger is defined as

$$\varepsilon = \frac{\dot{Q}}{\dot{Q}_{\max}} = \frac{\text{Actual heat transfer rate}}{\text{Maximum possible heat transfer rate}}$$

where

$$\dot{Q}_{\max} = C_{\min} (T_{h,\text{in}} - T_{c,\text{in}})$$

and  $C_{\min}$  is the smaller of  $C_h = \dot{m}_h c_{ph}$  and  $C_c = \dot{m}_c c_{pc}$ . The effectiveness of heat exchangers can be determined from effectiveness relations or charts.

The selection or design of a heat exchanger depends on several factors such as the heat transfer rate, cost, pressure drop, size, weight, construction type, materials, and operating environment.

## PROBLEMS\*

### Types of Heat Exchangers

**11-1C** Classify heat exchangers according to flow type and explain the characteristics of each type.

**11-2C** When is a heat exchanger classified as being compact? Do you think a double-pipe heat exchanger can be classified as a compact heat exchanger?

**11-3C** What is a regenerative heat exchanger? How does a static type of regenerative heat exchanger differ from a dynamic type?

**11-4C** What is the role of the baffles in a shell-and-tube heat exchanger? How does the presence of baffles affect the heat transfer and the pumping power requirements? Explain.

\*Problems designated by a "C" are concept questions, and students are encouraged to answer them all. Problems designated by an "E" are in English units, and the SI users can ignore them. Problems with the icon are solved using EES, and complete solutions together with parametric studies are included on the text website. Problems with the icon are comprehensive in nature, and are intended to be solved with an equation solver such as EES. Problems with the icon are Prevention through Design Problems.

**11-5C** Draw a 1-shell-pass and 6-tube-passes shell-and-tube heat exchanger. What are the advantages and disadvantages of using 6 tube passes instead of just 2 of the same diameter?

**11-6C** Draw a 2-shell-passes and 8-tube-passes shell-and-tube heat exchanger. What is the primary reason for using so many tube passes?

**11-7C** How does a cross-flow heat exchanger differ from a counter-flow one? What is the difference between mixed and unmixed fluids in cross-flow?

### The Overall Heat Transfer Coefficient

**11-8C** What are the heat transfer mechanisms involved during heat transfer in a liquid-to-liquid heat exchanger from the hot to the cold fluid?

**11-9C** Under what conditions is the thermal resistance of the tube in a heat exchanger negligible?

**11-10C** Consider a double-pipe parallel-flow heat exchanger of length  $L$ . The inner and outer diameters of the inner tube are  $D_1$  and  $D_2$ , respectively, and the inner diameter of the outer tube is  $D_3$ . Explain how you would determine the two heat transfer surface areas  $A_i$  and  $A_o$ . When is it reasonable to assume  $A_i \approx A_o \approx A_s$ ?

**11–11C** How is the thermal resistance due to fouling in a heat exchanger accounted for? How do the fluid velocity and temperature affect fouling?

**11–12C** What are the restrictions on the relation  $UA_s = U_i A_i = U_o A_o$  for a heat exchanger? Here  $A_s$  is the heat transfer surface area and  $U$  is the overall heat transfer coefficient.

**11–13C** In a thin-walled double-pipe heat exchanger, when is the approximation  $U = h_i$  a reasonable one? Here  $U$  is the overall heat transfer coefficient and  $h_i$  is the convection heat transfer coefficient inside the tube.

**11–14C** What are the common causes of fouling in a heat exchanger? How does fouling affect heat transfer and pressure drop?

**11–15C** Under what conditions can the overall heat transfer coefficient of a heat exchanger be determined from  $U = (1/h_i + 1/h_o)^{-1}$ ?

**11–16E** The tube in a heat exchanger has a 2-in. inner diameter and a 3-in. outer diameter. The thermal conductivity of the tube material is 0.5 Btu/h·ft·°F, while the inner surface heat transfer coefficient is 50 Btu/h·ft<sup>2</sup>·°F and the outer surface heat transfer coefficient is 10 Btu/h·ft<sup>2</sup>·°F. Determine the overall heat transfer coefficients based on the outer and inner surfaces.

**11–17** A long thin-walled double-pipe heat exchanger with tube and shell diameters of 1.0 cm and 2.5 cm, respectively, is used to condense refrigerant-134a by water at 20°C. The refrigerant flows through the tube, with a convection heat transfer coefficient of  $h_i = 4100 \text{ W/m}^2\cdot\text{K}$ . Water flows through the shell at a rate of 0.3 kg/s. Determine the overall heat transfer coefficient of this heat exchanger. *Answer: 1856 W/m<sup>2</sup>·K*

**11–18** Repeat Prob. 11–17 by assuming a 2-mm-thick layer of limestone ( $k = 1.3 \text{ W/m}\cdot\text{K}$ ) forms on the outer surface of the inner tube.

**11–19**  Reconsider Prob. 11–18. Using EES (or other) software, plot the overall heat transfer coefficient as a function of the limestone thickness as it varies from 1 mm to 3 mm, and discuss the results.

**11–20E** Water at an average temperature of 180°F and an average velocity of 4 ft/s flows through a thin-walled  $\frac{3}{4}$ -in-diameter tube. The water is cooled by air that flows across the tube with a velocity of 12 ft/s at an average temperature of 80°F. Determine the overall heat transfer coefficient.

**11–21** A jacketed-agitated vessel, fitted with a turbine agitator, is used for heating a water stream from 10°C to 54°C. The average heat transfer coefficient for water at the vessel's inner-wall can be estimated from  $Nu = 0.76Re^{2/3}Pr^{1/3}$ . Saturated steam at 100°C condenses in the jacket, for which the average heat transfer coefficient in kW/m<sup>2</sup>·K is:  $h_o = 13.1(T_g - T_w)^{-0.25}$ . The vessel dimensions are:  $D_t = 0.6 \text{ m}$ ,  $H = 0.6 \text{ m}$  and  $D_a = 0.2 \text{ m}$ . The agitator speed is 60 rpm. Calculate the mass rate of water that can be heated in this agitated vessel steadily.

**11–22E** A counter-flow heat exchanger is stated to have an overall heat transfer coefficient, based on outside tube area of 50 Btu/h·ft<sup>2</sup>·°F when operating at design and clean conditions. After a period of use, scale built-up in the heat exchanger gives a fouling factor of 0.002 h·ft<sup>2</sup>·°F/Btu. Determine (a) the overall heat transfer coefficient of the heat exchanger and (b) the percentage change in the overall heat transfer coefficient due to the scale built-up.

**11–23** Water at an average temperature of 110°C and an average velocity of 3.5 m/s flows through a 5-m-long stainless steel tube ( $k = 14.2 \text{ W/m}\cdot\text{K}$ ) in a boiler. The inner and outer diameters of the tube are  $D_i = 1.0 \text{ cm}$  and  $D_o = 1.4 \text{ cm}$ , respectively. If the convection heat transfer coefficient at the outer surface of the tube where boiling is taking place is  $h_o = 8400 \text{ W/m}^2\cdot\text{K}$ , determine the overall heat transfer coefficient  $U_i$  of this boiler based on the inner surface area of the tube.

**11–24** Repeat Prob. 11–23, assuming a fouling factor  $R_{f,i} = 0.0005 \text{ m}^2\cdot\text{K/W}$  on the inner surface of the tube.

**11–25**  Reconsider Prob. 11–24. Using EES (or other) software, plot the overall heat transfer coefficient based on the inner surface as a function of fouling factor as it varies from 0.0001 m<sup>2</sup>·K/W to 0.0008 m<sup>2</sup>·K/W, and discuss the results.

**11–26** A double-pipe heat exchanger is constructed of a copper ( $k = 380 \text{ W/m}\cdot\text{K}$ ) inner tube of internal diameter  $D_i = 1.2 \text{ cm}$  and external diameter  $D_o = 1.6 \text{ cm}$  and an outer tube of diameter 3.0 cm. The convection heat transfer coefficient is reported to be  $h_i = 700 \text{ W/m}^2\cdot\text{K}$  on the inner surface of the tube and  $h_o = 1400 \text{ W/m}^2\cdot\text{K}$  on its outer surface. For a fouling factor  $R_{f,i} = 0.0005 \text{ m}^2\cdot\text{K/W}$  on the tube side and  $R_{f,o} = 0.0002 \text{ m}^2\cdot\text{K/W}$  on the shell side, determine (a) the thermal resistance of the heat exchanger per unit length and (b) the overall heat transfer coefficients  $U_i$  and  $U_o$  based on the inner and outer surface areas of the tube, respectively.

**11–27**  Reconsider Prob. 11–26. Using EES (or other) software, investigate the effects of pipe conductivity and heat transfer coefficients on the thermal resistance of the heat exchanger. Let the thermal conductivity vary from 10 W/m·K to 400 W/m·K, the convection heat transfer coefficient from 500 W/m<sup>2</sup>·K to 1500 W/m<sup>2</sup>·K on the inner surface, and from 1000 W/m<sup>2</sup>·K to 2000 W/m<sup>2</sup>·K on the outer surface. Plot the thermal resistance of the heat exchanger as functions of thermal conductivity and heat transfer coefficients, and discuss the results.

**11–28** Hot engine oil with heat capacity rate of 4440 W/K (product of mass flow rate and specific heat) and an inlet temperature of 150°C flows through a double pipe heat exchanger. The double pipe heat exchanger is constructed of a 1.5-m-long copper pipe ( $k = 250 \text{ W/m}\cdot\text{K}$ ) with an inner tube of inside diameter 2 cm and outside tube diameter of 2.25 cm. The inner diameter of the outer tube of the double pipe heat exchanger is 6 cm. Oil flowing at a rate of 2 kg/s through inner tube exits the heat exchanger

at a temperature of 50°C. The cold fluid, i.e., water enters the heat exchanger at 20°C and exits at 70°C. Assuming the fouling factor on the oil side and water side to be 0.00015 m<sup>2</sup>·K/W and 0.0001 m<sup>2</sup>·K/W, respectively, determine the overall heat transfer coefficient on inner and outer surface of the copper tube.

### Analysis of Heat Exchangers

**11–29C** What are the common approximations made in the analysis of heat exchangers?

**11–30C** Under what conditions is the heat transfer relation

$$\dot{Q} = \dot{m}_c c_{pc} (T_{c,\text{out}} - T_{c,\text{in}}) = \dot{m}_h c_{ph} (T_{h,\text{in}} - T_{h,\text{out}})$$

valid for a heat exchanger?

**11–31C** Consider a condenser in which steam at a specified temperature is condensed by rejecting heat to the cooling water. If the heat transfer rate in the condenser and the temperature rise of the cooling water is known, explain how the rate of condensation of the steam and the mass flow rate of the cooling water can be determined. Also, explain how the total thermal resistance  $R$  of this condenser can be evaluated in this case.

**11–32C** What is the heat capacity rate? What can you say about the temperature changes of the hot and cold fluids in a heat exchanger if both fluids have the same capacity rate? What does a heat capacity of infinity for a fluid in a heat exchanger mean?

**11–33C** Under what conditions will the temperature rise of the cold fluid in a heat exchanger be equal to the temperature drop of the hot fluid?

**11–34** Show that the temperature profile of two fluid streams (hot and cold) that have the same heat capacity rates is parallel to each other at every section of the counter flow heat exchanger. *Hint:* Refer to the analysis presented in Sections 11–3 and 11–4 of the textbook.

### The Log Mean Temperature Difference Method

**11–35C** In the heat transfer relation  $\dot{Q} = UA_s \Delta T_{lm}$  for a heat exchanger, what is  $\Delta T_{lm}$  called? How is it calculated for a parallel-flow and counter-flow heat exchanger?

**11–36C** How does the log mean temperature difference for a heat exchanger differ from the arithmetic mean temperature difference? For specified inlet and outlet temperatures, which one of these two quantities is larger?

**11–37C** The temperature difference between the hot and cold fluids in a heat exchanger is given to be  $\Delta T_1$  at one end and  $\Delta T_2$  at the other end. Can the logarithmic temperature difference  $\Delta T_{lm}$  of this heat exchanger be greater than both  $\Delta T_1$  and  $\Delta T_2$ ? Explain.

**11–38C** Can the outlet temperature of the cold fluid in a heat exchanger be higher than the outlet temperature of the hot fluid in a parallel-flow heat exchanger? How about in a counter-flow heat exchanger? Explain.

**11–39C** Explain how the LMTD method can be used to determine the heat transfer surface area of a multipass shell-and-tube heat exchanger when all the necessary information, including the outlet temperatures, is given.

**11–40C** In the heat transfer relation  $\dot{Q} = UA_s F \Delta T_{lm}$  for a heat exchanger, what is the quantity  $F$  called? What does it represent? Can  $F$  be greater than one?

**11–41C** When the outlet temperatures of the fluids in a heat exchanger are not known, is it still practical to use the LMTD method? Explain.

**11–42C** For specified inlet and outlet temperatures, for what kind of heat exchanger will the  $\Delta T_{lm}$  be greatest: double-pipe parallel-flow, double-pipe counter-flow, cross-flow, or multipass shell-and-tube heat exchanger?

**11–43** A double-pipe parallel-flow heat exchanger is used to heat cold tap water with hot water. Hot water ( $c_p = 4.25 \text{ kJ/kg}\cdot\text{K}$ ) enters the tube at 85°C at a rate of 1.4 kg/s and leaves at 50°C. The heat exchanger is not well insulated, and it is estimated that 3 percent of the heat given up by the hot fluid is lost from the heat exchanger. If the overall heat transfer coefficient and the surface area of the heat exchanger are 1150 W/m<sup>2</sup>·K and 4 m<sup>2</sup>, respectively, determine the rate of heat transfer to the cold water and the log mean temperature difference for this heat exchanger.

FIGURE P11–43

**11–44** A stream of hydrocarbon ( $c_p = 2.2 \text{ kJ/kg}\cdot\text{K}$ ) is cooled at a rate of 720 kg/h from 150°C to 40°C in the tube side of a double-pipe counter-flow heat exchanger. Water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) enters the heat exchanger at 10°C at a rate of 540 kg/h. The outside diameter of the inner tube is 2.5 cm, and its length is 6.0 m. Calculate the overall heat transfer coefficient.

**11–45** A double-pipe parallel-flow heat exchanger is to heat water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) from 25°C to 60°C at a rate of 0.2 kg/s. The heating is to be accomplished by geothermal water ( $c_p = 4310 \text{ J/kg}\cdot\text{K}$ ) available at 140°C at a mass flow rate of 0.3 kg/s. The inner tube is thin-walled and has a diameter of 0.8 cm. If the overall heat transfer coefficient of the heat exchanger is 550 W/m<sup>2</sup>·K, determine the length of the tube required to achieve the desired heating.

**11–46**  Reconsider Prob. 11–45. Using EES (or other) software, investigate the effects of temperature and mass flow rate of geothermal water on the length of the tube. Let the temperature vary from 100°C to 200°C, and the mass flow

rate from 0.1 kg/s to 0.5 kg/s. Plot the length of the tube as functions of temperature and mass flow rate, and discuss the results.

**11-47** Glycerin ( $c_p = 2400 \text{ J/kg}\cdot\text{K}$ ) at 20°C and 0.5 kg/s is to be heated by ethylene glycol ( $c_p = 2500 \text{ J/kg}\cdot\text{K}$ ) at 60°C in a thin-walled double-pipe parallel-flow heat exchanger. The temperature difference between the two fluids is 15°C at the outlet of the heat exchanger. If the overall heat transfer coefficient is 240 W/m<sup>2</sup>·K and the heat transfer surface area is 3.2 m<sup>2</sup>, determine (a) the rate of heat transfer, (b) the outlet temperature of the glycerin, and (c) the mass flow rate of the ethylene glycol.

**11-48** A heat exchanger contains 400 tubes with inner diameter of 23 mm and outer diameter of 25 mm. The length of each tube is 3.7 m. The corrected log mean temperature difference is 23°C, while the inner surface convection heat transfer coefficient is 3410 W/m<sup>2</sup>·K and the outer surface convection heat transfer coefficient is 6820 W/m<sup>2</sup>·K. If the thermal resistance of the tubes is negligible, determine the heat transfer rate.

**11-49E** A single pass heat exchanger is to be designed to heat 100,000 lbm of water in an hour from 60°F to 100°F by condensation of water vapor at 230°F on the shell side. Each tube has an inner diameter of 1.2 in. and a wall thickness of 0.12 in. The inner surface convection heat transfer coefficient is 480 Btu/h·ft<sup>2</sup>·°F and the outer surface convection heat transfer coefficient is 2000 Btu/h·ft<sup>2</sup>·°F. If the inlet velocity of water ( $c_{pc} = 1 \text{ Btu/lbm}\cdot^{\circ}\text{F}$  and  $\rho = 62.3 \text{ lbm/ft}^3$ ) on the tube side is 4 ft/s, determine the required number of tubes and length of tubes. Assume the thermal resistance of the tubes is negligible.

**11-50** Consider the flow of engine oil ( $c_p = 2048 \text{ J/kg}\cdot\text{K}$ ) through a thin walled copper tube at a rate of 0.3 kg/s. The engine oil that enters the copper tube at an inlet temperature of 80°C is to be cooled by cold water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) flowing at a temperature of 20°C. It is desired to have exit temperature of the engine oil not greater than 40°C. The individual convective heat transfer coefficients on oil and water sides are 750 W/m<sup>2</sup>·K and 350 W/m<sup>2</sup>·K, respectively. If a thermocouple probe installed on the downstream side of the cooling water measures a temperature of 32°C, for a double pipe parallel flow heat exchanger determine (a) mass flow rate of the cooling water (b) log mean temperature difference and (c) area of heat exchanger.

FIGURE P11-50

**11-51** In a parallel flow heat exchanger, hot fluid enters the heat exchanger at a temperature of 150°C and a mass flow rate of 3 kg/s. The cooling medium enters the heat exchanger at a temperature of 30°C with a mass flow rate of 0.5 kg/s and leaves at a temperature of 70°C. The specific heat capacities of the hot and cold fluids are 1150 J/kg·K and 4180 J/kg·K, respectively. The convection heat transfer coefficient on the inner and outer side of the tube is 300 W/m<sup>2</sup>·K and 800 W/m<sup>2</sup>·K, respectively. For a fouling factor of 0.0003 m<sup>2</sup>·K/W on the tube side and 0.0001 m<sup>2</sup>·K/W on the shell side, determine (a) the overall heat transfer coefficient, (b) the exit temperature of the hot fluid and (c) surface area of the heat exchanger.

**11-52** Ethylene glycol is heated from 25°C to 40°C at a rate of 2.5 kg/s in a horizontal copper tube ( $k = 386 \text{ W/m}\cdot\text{K}$ ) with an inner diameter of 2.0 cm and an outer diameter of 2.5 cm. A saturated vapor ( $T_g = 110^\circ\text{C}$ ) condenses on the outside-tube surface with the heat transfer coefficient (in kW/m<sup>2</sup>·K) given by  $9.2/(T_g - T_w)^{0.25}$ , where  $T_w$  is the average outside-tube wall temperature. What tube length must be used? Take the properties of ethylene glycol to be  $\rho = 1109 \text{ kg/m}^3$ ,  $c_p = 2428 \text{ J/kg}\cdot\text{K}$ ,  $k = 0.253 \text{ W/m}\cdot\text{K}$ ,  $\mu = 0.01545 \text{ kg/m}\cdot\text{s}$ , and  $\Pr = 148.5$ .

**11-53** A counter-flow heat exchanger is stated to have an overall heat transfer coefficient of 284 W/m<sup>2</sup>·K when operating at design and clean conditions. Hot fluid enters the tube side at 93°C and exits at 71°C, while cold fluid enters the shell side at 27°C and exits at 38°C. After a period of use, built-up scale in the heat exchanger gives a fouling factor of 0.0004 m<sup>2</sup>·K/W. If the surface area is 93 m<sup>2</sup>, determine (a) the rate of heat transfer in the heat exchanger and (b) the mass flow rates of both hot and cold fluids. Assume both hot and cold fluids have a specific heat of 4.2 kJ/kg·K.

FIGURE P11-53

**11-54** A thin-walled double-pipe counter-flow heat exchanger is to be used to cool oil ( $c_p = 2200 \text{ J/kg}\cdot\text{K}$ ) from 150°C to 40°C at a rate of 2 kg/s by water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) that enters at 22°C at a rate of 1.5 kg/s. The diameter of the tube is 2.5 cm, and its length is 6 m. Determine the overall heat transfer coefficient of this heat exchanger.

- 11-55**  Reconsider Prob. 11-54. Using EES (or other) software, investigate the effects of oil exit temperature and water inlet temperature on the overall heat transfer coefficient of the heat exchanger. Let the oil exit temperature vary from 30°C to 70°C and the water inlet temperature from 5°C to 25°C. Plot the overall heat transfer coefficient as functions of the two temperatures, and discuss the results.

- 11-56** Engine oil ( $c_p = 2100 \text{ J/kg}\cdot\text{K}$ ) is to be heated from 20°C to 60°C at a rate of 0.3 kg/s in a 2-cm-diameter thin-walled copper tube by condensing steam outside at a temperature of 130°C ( $h_{fg} = 2174 \text{ kJ/kg}$ ). For an overall heat transfer coefficient of 650 W/m<sup>2</sup>·K, determine the rate of heat transfer and the length of the tube required to achieve it.

Answers: 25.2 kW, 7.0 m

FIGURE P11-56

- 11-57E** Geothermal water ( $c_p = 1.03 \text{ Btu/lbm}\cdot^\circ\text{F}$ ) is to be used as the heat source to supply heat to the hydronic heating system of a house at a rate of 40 Btu/s in a double-pipe counter-flow heat exchanger. Water ( $c_p = 1.0 \text{ Btu/lbm}\cdot^\circ\text{F}$ ) is heated from 140°F to 200°F in the heat exchanger as the geothermal water is cooled from 270°F to 180°F. Determine the mass flow rate of each fluid and the total thermal resistance of this heat exchanger.

- 11-58** Cold water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) leading to a shower enters a thin-walled double-pipe counter-flow heat exchanger at 15°C at a rate of 1.25 kg/s and is heated to 45°C by hot water ( $c_p = 4190 \text{ J/kg}\cdot\text{K}$ ) that enters at 100°C at a rate of 3 kg/s. If the overall heat transfer coefficient is 880 W/m<sup>2</sup>·K, determine the rate of heat transfer and the heat transfer surface area of the heat exchanger.

- 11-59E** Steam is to be condensed on the shell side of a 1-shell-pass and 8-tube-passes condenser, with 50 tubes in each pass at 90°F ( $h_{fg} = 1043 \text{ Btu/lbm}$ ). Cooling water ( $c_p = 1.0 \text{ Btu/lbm}\cdot^\circ\text{F}$ ) enters the tubes at 60°F and leaves at 73°F. The tubes are thin walled and have a diameter of 3/4 in and length of 5 ft per pass. If the overall heat transfer coefficient is 600 Btu/h·ft<sup>2</sup>·°F, determine (a) the rate of heat transfer, (b) the rate of condensation of steam, and (c) the mass flow rate of cold water.

FIGURE P11-59E

- 11-60E**  Reconsider Prob. 11-59E. Using EES (or other) software, investigate the effect of the condensing steam temperature on the rate of heat transfer, the rate of condensation of steam, and the mass flow rate of cold water. Let the steam temperature vary from 80°F to 120°F. Plot the rate of heat transfer, the condensation rate of steam, and the mass flow rate of cold water as a function of steam temperature, and discuss the results.

- 11-61** Hot exhaust gases of a stationary diesel engine are to be used to generate steam in an evaporator. Exhaust gases ( $c_p = 1051 \text{ J/kg}\cdot\text{K}$ ) enter the heat exchanger at 550°C at a rate of 0.25 kg/s while water enters as saturated liquid and evaporates at 200°C ( $h_{fg} = 1941 \text{ kJ/kg}$ ). The heat transfer surface area of the heat exchanger based on water side is 0.5 m<sup>2</sup> and overall heat transfer coefficient is 1780 W/m<sup>2</sup>·K. Determine the rate of heat transfer, the exit temperature of exhaust gases, and the rate of evaporation of water.

- 11-62**  Reconsider Prob. 11-61. Using EES (or other) software, investigate the effect of the exhaust gas inlet temperature on the rate of heat transfer, the exit temperature of exhaust gases, and the rate of evaporation of water. Let the temperature of exhaust gases vary from 300°C to 600°C. Plot the rate of heat transfer, the exit temperature of exhaust gases, and the rate of evaporation of water as a function of the temperature of the exhaust gases, and discuss the results.

- 11-63** In a textile manufacturing plant, the waste dyeing water ( $c_p = 4295 \text{ J/kg}\cdot\text{K}$ ) at 75°C is to be used to preheat fresh water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) at 15°C at the same flow rate in a double-pipe counter-flow heat exchanger. The heat transfer surface area of the heat exchanger is 1.65 m<sup>2</sup> and the overall heat transfer coefficient is 625 W/m<sup>2</sup>·K. If the rate of heat transfer in the heat exchanger is 35 kW, determine the outlet temperature and the mass flow rate of each fluid stream.

FIGURE P11-63

**11-64** A performance test is being conducted on a double pipe counter flow heat exchanger that carries engine oil and water at a flow rate of 2.5 kg/s and 1.75 kg/s, respectively. Since the heat exchanger has been in service over a long period of time it is suspected that the fouling might have developed inside the heat exchanger that might have affected the overall heat transfer coefficient. The test to be carried out is such that, for a designed value of the overall heat transfer coefficient of 450 W/m<sup>2</sup>·K and a surface area of 7.5 m<sup>2</sup>, the oil must be heated from 25°C to 55 °C by passing hot water at 100°C ( $c_p = 4206 \text{ J/kg}\cdot\text{K}$ ) at the flow rates mentioned above. Determine if the fouling has affected the overall heat transfer coefficient. If yes, then what is the magnitude of the fouling resistance?

**11-65** In an industrial facility a counter flow double pipe heat exchanger uses superheated steam at a temperature of 250°C to heat feed water at 30°C. The superheated steam experiences a temperature drop of 70°C as it exits the heat exchanger. The water to be heated flows through the heat exchanger tube of negligible thickness at a constant rate of 3.47 kg/s. The convective heat transfer coefficient on the superheated steam and water side is 850 W/m<sup>2</sup>·K and 1250 W/m<sup>2</sup>·K, respectively. To account for the fouling due to chemical impurities that might be present in the feed water, use an appropriate fouling factor for the water side. Determine (a) the heat exchanger area required to maintain the exit temperature of the water to a minimum of 70°C, and (b) what would be the required heat exchanger area in case of parallel flow arrangement?

FIGURE P11-65

**11-66** A test is conducted to determine the overall heat transfer coefficient in a shell-and-tube oil-to-water heat exchanger that has 24 tubes of internal diameter 1.2 cm and length 2 m in a single shell. Cold water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ )

enters the tubes at 20°C at a rate of 3 kg/s and leaves at 55°C. Oil ( $c_p = 2150 \text{ J/kg}\cdot\text{K}$ ) flows through the shell and is cooled from 120°C to 45°C. Determine the overall heat transfer coefficient  $U_i$  of this heat exchanger based on the inner surface area of the tubes. *Answer: 8.31 kW/m<sup>2</sup>·K*

**11-67** A shell-and-tube heat exchanger is used for heating 10 kg/s of oil ( $c_p = 2.0 \text{ kJ/kg}\cdot\text{K}$ ) from 25°C to 46°C. The heat exchanger has 1-shell pass and 6-tube passes. Water enters the shell side at 80°C and leaves at 60°C. The overall heat transfer coefficient is estimated to be 1000 W/m<sup>2</sup>·K. Calculate the rate of heat transfer and the heat transfer area.

**11-68E** A 1-shell-pass and 8-tube-passes heat exchanger is used to heat glycerin ( $c_p = 0.60 \text{ Btu/lbm}\cdot^{\circ}\text{F}$ ) from 65°F to 140°F by hot water ( $c_p = 1.0 \text{ Btu/lbm}\cdot^{\circ}\text{F}$ ) that enters the thin-walled 0.5-in-diameter tubes at 175°F and leaves at 120°F. The total length of the tubes in the heat exchanger is 500 ft. The convection heat transfer coefficient is 4 Btu/h·ft<sup>2</sup>·°F on the glycerin (shell) side and 50 Btu/h·ft<sup>2</sup>·°F on the water (tube) side. Determine the rate of heat transfer in the heat exchanger (a) before any fouling occurs and (b) after fouling with a fouling factor of 0.002 h·ft<sup>2</sup>·°F/Btu on the outer surfaces of the tubes.

**11-69** A shell-and-tube heat exchanger with 2-shell passes and 12-tube passes is used to heat water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) with ethylene glycol ( $c_p = 2680 \text{ J/kg}\cdot\text{K}$ ). Water enters the tubes at 22°C at a rate of 0.8 kg/s and leaves at 70°C. Ethylene glycol enters the shell at 110°C and leaves at 60°C. If the overall heat transfer coefficient based on the tube side is 280 W/m<sup>2</sup>·K, determine the rate of heat transfer and the heat transfer surface area on the tube side.

**11-70** Reconsider Prob. 11-69. Using EES (or other) software, investigate the effect of the mass flow rate of water on the rate of heat transfer and the tube-side surface area. Let the mass flow rate vary from 0.4 kg/s to 2.2 kg/s. Plot the rate of heat transfer and the surface area as a function of the mass flow rate, and discuss the results.

**11-71E** Oil is being cooled from 180°F to 120°F in a 1-shell and 2-tube heat exchanger with an overall heat transfer coefficient of 40 Btu/h ft<sup>2</sup>·°F. Water ( $c_{pc} = 1.0 \text{ Btu/lbm}\cdot^{\circ}\text{F}$ ) enters at 80°F and exits at 100°F with a mass flow rate of 20,000 lbm/h, determine (a) the log mean temperature difference and (b) the surface area of the heat exchanger.

FIGURE P11-71E

**11-72** A shell-and-tube heat exchanger with 2-shell passes and 12-tube passes is used to heat water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) in

the tubes from 20°C to 70°C at a rate of 4.5 kg/s. Heat is supplied by hot oil ( $c_p = 2300 \text{ J/kg}\cdot\text{K}$ ) that enters the shell side at 170°C at a rate of 10 kg/s. For a tube-side overall heat transfer coefficient of 350 W/m<sup>2</sup>·K, determine the heat transfer surface area on the tube side. *Answer: 25.7 m<sup>2</sup>*

**11-73** Repeat Prob. 11-72 for a mass flow rate of 3 kg/s for water.

**11-74** A shell-and-tube heat exchanger with 2-shell passes and 8-tube passes is used to heat ethyl alcohol ( $c_p = 2670 \text{ J/kg}\cdot\text{K}$ ) in the tubes from 25°C to 70°C at a rate of 2.1 kg/s. The heating is to be done by water ( $c_p = 4190 \text{ J/kg}\cdot\text{K}$ ) that enters the shell side at 95°C and leaves at 45°C. If the overall heat transfer coefficient is 950 W/m<sup>2</sup>·K, determine the heat transfer surface area of the heat exchanger.

FIGURE P11-74

**11-75** Consider a shell and tube heat exchanger in a milk pasteurizing unit in which the milk flowing is to be heated from 20°C by hot water initially at 140°C and flowing at a rate of 5 kg/s. The milk flows through 30 thin-walled tubes with an inside diameter of 20 mm with each tube making 10 passes through the shell. The average convective heat transfer coefficients on the milk and water side are 450 W/m<sup>2</sup>·K and 1100 W/m<sup>2</sup>·K, respectively. In order to complete the pasteurizing process and hence restrict the microbial growth in the milk, it is required to have the exit temperature of milk attain at least 70°C. As a design engineer, your job is to decide upon the shell width (tube length in each pass) so that the milk exit temperature of 70°C can be achieved. One of the design requirements is that the exit temperature of hot water should be at least 10°C higher than the exit temperature of milk.

FIGURE P11-75

**11-76E** A single-pass cross-flow heat exchanger is used to cool jacket water ( $c_p = 1.0 \text{ Btu/lbm}\cdot^{\circ}\text{F}$ ) of a diesel engine from 190°F to 140°F, using air ( $c_p = 0.245 \text{ Btu/lbm}\cdot^{\circ}\text{F}$ ) with inlet temperature of 90°F. Both air flow and water flow are unmixed. If the water and air mass flow rates are 92,000 lbm/h and 400,000 lbm/h, respectively, determine the log mean temperature difference for this heat exchanger.

FIGURE P11-76

**11-77** A single-pass cross-flow heat exchanger with both fluids unmixed has water entering at 16°C and exiting at 33°C, while oil ( $c_p = 1.93 \text{ kJ/kg}\cdot\text{K}$  and  $\rho = 870 \text{ kg/m}^3$ ) flowing at 0.19 m<sup>3</sup>/min enters at 38°C and exits at 29°C. If the surface area of the heat exchanger is 20 m<sup>2</sup>, determine the value of the overall heat transfer coefficient.

FIGURE P11-77

### The Effectiveness–NTU Method

**11-78C** What does the effectiveness of a heat exchanger represent? Can effectiveness be greater than one? On what factors does the effectiveness of a heat exchanger depend?

**11-79C** For a specified fluid pair, inlet temperatures, and mass flow rates, what kind of heat exchanger will have the highest effectiveness: double-pipe parallel-flow, double-pipe counter-flow, cross-flow, or multipass shell-and-tube heat exchanger?

**11-80C** Explain how you can evaluate the outlet temperatures of the cold and hot fluids in a heat exchanger after its effectiveness is determined.

**11-81C** Can the temperature of the hot fluid drop below the inlet temperature of the cold fluid at any location in a heat exchanger? Explain.

**11–82C** Can the temperature of the cold fluid rise above the inlet temperature of the hot fluid at any location in a heat exchanger? Explain.

**11–83C** Consider a heat exchanger in which both fluids have the same specific heats but different mass flow rates. Which fluid will experience a larger temperature change: the one with the lower or higher mass flow rate?

**11–84C** Explain how the maximum possible heat transfer rate  $\dot{Q}_{\max}$  in a heat exchanger can be determined when the mass flow rates, specific heats, and the inlet temperatures of the two fluids are specified. Does the value of  $\dot{Q}_{\max}$  depend on the type of the heat exchanger?

**11–85C** Under what conditions can a counter-flow heat exchanger have an effectiveness of one? What would your answer be for a parallel-flow heat exchanger?

**11–86C** Consider a double-pipe counter-flow heat exchanger. In order to enhance heat transfer, the length of the heat exchanger is now doubled. Do you think its effectiveness will also double?

**11–87C** Consider a shell-and-tube water-to-water heat exchanger with identical mass flow rates for both the hot- and cold-water streams. Now the mass flow rate of the cold water is reduced by half. Will the effectiveness of this heat exchanger increase, decrease, or remain the same as a result of this modification? Explain. Assume the overall heat transfer coefficient and the inlet temperatures remain the same.

**11–88C** Consider two double-pipe counter-flow heat exchangers that are identical except that one is twice as long as the other one. Which heat exchanger is more likely to have a higher effectiveness?

**11–89C** How is the NTU of a heat exchanger defined? What does it represent? Is a heat exchanger with a very large NTU (say, 10) necessarily a good one to buy?

**11–90C** Consider a heat exchanger that has an NTU of 4. Someone proposes to double the size of the heat exchanger and thus double the NTU to 8 in order to increase the effectiveness of the heat exchanger and thus save energy. Would you support this proposal?

**11–91C** Consider a heat exchanger that has an NTU of 0.1. Someone proposes to triple the size of the heat exchanger and thus triple the NTU to 0.3 in order to increase the effectiveness of the heat exchanger and thus save energy. Would you support this proposal?

**11–92** The radiator in an automobile is a cross-flow heat exchanger ( $UA_s = 10 \text{ kW/K}$ ) that uses air ( $c_p = 1.00 \text{ kJ/kg}\cdot\text{K}$ ) to cool the engine-coolant fluid ( $c_p = 4.00 \text{ kJ/kg}\cdot\text{K}$ ). The engine fan draws  $30^\circ\text{C}$  air through this radiator at a rate of  $10 \text{ kg/s}$  while the coolant pump circulates the engine coolant at a rate of  $5 \text{ kg/s}$ . The coolant enters this radiator at  $80^\circ\text{C}$ . Under these conditions, the effectiveness of the radiator is 0.4. Determine (a) the outlet temperature of the air and (b) the rate of heat transfer between the two fluids.

**11–93** Consider an oil-to-oil double-pipe heat exchanger whose flow arrangement is not known. The temperature measurements indicate that the cold oil enters at  $20^\circ\text{C}$  and leaves at  $55^\circ\text{C}$ , while the hot oil enters at  $80^\circ\text{C}$  and leaves at  $45^\circ\text{C}$ . Do you think this is a parallel-flow or counter-flow heat exchanger? Why? Assuming the mass flow rates of both fluids to be identical, determine the effectiveness of this heat exchanger.

**11–94E** Hot water enters a double-pipe counter-flow water-to-oil heat exchanger at  $190^\circ\text{F}$  and leaves at  $100^\circ\text{F}$ . Oil enters at  $70^\circ\text{F}$  and leaves at  $130^\circ\text{F}$ . Determine which fluid has the smaller heat capacity rate and calculate the effectiveness of this heat exchanger.

**11–95** Glycerin ( $c_p = 2400 \text{ J/kg}\cdot\text{K}$ ) at  $20^\circ\text{C}$  and  $0.3 \text{ kg/s}$  is to be heated by ethylene glycol ( $c_p = 2500 \text{ J/kg}\cdot\text{K}$ ) at  $60^\circ\text{C}$  and the same mass flow rate in a thin-walled double-pipe parallel-flow heat exchanger. If the overall heat transfer coefficient is  $380 \text{ W/m}^2\cdot\text{K}$  and the heat transfer surface area is  $5.3 \text{ m}^2$ , determine (a) the rate of heat transfer and (b) the outlet temperatures of the glycerin and the glycol.

**11–96** Hot water ( $c_{ph} = 4188 \text{ J/kg}\cdot\text{K}$ ) with mass flow rate of  $2.5 \text{ kg/s}$  at  $100^\circ\text{C}$  enters a thin-walled concentric tube counter-flow heat exchanger with a surface area of  $23 \text{ m}^2$  and an overall heat transfer coefficient of  $1000 \text{ W/m}^2\cdot\text{K}$ . Cold water ( $c_{pc} = 4178 \text{ J/kg}\cdot\text{K}$ ) with mass flow rate of  $5 \text{ kg/s}$  enters the heat exchanger at  $20^\circ\text{C}$ , determine (a) the heat transfer rate for the heat exchanger and (b) the outlet temperatures of the cold and hot fluids. After a period of operation, the overall heat transfer coefficient is reduced to  $500 \text{ W/m}^2\cdot\text{K}$ , determine (c) the fouling factor that caused the reduction in the overall heat transfer coefficient.

**11–97** Water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) is to be heated by solar-heated hot air ( $c_p = 1010 \text{ J/kg}\cdot\text{K}$ ) in a double-pipe counter-flow heat exchanger. Air enters the heat exchanger at  $90^\circ\text{C}$  at a rate of  $0.3 \text{ kg/s}$ , while water enters at  $22^\circ\text{C}$  at a rate of  $0.1 \text{ kg/s}$ . The overall heat transfer coefficient based on the inner side of the tube is given to be  $80 \text{ W/m}^2\cdot\text{K}$ . The length of the tube is  $12 \text{ m}$  and the internal diameter of the tube is  $1.2 \text{ cm}$ . Determine the outlet temperatures of the water and the air.

**11–98**  Reconsider Prob. 11–97. Using EES (or other) software, investigate the effects of the mass flow rate of water and the tube length on the outlet temperatures of water and air. Let the mass flow rate vary from  $0.05 \text{ kg/s}$  to  $1.0 \text{ kg/s}$  and the tube length from  $5 \text{ m}$  to  $25 \text{ m}$ . Plot the outlet temperatures of the water and the air as functions of the mass flow rate and the tube length, and discuss the results.

**11–99** Cold water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) leading to a shower enters a thin-walled double-pipe counter-flow heat exchanger at  $15^\circ\text{C}$  at a rate of  $0.25 \text{ kg/s}$  and is heated to  $45^\circ\text{C}$  by hot water ( $c_p = 4190 \text{ J/kg}\cdot\text{K}$ ) that enters at  $100^\circ\text{C}$  at a rate of  $3 \text{ kg/s}$ . If the overall heat transfer coefficient is  $950 \text{ W/m}^2\cdot\text{K}$ , determine the rate of heat transfer and the heat transfer

surface area of the heat exchanger using the  $\varepsilon$ -NTU method.

*Answers:* 31.35 kW, 0.482 m<sup>2</sup>

FIGURE P11-99

- 11-100** Reconsider Prob. 11-99. Using EES (or other) software, investigate the effects of the inlet temperature of hot water and the heat transfer coefficient on the rate of heat transfer and the surface area. Let the inlet temperature vary from 60°C to 120°C and the overall heat transfer coefficient from 750 W/m<sup>2</sup>·K to 1250 W/m<sup>2</sup>·K. Plot the rate of heat transfer and surface area as functions of the inlet temperature and the heat transfer coefficient, and discuss the results.

**11-101E** A thin-walled double-pipe, counter-flow heat exchanger is to be used to cool oil ( $c_p = 0.525 \text{ Btu/lbm} \cdot ^\circ\text{F}$ ) from 300°F to 105°F at a rate of 5 lbm/s by water ( $c_p = 1.0 \text{ Btu/lbm} \cdot ^\circ\text{F}$ ) that enters at 70°F at a rate of 3 lbm/s. The diameter of the tube is 5 in and its length is 200 ft. Determine the overall heat transfer coefficient of this heat exchanger using (a) the LMTD method and (b) the  $\varepsilon$ -NTU method.

**11-102** In an industrial facility, a countercurrent double-pipe heat exchanger is used to heat the glycerin flowing at a rate of 1.5 kg/s from 10°C to 50°C by passing hot water at an inlet temperature of 120°C. The hot water experiences a temperature drop of 50°C as it flows through the heat exchanger. The overall heat transfer coefficient of the heat exchanger may be assumed to be 950 W/m<sup>2</sup>·K. A similar arrangement is to be installed at another location and it is proposed to use two small heat exchangers of same surface area to be arranged in series instead of one single large heat exchanger. However, it is first required to compare the surface area of the two small heat exchangers against that of the single large heat exchanger, since the available space is a major constraint for the proposed design. The arrangement of the heat exchangers is as shown in Fig. P11-102. The water flow rate is split between the two heat exchangers such that 60% would go to the first heat exchanger and the remaining 40% would go to the second heat exchanger. The overall heat transfer coefficient of the two small heat exchangers is assumed to remain same as that of the large heat exchanger. As a design engineer, for both cases determine the heat exchanger (a) effectiveness, (b) NTU, (c) surface area, and (d) choice of the heat exchanger if the construction cost of the smaller heat exchangers is about 15% higher than a single large heat exchanger per unit surface area.

FIGURE P11-102

**11-103E** A 1-shell and 2-tube type heat exchanger has an overall heat transfer coefficient of 300 Btu/h·ft<sup>2</sup>·°F. The shell side fluid has a heat capacity rate of 20,000 Btu/h·°F, while the tube side fluid has a heat capacity rate of 40,000 Btu/h·°F. The inlet temperatures on the shell side and tube side are 200°F and 90°F, respectively. If the total heat transfer area is 100 ft<sup>2</sup>, determine (a) the heat transfer effectiveness and (b) the actual heat transfer rate in the heat exchanger.

**11-104** In a 1-shell and 2-tube heat exchanger, cold water with inlet temperature of 20°C is heated by hot water supplied at the inlet at 80°C. The cold and hot water flow rates are 5000 kg/h and 10,000 kg/h, respectively. If the shell-and-tube heat exchanger has a  $UA_s$  value of 11,600 W/K, determine the cold water and hot water outlet temperatures. Assume  $c_{pc} = 4178 \text{ J/kg} \cdot \text{K}$  and  $c_{ph} = 4188 \text{ J/kg} \cdot \text{K}$ .

**11-105** Hot oil ( $c_p = 2200 \text{ J/kg} \cdot \text{K}$ ) is to be cooled by water ( $c_p = 4180 \text{ J/kg} \cdot \text{K}$ ) in a 2-shell-passes and 12-tube-passes heat exchanger. The tubes are thin-walled and are made of copper with a diameter of 1.8 cm. The length of each tube pass in the heat exchanger is 3 m, and the overall heat transfer coefficient is 340 W/m<sup>2</sup>·K. Water flows through the tubes at a total rate of 0.1 kg/s, and the oil through the shell at a rate of 0.2 kg/s. The water and the oil enter at temperatures 18°C and 160°C, respectively. Determine the rate of heat transfer in the heat exchanger and the outlet temperatures of the water and the oil.

*Answers:* 36.2 kW, 104.6°C, 77.7°C

FIGURE P11-105

**11-106E** Oil is being cooled from 180°F to 120°F in a 1-shell and 2-tube heat exchanger with an overall heat transfer coefficient of 40 Btu/h·ft<sup>2</sup>·°F. Water ( $c_{pc} = 1.0 \text{ Btu/lbm} \cdot ^\circ\text{F}$ ) enters at 80°F and exits at 100°F with a mass flow rate of 20,000 lbm/h, determine (a) the NTU value and (b) the surface area of the heat exchanger.

FIGURE P11-106E

**11-107** A shell-and-tube heat exchanger with 2-shell passes and 8-tube passes is used to heat ethyl alcohol ( $c_p = 2670 \text{ J/kg} \cdot \text{K}$ ) in the tubes from 25°C to 70°C at a rate of 2.1 kg/s. The heating is to be done by water ( $c_p = 4190 \text{ J/kg} \cdot \text{K}$ ) that enters the shell at 95°C and leaves at 60°C. If the overall heat transfer coefficient is 800 W/m<sup>2</sup>·K, determine the heat transfer surface area of the heat exchanger using (a) the LMTD method and (b) the  $\varepsilon$ -NTU method.  
*Answer: (a) 11.4 m<sup>2</sup>*

**11-108** Cold water ( $c_p = 4180 \text{ J/kg} \cdot \text{K}$ ) enters the tubes of a heat exchanger with 2-shell passes and 23-tube passes at 14°C at a rate of 3 kg/s, while hot oil ( $c_p = 2200 \text{ J/kg} \cdot \text{K}$ ) enters the shell at 200°C at the same mass flow rate. The overall heat transfer coefficient based on the outer surface of the tube is 300 W/m<sup>2</sup>·K and the heat transfer surface area on that side is 20 m<sup>2</sup>. Determine the rate of heat transfer using (a) the LMTD method and (b) the  $\varepsilon$ -NTU method.

**11-109E** In a one-shell and eight-tube pass heat exchanger, the temperature of water flowing at rate of 50,000 lbm/h is raised from 70°F to 150°F. Hot air ( $c_p = 0.25 \text{ Btu/lbm} \cdot ^\circ\text{F}$ ) that flows on the tube side enters the heat exchanger at 600°F and exits at 300°F. If the convection heat transfer coefficient on the outer surface of the tubes is 30 Btu/h·ft<sup>2</sup>·°F, determine the surface area of the heat exchanger using both LMTD and  $\varepsilon$ -NTU methods. Account for the possible fouling resistance of 0.0015 and 0.001 h·ft<sup>2</sup>·°F/Btu on water and air side, respectively.

**11-110** Air ( $c_p = 1005 \text{ J/kg} \cdot \text{K}$ ) enters a cross-flow heat exchanger at 20°C at a rate of 3 kg/s, where it is heated by a hot water stream ( $c_p = 4190 \text{ J/kg} \cdot \text{K}$ ) that enters the heat exchanger at 70°C at a rate of 1 kg/s. Determine the maximum heat transfer rate and the outlet temperatures of both fluids for that case.

**11-111** A cross-flow heat exchanger with both fluids unmixed has an overall heat transfer coefficient of 200 W/m<sup>2</sup>·K, and a heat transfer surface area of 400 m<sup>2</sup>. The hot fluid has a heat capacity of 40,000 W/K, while the cold fluid has a heat capacity of 80,000 W/K. If the inlet temperatures of both hot

and cold fluids are 80°C and 20°C, respectively, determine the exit temperature of the cold fluid.

**11-112** A cross-flow air-to-water heat exchanger with an effectiveness of 0.65 is used to heat water ( $c_p = 4180 \text{ J/kg} \cdot \text{K}$ ) with hot air ( $c_p = 1010 \text{ J/kg} \cdot \text{K}$ ). Water enters the heat exchanger at 20°C at a rate of 4 kg/s, while air enters at 100°C at a rate of 9 kg/s. If the overall heat transfer coefficient based on the water side is 260 W/m<sup>2</sup>·K, determine the heat transfer surface area of the heat exchanger on the water side. Assume both fluids are unmixed. *Answer: 52.4 m<sup>2</sup>*

**11-113** Cold water ( $c_p = 4.18 \text{ kJ/kg} \cdot \text{K}$ ) enters a cross-flow heat exchanger at 14°C at a rate of 0.35 kg/s where it is heated by hot air ( $c_p = 1.0 \text{ kJ/kg} \cdot \text{K}$ ) that enters the heat exchanger at 65°C at a rate of 0.8 kg/s and leaves at 25°C. Determine the maximum outlet temperature of the cold water and the effectiveness of this heat exchanger.

FIGURE P11-113

**11-114** Oil in an engine is being cooled by air in a cross-flow heat exchanger, where both fluids are unmixed. Oil ( $c_{ph} = 2047 \text{ J/kg} \cdot \text{K}$ ) flowing with a flow rate of 0.026 kg/s enters the heat exchanger at 75°C, while air ( $c_{pc} = 1007 \text{ J/kg} \cdot \text{K}$ ) enters at 30°C with a flow rate of 0.21 kg/s. The overall heat transfer coefficient of the heat exchanger is 53 W/m<sup>2</sup>·K and the total surface area is 1 m<sup>2</sup>. Determine (a) the heat transfer effectiveness and (b) the outlet temperature of the oil.

FIGURE P11-114

**11-115** A cross-flow heat exchanger consists of 80 thin-walled tubes of 3-cm diameter located in a duct of 1 m × 1 m cross section. There are no fins attached to the tubes. Cold water ( $c_p = 4180 \text{ J/kg} \cdot \text{K}$ ) enters the tubes at 18°C with an average

velocity of 3 m/s, while hot air ( $c_p = 1010 \text{ J/kg}\cdot\text{K}$ ) enters the channel at  $130^\circ\text{C}$  and 105 kPa at an average velocity of 12 m/s. If the overall heat transfer coefficient is  $130 \text{ W/m}^2\cdot\text{K}$ , determine the outlet temperatures of both fluids and the rate of heat transfer.

**FIGURE P11–115**

**11-116** Consider a recuperative cross flow heat exchanger (both fluids unmixed) used in a gas turbine system that carries the exhaust gases at a flow rate of  $7.5 \text{ kg/s}$  and a temperature of  $500^\circ\text{C}$ . The air initially at  $30^\circ\text{C}$  and flowing at a rate of  $15 \text{ kg/s}$  is to be heated in the recuperator. The convective heat transfer coefficients on the exhaust gas and air side are  $750 \text{ W/m}^2\cdot\text{K}$  and  $300 \text{ W/m}^2\cdot\text{K}$ , respectively. Due to long term use of the gas turbine the recuperative heat exchanger is subject to fouling on both gas and air side that offers a resistance of  $0.0004 \text{ m}^2\cdot\text{K/W}$  each. Take the properties of exhaust gas to be the same as that of air ( $c_p = 1069 \text{ J/kg}\cdot\text{K}$ ). If the exit temperature of the exhaust gas is  $320^\circ\text{C}$  determine (a) if the air could be heated to a temperature of  $150^\circ\text{C}$  (b) the area of heat exchanger (c) if the answer to part (a) is no, then determine what should be the air mass flow rate in order to attain the desired exit temperature of  $150^\circ\text{C}$  and (d) plot variation of the exit air temperature over a temperature range of  $75^\circ\text{C}$  to  $300^\circ\text{C}$  with air mass flow rate assuming all the other conditions remain the same.

**FIGURE P11–116**

**11-117** Consider operation of a single pass cross flow heat exchanger with water ( $c_p = 4193 \text{ J/kg}\cdot\text{K}$ ) (mixed) and methanol ( $c_p = 2577 \text{ J/kg}\cdot\text{K}$ ) (unmixed). Water entering and exiting the heat exchanger at  $90^\circ\text{C}$  and  $60^\circ\text{C}$ , respectively is used to heat the methanol initially at  $10^\circ\text{C}$ . The overall heat transfer coefficient and the total heat transfer rate is estimated to be  $650 \text{ W/m}^2\cdot\text{K}$  and  $250 \text{ kW}$ , respectively. In order to achieve an

effectiveness of at least 0.5, (a) what would be the mass flow rate of water and heat exchanger surface area? (b) If the mass flow rate of water is changed within  $\pm 30\%$  of that determined in part (a) with the same surface area ( $A_s$ ), plot the variation of heat transfer rate, methanol exit temperature, overall heat transfer coefficient and the effectiveness of heat exchanger with respect to change in the water flow rate.

**11-118** Consider a cross flow engine oil heater that uses ethylene glycol flowing at a temperature of  $110^\circ\text{C}$  to heat the oil initially at  $10^\circ\text{C}$ . The ethylene glycol enters a tube bank consisting of copper tubes ( $k = 250 \text{ W/m}\cdot\text{K}$ ) with staggered arrangement in a  $0.5 \text{ m} \times 0.5 \text{ m}$  plenum. The outside diameter of the  $0.5\text{-m}$ -long copper tubes is 25 mm and has a wall thickness of 2 mm. The longitudinal and transverse pitch of the rod bundles is 0.035 m each. The engine oil to be heated flows inside the tubes with a mass flow rate of  $4.05 \text{ kg/s}$ . Take the heat transfer coefficient of the oil to be  $2500 \text{ W/m}^2\cdot\text{K}$ . If the minimum desired exit temperature of oil is  $70^\circ\text{C}$  and the measured exit temperature of ethylene glycol is  $90^\circ\text{C}$ , determine (a) mass flow rate of ethylene glycol and (b) number of tube rows. In your calculation use the following properties for the ethylene glycol.

$$\rho = 1062 \text{ kg/m}^3 \quad \mu = 2.499 \times 10^{-3} \text{ kg/m}\cdot\text{s}$$

$$k = 0.262 \text{ W/m}\cdot\text{K} \quad c_p = 2742 \text{ J/kg}\cdot\text{K}$$

$$\Pr = 26.12 \quad \Pr_{s@40^\circ\text{C}} = 96.97$$

**FIGURE P11–118**

**11-119** Water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) enters the 2.5-cm-internal-diameter tube of a double-pipe counter-flow heat exchanger at  $17^\circ\text{C}$  at a rate of  $1.8 \text{ kg/s}$ . Water is heated by steam condensing at  $120^\circ\text{C}$  ( $h_{fg} = 2203 \text{ kJ/kg}$ ) in the shell. If the overall heat transfer coefficient of the heat exchanger is  $700 \text{ W/m}^2\cdot\text{K}$ , determine the length of the tube required in order to heat the water to  $80^\circ\text{C}$  using (a) the LMTD method and (b) the  $\varepsilon$ –NTU method.

**11-120** Ethanol is vaporized at  $78^\circ\text{C}$  ( $h_{fg} = 846 \text{ kJ/kg}$ ) in a double-pipe parallel-flow heat exchanger at a rate of  $0.03 \text{ kg/s}$  by hot oil ( $c_p = 2200 \text{ J/kg}\cdot\text{K}$ ) that enters at  $120^\circ\text{C}$ . If the heat transfer surface area and the overall heat transfer coefficients are  $6.2 \text{ m}^2$  and  $320 \text{ W/m}^2\cdot\text{K}$ , respectively, determine the outlet temperature and the mass flow rate of oil using (a) the LMTD method and (b) the  $\varepsilon$ –NTU method.

FIGURE P11–120

- 11–121** Saturated water vapor at 100°C condenses in a 1-shell and 2-tube heat exchanger with a surface area of 0.5 m<sup>2</sup> and an overall heat transfer coefficient of 2000 W/m<sup>2</sup>·K. Cold water ( $c_{pc} = 4179 \text{ J/kg}\cdot\text{K}$ ) flowing at 0.5 kg/s enters the tube side at 15°C, determine (a) the heat transfer effectiveness, (b) the outlet temperature of the cold water, and (c) the heat transfer rate for the heat exchanger.

FIGURE P11–121

- 11–122** Steam is to be condensed on the shell side of a 1-shell-pass and 8-tube-passes condenser, with 50 tubes in each pass, at 30°C ( $h_{fg} = 2431 \text{ kJ/kg}$ ). Cooling water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) enters the tubes at 15°C at a rate of 1800 kg/h. The tubes are thin-walled, and have a diameter of 1.5 cm and length of 2 m per pass. If the overall heat transfer coefficient is 3000 W/m<sup>2</sup>·K, determine (a) the rate of heat transfer and (b) the rate of condensation of steam.

FIGURE P11–122

- 11–123** Reconsider Prob. 11–122. Using EES (or other) software, investigate the effects of the condensing steam temperature and the tube diameter on the rate of heat transfer and the rate of condensation of steam. Let the steam

temperature vary from 20°C to 70°C and the tube diameter from 1.0 cm to 2.0 cm. Plot the rate of heat transfer and the rate of condensation as functions of steam temperature and tube diameter, and discuss the results.

- 11–124E** Consider a closed loop heat exchanger that carries exit water ( $c_p = 1 \text{ Btu/lbm}\cdot\text{°F}$  and  $\rho = 62.4 \text{ lbm/ft}^3$ ) of a condenser side initially at 100°F. The water flows through a 500 ft long stainless steel pipe of 1 in inner diameter immersed in a large lake. The temperature of lake water surrounding the heat exchanger is 45°F. The overall heat transfer coefficient of the heat exchanger is estimated to be 250 Btu/h·ft<sup>2</sup>·°F. What is the exit temperature of the water from the immersed heat exchanger if it flows through the pipe at an average velocity of 9 ft/s? Use  $\varepsilon - \text{NTU}$  method for analysis.

- 11–125** Consider the flow of saturated steam at 270.1 kPa that flows through the shell side of a shell-and-tube heat exchanger while the water flows through 4 tubes of diameter 1.25 cm at a rate of 0.25 kg/s through each tube. The water enters the tubes of heat exchanger at 20°C and exits at 60°C. Due to the heat exchange with the cold fluid, steam is condensed on the tubes external surface. The convection heat transfer coefficient on the steam side is 1500 W/m<sup>2</sup>·K, while the fouling resistance for the steam and water may be taken as 0.00015 and 0.0001 m<sup>2</sup>·K/W, respectively. Using the NTU method, determine (a) effectiveness of the heat exchanger, (b) length of the tube, and (c) rate of steam condensation.

FIGURE P11–125

- 11–126** Consider a condenser unit (shell and tube heat exchanger) of an HVAC facility where saturated refrigerant R134a at a saturation pressure of 1318.6 kPa and at a rate of 2.5 kg/s flows through thin-walled copper tubes. The refrigerant enters the condenser as saturated vapor and it is desired to have a saturated liquid refrigerant at the exit. The cooling of refrigerant is carried out by cold water that enters the heat exchanger at 10°C and exits at 40°C. Assuming initial overall heat transfer coefficient of the heat exchanger to be 3500 W/m<sup>2</sup>·K, determine the surface area of the heat exchanger and the mass flow rate of cooling water for complete condensation of the refrigerant. In practice, over a long period of time,

fouling occurs inside the heat exchanger that reduces its overall heat transfer coefficient and causes the mass flow rate of cooling water to increase. Increase in the mass flow rate of cooling water will require additional pumping power making the heat exchange process uneconomical. To prevent the condenser unit from under performance, assume that fouling has occurred inside the heat exchanger and has reduced its overall heat transfer coefficient by 20%. For the same inlet temperature and flow rate of refrigerant, determine the new flow rate of cooling water to ensure complete condensation of the refrigerant at the heat exchanger exit.

### Selection of Heat Exchangers

**11-127C** There are two heat exchangers that can meet the heat transfer requirements of a facility. Both have the same pumping power requirements, the same useful life, and the same price tag. But one is heavier and larger in size. Under what conditions would you choose the smaller one?

**11-128C** There are two heat exchangers that can meet the heat transfer requirements of a facility. One is smaller and cheaper but requires a larger pump, while the other is larger and more expensive but has a smaller pressure drop and thus requires a smaller pump. Both heat exchangers have the same life expectancy and meet all other requirements. Explain which heat exchanger you would choose and under what conditions.

**11-129C** A heat exchanger is to be selected to cool a hot liquid chemical at a specified rate to a specified temperature. Explain the steps involved in the selection process.

**11-130** A heat exchanger is to cool oil ( $c_p = 2200 \text{ J/kg}\cdot\text{K}$ ) at a rate of 13 kg/s from 120°C to 50°C by air. Determine the heat transfer rating of the heat exchanger and propose a suitable type.

**11-131** A shell-and-tube process heater is to be selected to heat water ( $c_p = 4190 \text{ J/kg}\cdot\text{K}$ ) from 20°C to 90°C by steam flowing on the shell side. The heat transfer load of the heater is 600 kW. If the inner diameter of the tubes is 1 cm and the velocity of water is not to exceed 3 m/s, determine how many tubes need to be used in the heat exchanger.

**FIGURE P11-131**

**11-132** Reconsider Prob. 11-131. Using EES (or other) software, plot the number of tube passes as a

function of water velocity as it varies from 1 m/s to 8 m/s, and discuss the results.

**11-133** The condenser of a large power plant is to remove 500 MW of heat from steam condensing at 30°C ( $h_{fg} = 2431 \text{ kJ/kg}$ ). The cooling is to be accomplished by cooling water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) from a nearby river, which enters the tubes at 18°C and leaves at 26°C. The tubes of the heatexchanger have an internal diameter of 2 cm, and the overall heat transfer coefficient is 3500 W/m<sup>2</sup>·K. Determine the total length of the tubes required in the condenser. What type of heat exchanger is suitable for this task?

**11-134** Repeat Prob. 11-133 for a heat transfer load of 50 MW.

**11-135** A shell-and-tube heat exchanger is to be designed to cool down the petroleum-based organic vapor available at a flow rate of 5 kg/s and at a saturation temperature of 75°C. The cold water ( $c_p = 4187 \text{ J/kg}\cdot\text{K}$ ) used for its condensation is supplied at a rate of 25 kg/s and a temperature of 15°C. The cold water flows through copper tubes with an outside diameter of 20 mm, a thickness of 2 mm, and a length of 5 m. The overall heat transfer coefficient is assumed to be 550 W/m<sup>2</sup>·K and the latent heat of vaporization of the organic vapor may be taken to be 580 kJ/kg. Assuming negligible thermal resistance due to pipe wall thickness, determine the number of tubes required.

**11-136E** Water flowing through the tube side of a shell-and-tube cross-flow heat exchanger at a rate of 40,000 lbm/h is heated from 80°F to 110°F. On the shell side water at 175°F flows through one shell pass at a rate of 30,000 lbm/h and acts as a heating fluid. The overall heat transfer coefficient of the heat exchanger is 220 Btu/h·ft<sup>2</sup>·°F and the average velocity of water flowing through a 0.75-in-inside-diameter pipe is 1.5 ft/s. Because of the space limitations, it is desired to limit the tube length below 8 ft. Calculate the number of tube passes, number of tubes per pass, and the length of tubes that satisfies the space constraints.

**11-137** Saturated liquid benzene flowing at a rate of 5 kg/s is to be cooled from 75°C to 45°C by using a source of cold water ( $c_p = 4187 \text{ J/kg}\cdot\text{K}$ ) flowing at 3.5 kg/s and 15°C through a 20-mm-diameter tube of negligible wall thickness. The overall heat transfer coefficient of the heat exchanger is estimated to be 750 W/m<sup>2</sup>·K. If the specific heat of the liquid benzene is 1839 J/kg·K and assuming that the capacity ratio and effectiveness remain the same, determine the heat exchanger surface area for the following four heat exchangers: (a) parallel flow, (b) counter flow, (c) shell-and-tube heat exchanger with 2-shell passes and 40-tube passes, and (d) cross-flow heat exchanger with one fluid mixed (liquid benzene) and other fluid unmixed (water).

### Special Topic: The Human Cardiovascular System as a Counter-Current Heat Exchanger

**11-138C** Describe the cardiovascular counter-current mechanism in the human body.

**11-139C** Discuss the differences between the cardiovascular counter-current design and standard engineering counter-current designs.

**11-140C** How do heavy clothing and extreme environmental conditions affect the cardiovascular counter-current exchanger?

**11-141** Calculate the total thermal resistance of the cardiovascular heat exchanger, assuming that the thermal conductivity of the system is  $k = 0.670 \text{ W/m}\cdot\text{K}$  and the convection heat transfer coefficients are  $h_{\text{artery}} = 300 \text{ W/m}^2\cdot\text{K}$  and  $h_{\text{vein}} = 190 \text{ W/m}^2\cdot\text{K}$ . The artery has an exterior diameter of  $500 \mu\text{m}$ , the vein has an exterior diameter of  $600 \mu\text{m}$  and the length of both blood vessels is 50 cm.

**11-142** How would the answer to Prob. 11-141 be altered if we tried to approximate the heat transfer loss through the blood vessel with a fouling factor to describe physiological inhomogeneities? Assume that the fouling factor for the artery is  $0.0005 \text{ m}^2\cdot\text{K/W}$  and the fouling factor for the vein is  $0.0003 \text{ m}^2\cdot\text{K/W}$ .

**11-143** The cardiovascular counter-current heat exchanger mechanism is to warm venous blood from  $28^\circ\text{C}$  to  $35^\circ\text{C}$  at a mass flow rate of  $2 \text{ g/s}$ . The artery inflow temperature is  $37^\circ\text{C}$  at a mass flow rate of  $5 \text{ g/s}$ . The average diameter of the vein is  $5 \text{ cm}$  and the overall heat transfer coefficient is  $125 \text{ W/m}^2\cdot\text{K}$ . Determine the overall blood vessel length needed to warm the venous blood to  $35^\circ\text{C}$  if the specific heat of both arterial and venous blood is constant and equal to  $3475 \text{ J/kg}\cdot\text{K}$ .

**11-144** The cardiovascular counter-current heat exchanger has an overall heat transfer coefficient of  $100 \text{ W/m}^2\cdot\text{K}$ . Arterial blood enters at  $37^\circ\text{C}$  and exits at  $27^\circ\text{C}$ . Venous blood enters at  $25^\circ\text{C}$  and exits at  $34^\circ\text{C}$ . Determine the mass flow rates of the arterial blood and venous blood in  $\text{g/s}$  if the specific heat of both arterial and venous blood is constant and equal to  $3475 \text{ J/kg}\cdot\text{K}$ , and the surface area of the heat transfer to occur is  $0.15 \text{ cm}^2$ .

### Review Problems

**11-145** Consider a water-to-water double-pipe heat exchanger whose flow arrangement is not known. The temperature measurements indicate that the cold water enters at  $20^\circ\text{C}$  and leaves at  $50^\circ\text{C}$ , while the hot water enters at  $80^\circ\text{C}$  and leaves at  $45^\circ\text{C}$ . Do you think this is a parallel-flow or counter-flow heat exchanger? Explain.

**11-146** By taking the limit as  $\Delta T_2 \rightarrow \Delta T_1$ , show that when  $\Delta T_1 = \Delta T_2$  for a heat exchanger, the  $\Delta T_{\text{lm}}$  relation reduces to  $\Delta T_{\text{lm}} = \Delta T_1 = \Delta T_2$ .

**11-147E** Water ( $c_p = 1.0 \text{ Btu/lbm}\cdot{}^\circ\text{F}$ ) is to be heated by solar-heated hot air ( $c_p = 0.24 \text{ Btu/lbm}\cdot{}^\circ\text{F}$ ) in a double-pipe counter-flow heat exchanger. Air enters the heat exchanger at  $190^\circ\text{F}$  at a rate of  $0.7 \text{ lbm/s}$  and leaves at  $135^\circ\text{F}$ . Water enters at  $70^\circ\text{F}$  at a rate of  $0.35 \text{ lbm/s}$ . The overall heat transfer coefficient based on the inner side of the tube is given to be  $20 \text{ Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F}$ . Determine the length of the tube required for a tube internal diameter of  $0.5 \text{ in}$ .

**11-148** A shell-and-tube heat exchanger with 1-shell pass and 14-tube passes is used to heat water in the tubes with geothermal steam condensing at  $120^\circ\text{C}$  ( $h_{fg} = 2203 \text{ kJ/kg}$ ) on the shell side. The tubes are thin-walled and have a diameter of  $2.4 \text{ cm}$  and length of  $3.2 \text{ m}$  per pass. Water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) enters the tubes at  $22^\circ\text{C}$  at a rate of  $3.9 \text{ kg/s}$ . If the temperature difference between the two fluids at the exit is  $46^\circ\text{C}$ , determine (a) the rate of heat transfer, (b) the rate of condensation of steam, and (c) the overall heat transfer coefficient.

FIGURE P11-148

**11-149** Hot water at  $60^\circ\text{C}$  is cooled to  $36^\circ\text{C}$  through the tube side of a 1-shell pass and 2-tube passes heat exchanger. The coolant is also a water stream, for which the inlet and outlet temperatures are  $7^\circ\text{C}$  and  $31^\circ\text{C}$ , respectively. The overall heat transfer coefficient and the heat transfer area are  $950 \text{ W/m}^2\cdot\text{K}$  and  $15 \text{ m}^2$ , respectively. Calculate the mass flow rates of hot and cold water streams in steady operation.

**11-150** Cold water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) enters the tubes of a heat exchanger with 2-shell passes and 20-tube passes at  $20^\circ\text{C}$  at a rate of  $3 \text{ kg/s}$ , while hot oil ( $c_p = 2200 \text{ J/kg}\cdot\text{K}$ ) enters the shell at  $130^\circ\text{C}$  at the same mass flow rate and leaves at  $60^\circ\text{C}$ . If the overall heat transfer coefficient based on the outer surface of the tube is  $220 \text{ W/m}^2\cdot\text{K}$ , determine (a) the rate of heat transfer and (b) the heat transfer surface area on the outer side of the tube.

FIGURE P11-150

**11-151** A shell-and-tube heat exchanger is used for cooling 47 kg/s of a process stream flowing through the tubes from 160°C to 100°C. This heat exchanger has a total of 100 identical tubes, each with an inside diameter of 2.5 cm and negligible wall thickness. The average properties of the process stream are:  $\rho = 950 \text{ kg/m}^3$ ,  $k = 0.50 \text{ W/m}\cdot\text{K}$ ,  $c_p = 3.5 \text{ kJ/kg}\cdot\text{K}$  and  $\mu = 2.0 \text{ mPa}\cdot\text{s}$ . The coolant stream is water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) at a flow rate of 66 kg/s and an inlet temperature of 10°C, which yields an average shell-side heat transfer coefficient of 4.0 kW/m<sup>2</sup>·K. Calculate the tube length if the heat exchanger has (a) a 1-shell pass and a 1-tube pass and (b) a 1-shell pass and 4-tube passes.

**11-152** A 2-shell passes and 4-tube passes heat exchanger is used for heating a hydrocarbon stream ( $c_p = 2.0 \text{ kJ/kg}\cdot\text{K}$ ) steadily from 20°C to 50°C. A water stream enters the shell-side at 80°C and leaves at 40°C. There are 160 thin-walled tubes, each with a diameter of 2.0 cm and length of 1.5 m. The tube-side and shell-side heat transfer coefficients are 1.6 and 2.5 kW/m<sup>2</sup>·K, respectively. (a) Calculate the rate of heat transfer and the mass rates of water and hydrocarbon streams. (b) With usage, the outlet hydrocarbon-stream temperature was found to decrease by 5°C due to the deposition of solids on the tube surface. Estimate the magnitude of fouling factor.

**11-153** A shell-and-tube heat exchanger with 2-shell passes and 4-tube passes is used for cooling oil ( $c_p = 2.0 \text{ kJ/kg}\cdot\text{K}$ ) from 125°C to 55°C. The coolant is water, which enters the shell side at 25°C and leaves at 46°C. The overall heat transfer coefficient is 900 W/m<sup>2</sup>·K. For an oil flow rate of 10 kg/s, calculate the cooling water flow rate and the heat transfer area.

**11-154** Saturated water vapor at 100°C condenses in the shell side of a 1-shell and 2-tube heat exchanger with a surface area of 0.5 m<sup>2</sup> and an overall heat transfer coefficient of 2000 W/m<sup>2</sup>·K. Cold water ( $c_{pc} = 4179 \text{ J/kg}\cdot\text{K}$ ) flowing at 0.5 kg/s enters the tube side at 15°C, determine the outlet temperature of the cold water and the heat transfer rate for the heat exchanger.

FIGURE P11-154

**11-155** A single-pass cross-flow heat exchanger uses hot air (mixed) to heat water (unmixed), flowing with a mass flow rate of 3 kg/s, from 30°C to 80°C. The hot air enters and exits the heat exchanger at 220°C and 100°C, respectively. If the overall heat transfer coefficient is 200 W/m<sup>2</sup>·K, determine the required surface area.

FIGURE P11-155

**11-156** The condenser of a room air conditioner is designed to reject heat at a rate of 15,000 kJ/h from refrigerant-134a as the refrigerant is condensed at a temperature of 40°C. Air ( $c_p = 1005 \text{ J/kg}\cdot\text{K}$ ) flows across the finned condenser coils, entering at 25°C and leaving at 35°C. If the overall heat transfer coefficient based on the refrigerant side is 150 W/m<sup>2</sup>·K, determine the heat transfer area on the refrigerant side.

FIGURE P11-156

**11-157** Oil in an engine is being cooled by air in a cross-flow heat exchanger, where both fluids are unmixed. Oil ( $c_{ph} = 2047 \text{ J/kg}\cdot\text{K}$ ) flowing with a flow rate of 0.026 kg/s enters the tube side at 75°C, while air ( $c_{pc} = 1007 \text{ J/kg}\cdot\text{K}$ ) enters the shell side at 30°C with a flow rate of 0.21 kg/s. The overall heat transfer coefficient of the heat exchanger is 53 W/m<sup>2</sup>·K and the total surface area is 1 m<sup>2</sup>. If the correction factor is  $F = 0.96$ , determine the outlet temperatures of the oil and air.

FIGURE P11-157

**11-158** Consider a water-to-water counter-flow heat exchanger with these specifications. Hot water enters at 95°C while cold water enters at 20°C. The exit temperature of hot water is 15°C greater than that of cold water, and the mass flow rate of hot water is 50 percent greater than that of cold water. The product of heat transfer surface area and the overall heat transfer coefficient is 1400 W/K. Taking the specific heat of both cold and hot water to be  $c_p = 4180 \text{ J/kg}\cdot\text{K}$ , determine (a) the outlet temperature of the cold water, (b) the effectiveness of the heat exchanger, (c) the mass flow rate of the cold water, and (d) the heat transfer rate.

FIGURE P11-158

**11-159** Geothermal water ( $c_p = 4250 \text{ J/kg}\cdot\text{K}$ ) at 75°C is to be used to heat fresh water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) at 17°C at a rate of 1.2 kg/s in a double-pipe counter-flow heat exchanger. The heat transfer surface area is 25 m<sup>2</sup>, the overall heat transfer coefficient is 480 W/m<sup>2</sup>·K, and the mass flow rate of geothermal water is larger than that of fresh water. If the effectiveness of the heat exchanger is desired to be 0.823, determine the mass flow rate of geothermal water and the outlet temperatures of both fluids.

**11-160** A cross-flow heat exchanger with both fluids unmixed has an overall heat transfer coefficient of 200 W/m<sup>2</sup>·K, and a heat transfer surface area of 400 m<sup>2</sup>. The hot fluid has a heat capacity of 40,000 W/K, while the cold fluid has a heat capacity of 80,000 W/K. If the inlet temperatures of both hot and cold fluids are 80°C and 20°C, respectively, determine (a) the exit temperature of the hot fluid and (b) the rate of heat transfer in the heat exchanger.

**11-161** In a chemical plant, a certain chemical is heated by hot water supplied by a natural gas furnace. The hot water ( $c_p = 4180 \text{ J/kg}\cdot\text{K}$ ) is then discharged at 60°C at a rate of 8 kg/min. The plant operates 8 h a day, 5 days a week, 52 weeks a year. The furnace has an efficiency of 78 percent, and the cost of the natural gas is \$1.00 per therm (1 therm = 105,500 kJ). The average temperature of the cold water entering the furnace throughout the year is 14°C. In order to save energy, it is proposed to install a water-to-water heat exchanger to preheat the incoming cold water by the drained hot water. Assuming that the heat exchanger will recover 72 percent of the available heat in the hot water, determine the heat transfer rating of the heat exchanger that needs to be purchased and suggest a suitable type. Also, determine the amount of money this heat exchanger will save the company per year from natural gas savings.

**11-162** A single-pass cross-flow heat exchanger with both fluids unmixed has water entering at 16°C and exiting at 33°C, while oil ( $c_p = 1.93 \text{ kJ/kg}\cdot\text{K}$  and  $\rho = 870 \text{ kg/m}^3$ ) flowing at 0.19 m<sup>3</sup>/min enters at 38°C and exits at 29°C. If the surface area of the heat exchanger is 20 m<sup>2</sup>, determine (a) the NTU value and (b) the value of the overall heat transfer coefficient.

FIGURE P11-162

**11-163** Air at 18°C ( $c_p = 1006 \text{ J/kg}\cdot\text{K}$ ) is to be heated to 58°C by hot oil at 80°C ( $c_p = 2150 \text{ J/kg}\cdot\text{K}$ ) in a cross-flow heat exchanger with air mixed and oil unmixed. The product of heat transfer surface area and the overall heat transfer coefficient is 750 W/K and the mass flow rate of air is twice that of oil. Determine (a) the effectiveness of the heat exchanger, (b) the mass flow rate of air, and (c) the rate of heat transfer.

**11-164** The mass flow rate, specific heat, and inlet temperature of the tube-side stream in a double-pipe, parallel-flow heat exchanger are 2700 kg/h, 2.0 kJ/kg·K, and 120°C, respectively. The mass flow rate, specific heat, and inlet temperature of the other stream are 1800 kg/h, 4.2 kJ/kg·K, and 20°C, respectively. The heat transfer area and overall heat transfer coefficient are 0.50 m<sup>2</sup> and 2.0 kW/m<sup>2</sup>·K, respectively. Find the outlet temperatures of both streams in steady operation using (a) the LMTD method and (b) the effectiveness–NTU method.

**11-165** During an experiment, a plate heat exchanger that is used to transfer heat from a hot-water stream to a cold-water stream is tested, and the following measurements are taken:

|                         | Hot water stream | Cold water stream |
|-------------------------|------------------|-------------------|
| Inlet temperature, °C   | 38.9             | 14.3              |
| Outlet temperature, °C  | 27.0             | 19.8              |
| Volume flow rate, L/min | 2.5              | 4.5               |

The heat transfer area is calculated to be 0.0400 m<sup>2</sup>.

- (a) Calculate the rate of heat transfer to the cold water.
- (b) Calculate the overall heat transfer coefficient.
- (c) Determine if the heat exchanger is truly adiabatic. If not, determine the fraction of heat loss and calculate the heat transfer efficiency.
- (d) Determine the effectiveness and the NTU values of the heat exchanger.

Also, discuss if the measured values are reasonable.

### Fundamentals of Engineering (FE) Exam Problems

**11-166** Saturated water vapor at 40°C is to be condensed as it flows through the tubes of an air-cooled condenser at a rate of 0.2 kg/s. The condensate leaves the tubes as a saturated liquid at 40°C. The rate of heat transfer to air is

- (a) 34 kJ/s      (b) 268 kJ/s      (c) 453 kJ/s  
 (d) 481 kJ/s      (e) 515 kJ/s

**11-167** Consider a double-pipe heat exchanger with a tube diameter of 10 cm and negligible tube thickness. The total thermal resistance of the heat exchanger was calculated to be 0.025 K/W when it was first constructed. After some prolonged use, fouling occurs at both the inner and outer surfaces with the fouling factors 0.00045 m<sup>2</sup>·K/W and 0.00015 m<sup>2</sup>·K/W, respectively. The percentage decrease in the rate of heat transfer for this heat exchanger due to fouling is

- (a) 2.3%      (b) 6.8%      (c) 7.1%  
 (d) 7.6%      (e) 8.5%

**11-168** Hot water coming from the engine is to be cooled by ambient air in a car radiator. The aluminum tubes in which the water flows have a diameter of 4 cm and negligible thickness. Fins are attached on the outer surface of the tubes in order to increase the heat transfer surface area on the air side. The heat transfer coefficients on the inner and outer surfaces are 2000 and 150 W/m<sup>2</sup>·K, respectively. If the effective surface area on the finned side is 10 times the inner surface area, the overall heat transfer coefficient of this heat exchanger based on the inner surface area is

- (a) 150 W/m<sup>2</sup>·K      (b) 857 W/m<sup>2</sup>·K      (c) 1075 W/m<sup>2</sup>·K  
 (d) 2000 W/m<sup>2</sup>·K      (e) 2150 W/m<sup>2</sup>·K

**11-169** A heat exchanger is used to heat cold water entering at 8°C at a rate of 1.2 kg/s by hot air entering at 90°C at rate of 2.5 kg/s. The highest rate of heat transfer in the heat exchanger is

- (a) 205 kW      (b) 411 kW      (c) 311 kW  
 (d) 114 kW      (e) 78 kW

**11-170** Cold water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) enters a heat exchanger at 15°C at a rate of 0.5 kg/s, where it is heated by hot air ( $c_p = 1.0 \text{ kJ/kg}\cdot\text{K}$ ) that enters the heat exchanger at 50°C at a rate of 1.8 kg/s. The maximum possible heat transfer rate in this heat exchanger is

- (a) 51.1 kW      (b) 63.0 kW      (c) 66.8 kW  
 (d) 73.2 kW      (e) 80.0 kW

**11-171** Hot oil ( $c_p = 2.1 \text{ kJ/kg}\cdot\text{K}$ ) at 110°C and 8 kg/s is to be cooled in a heat exchanger by cold water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) entering at 10°C and at a rate of 2 kg/s. The lowest temperature that oil can be cooled in this heat exchanger is

- (a) 10.0°C      (b) 33.5°C      (c) 46.1°C  
 (d) 60.2°C      (e) 71.4°C

**11-172** Cold water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) enters a counter-flow heat exchanger at 18°C at a rate of 0.7 kg/s where it is heated by hot air ( $c_p = 1.0 \text{ kJ/kg}\cdot\text{K}$ ) that enters the heat exchanger at 50°C at a rate of 1.6 kg/s and leaves

at 25°C. The maximum possible outlet temperature of the cold water is

- (a) 25.0°C      (b) 32.0°C      (c) 35.5°C  
 (d) 39.7°C      (e) 50.0°C

**11-173** A heat exchanger is used to condense steam coming off the turbine of a steam power plant by cold water from a nearby lake. The cold water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) enters the condenser at 16°C at a rate of 20 kg/s and leaves at 25°C, while the steam condenses at 45°C. The condenser is not insulated, and it is estimated that heat at a rate of 8 kW is lost from the condenser to the surrounding air. The rate at which the steam condenses is

- (a) 0.282 kg/s      (b) 0.290 kg/s      (c) 0.305 kg/s  
 (d) 0.314 kg/s      (e) 0.318 kg/s

**11-174** An air handler is a large unmixed heat exchanger used for comfort control in large buildings. In one such application, chilled water ( $c_p = 4.2 \text{ kJ/kg}\cdot\text{K}$ ) enters an air handler at 5°C and leaves at 12°C with a flow rate of 1000 kg/h. This cold water cools 5000 kg/h of air ( $c_p = 1.0 \text{ kJ/kg}\cdot\text{K}$ ) which enters the air handler at 25°C. If these streams are in counter-flow and the water-stream conditions remain fixed, the minimum temperature at the air outlet is

- (a) 5°C      (b) 12°C      (c) 19°C  
 (d) 22°C      (e) 25°C

**11-175** An air handler is a large unmixed heat exchanger used for comfort control in large buildings. In one such application, chilled water ( $c_p = 4.2 \text{ kJ/kg}\cdot\text{K}$ ) enters an air handler at 5°C and leaves at 12°C with a flow rate of 1000 kg/h. This cold water cools air ( $c_p = 1.0 \text{ kJ/kg}\cdot\text{K}$ ) from 25°C to 15°C. The rate of heat transfer between the two streams is

- (a) 8.2 kW      (b) 23.7 kW      (c) 33.8 kW  
 (d) 44.8 kW      (e) 52.8 kW

**11-176** In a parallel-flow, liquid-to-liquid heat exchanger, the inlet and outlet temperatures of the hot fluid are 150°C and 90°C while that of the cold fluid are 30°C and 70°C, respectively. For the same overall heat transfer coefficient, the percentage decrease in the surface area of the heat exchanger if counter-flow arrangement is used is

- (a) 3.9%      (b) 9.7%      (c) 14.5%  
 (d) 19.7%      (e) 24.6%

**11-177** A counter-flow heat exchanger is used to cool oil ( $c_p = 2.20 \text{ kJ/kg}\cdot\text{K}$ ) from 110°C to 85°C at a rate of 0.75 kg/s by cold water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) that enters the heat exchanger at 20°C at a rate of 0.6 kg/s. If the overall heat transfer coefficient is 800 W/m<sup>2</sup>·K, the heat transfer area of the heat exchanger is

- (a) 0.745 m<sup>2</sup>      (b) 0.760 m<sup>2</sup>      (c) 0.775 m<sup>2</sup>  
 (d) 0.790 m<sup>2</sup>      (e) 0.805 m<sup>2</sup>

**11-178** The radiator in an automobile is a cross-flow heat exchanger ( $UA_s = 10 \text{ kW/K}$ ) that uses air ( $c_p = 1.00 \text{ kJ/kg}\cdot\text{K}$ ) to cool the engine coolant fluid ( $c_p = 4.00 \text{ kJ/kg}\cdot\text{K}$ ). The engine fan draws 30°C air through this radiator at a rate of 10 kg/s while the coolant pump circulates the engine coolant at a rate of 5 kg/s. The coolant enters this radiator at 80°C.

Under these conditions, what is the number of transfer units (NTU) of this radiator?

- (a) 1    (b) 2    (c) 3    (d) 4    (e) 5

**11-179** In a parallel-flow, water-to-water heat exchanger, the hot water enters at 75°C at a rate of 1.2 kg/s and cold water enters at 20°C at a rate of 0.9 kg/s. The overall heat transfer coefficient and the surface area for this heat exchanger are 750 W/m<sup>2</sup>·K and 6.4 m<sup>2</sup>, respectively. The specific heat for both the hot and cold fluid may be taken to be 4.18 kJ/kg·K. For the same overall heat transfer coefficient and the surface area, the increase in the effectiveness of this heat exchanger if counter-flow arrangement is used is

- (a) 0.09    (b) 0.11    (c) 0.14    (d) 0.17    (e) 0.19

**11-180** In a parallel-flow heat exchanger, the NTU is calculated to be 2.5. The lowest possible effectiveness for this heat exchanger is

- (a) 10%    (b) 27%    (c) 41%    (d) 50%    (e) 92%

**11-181** Cold water ( $c_p = 4.18 \text{ kJ/kg}\cdot\text{K}$ ) enters a counter-flow heat exchanger at 10°C at a rate of 0.35 kg/s, where it is heated by hot air ( $c_p = 1.0 \text{ kJ/kg}\cdot\text{K}$ ) that enters the heat exchanger at 50°C at a rate of 1.9 kg/s and leaves at 25°C. The effectiveness of this heat exchanger is

- (a) 0.50    (b) 0.63    (c) 0.72    (d) 0.81    (e) 0.89

**11-182** Steam is to be condensed on the shell side of a 2-shell-passes and 8-tube-passes condenser, with 20 tubes in each pass. Cooling water enters the tubes a rate of 2 kg/s. If the heat transfer area is 14 m<sup>2</sup> and the overall heat transfer coefficient is 1800 W/m<sup>2</sup>·K, the effectiveness of this condenser is

- (a) 0.70    (b) 0.80    (c) 0.90    (d) 0.95    (e) 1.0

**11-183** Water is boiled at 150°C in a boiler by hot exhaust gases ( $c_p = 1.05 \text{ kJ/kg}\cdot\text{C}$ ) that enter the boiler at 400°C at a rate of 0.4 kg/s and leaves at 200°C. The surface area of the heat exchanger is 0.64 m<sup>2</sup>. The overall heat transfer coefficient of this heat exchanger is

- (a) 940 W/m<sup>2</sup>·K    (b) 1056 W/m<sup>2</sup>·K    (c) 1145 W/m<sup>2</sup>·K  
(d) 1230 W/m<sup>2</sup>·K    (e) 1393 W/m<sup>2</sup>·K

**11-184** An air-cooled condenser is used to condense isobutane in a binary geothermal power plant. The isobutane is condensed at 85°C by air ( $c_p = 1.0 \text{ kJ/kg}\cdot\text{K}$ ) that enters at 22°C at a rate of 18 kg/s. The overall heat transfer coefficient and the surface area for this heat exchanger are 2.4 kW/m<sup>2</sup>·K and 1.25 m<sup>2</sup>, respectively. The outlet temperature of air is

- (a) 45.4°C    (b) 40.9°C    (c) 37.5°C  
(d) 34.2°C    (e) 31.7°C

### Design and Essay Problems

**11-185** Write an interactive computer program that will give the effectiveness of a heat exchanger and the outlet temperatures of both the hot and cold fluids when the type of fluids, the inlet temperatures, the mass flow rates, the heat transfer surface area, the overall heat transfer coefficient, and the type

of heat exchanger are specified. The program should allow the user to select from the fluids water, engine oil, glycerin, ethyl alcohol, and ammonia. Assume constant specific heats at about room temperature.

**11-186** Water flows through a shower head steadily at a rate of 8 kg/min. The water is heated in an electric water heater from 15°C to 45°C. In an attempt to conserve energy, it is proposed to pass the drained warm water at a temperature of 38°C through a heat exchanger to preheat the incoming cold water. Design a heat exchanger that is suitable for this task, and discuss the potential savings in energy and money for your area.

**11-187** Open the engine compartment of your car and search for heat exchangers. How many do you have? What type are they? Why do you think those specific types are selected? If you were redesigning the car, would you use different kinds? Explain.

**11-188** Write an essay on the static and dynamic types of regenerative heat exchangers and compile information about the manufacturers of such heat exchangers. Choose a few models by different manufacturers and compare their costs and performance.

**11-189** Design a hydrocooling unit that can cool fruits and vegetables from 30°C to 5°C at a rate of 20,000 kg/h under the following conditions:

The unit will be of flood type that will cool the products as they are conveyed into the channel filled with water. The products will be dropped into the channel filled with water at one end and picked up at the other end. The channel can be as wide as 3 m and as high as 90 cm. The water is to be circulated and cooled by the evaporator section of a refrigeration system. The refrigerant temperature inside the coils is to be -2°C, and the water temperature is not to drop below 1°C and not to exceed 6°C.

Assuming reasonable values for the average product density, specific heat, and porosity (the fraction of air volume in a box), recommend reasonable values for the quantities related to the thermal aspects of the hydrocooler, including (a) how long the fruits and vegetables need to remain in the channel, (b) the length of the channel, (c) the water velocity through the channel, (d) the velocity of the conveyor and thus the fruits and vegetables through the channel, (e) the refrigeration capacity of the refrigeration system, and (f) the type of heat exchanger for the evaporator and the surface area on the water side.

**11-190** A company owns a refrigeration system whose refrigeration capacity is 200 tons (1 ton of refrigeration = 211 kJ/min), and you are to design a forced-air cooling system for fruits whose diameters do not exceed 7 cm under the following conditions:

The fruits are to be cooled from 28°C to an average temperature of 8°C. The air temperature is to remain above -2°C and

below 10°C at all times, and the velocity of air approaching the fruits must remain under 2 m/s. The cooling section can be as wide as 3.5 m and as high as 2 m.

Assuming reasonable values for the average fruit density, specific heat, and porosity (the fraction of air volume in a box), recommend reasonable values for the quantities related to the thermal aspects of the forced-air cooling, including (a) how long the fruits need to remain in the cooling section, (b) the length of the cooling section, (c) the air velocity approaching the cooling section, (d) the product cooling capacity of the system, in kg fruit/h, (e) the volume flow rate of air, and (f) the type of heat exchanger for the evaporator and the surface area on the air side.

**11-191** A counterflow double-pipe heat exchanger with  $A_s = 9.0 \text{ m}^2$  is used for cooling a liquid stream ( $c_p = 3.15 \text{ kJ/kg}\cdot\text{K}$ ) at a rate of 10.0 kg/s with an inlet temperature of 90°C. The coolant ( $c_p = 4.2 \text{ kJ/kg}\cdot\text{K}$ ) enters the heat exchanger at a rate

of 8.0 kg/s with an inlet temperature of 10°C. The plant data gave the following equation for the overall heat transfer coefficient in  $\text{W/m}^2\cdot\text{K}$ :  $U = 600/(1/\dot{m}_c^{0.8} + 2/\dot{m}_h^{0.8})$ , where  $\dot{m}_c$  and  $\dot{m}_h$  are the cold-and hot-stream flow rates in kg/s, respectively.

(a) Calculate the rate of heat transfer and the outlet stream temperatures for this unit. (b) The existing unit is to be replaced. A vendor is offering a very attractive discount on two identical heat exchangers that are presently stocked in its warehouse, each with  $A_s = 5 \text{ m}^2$ . Because the tube diameters in the existing and new units are the same, the above heat transfer coefficient equation is expected to be valid for the new units as well. The vendor is proposing that the two new units could be operated in parallel, such that each unit would process exactly one-half the flow rate of each of the hot and cold streams in a counterflow manner; hence, they together would meet (or exceed) the present plant heat duty. Give your recommendation, with supporting calculations, on this replacement proposal.

## FUNDAMENTALS OF THERMAL RADIATION

**S**o far, we have considered the conduction and convection modes of heat transfer, which are related to the nature of the media involved and the presence of fluid motion, among other things. We now turn our attention to the third mechanism of heat transfer: *radiation*, which is characteristically different from the other two.

We start this chapter with a discussion of *electromagnetic waves* and the *electromagnetic spectrum*, with particular emphasis on *thermal radiation*. Then we introduce the idealized *blackbody*, *blackbody radiation*, and *blackbody radiation function*, together with the *Stefan–Boltzmann law*, *Planck's law*, and *Wien's displacement law*.

Radiation is emitted by every point on a plane surface in all directions into the hemisphere above the surface. The quantity that describes the magnitude of radiation emitted or incident in a specified direction in space is the *radiation intensity*. Various radiation fluxes such as *emissive power*, *irradiation*, and *radiosity* are expressed in terms of intensity. This is followed by a discussion of radiative properties of materials such as *emissivity*, *absorptivity*, *reflectivity*, and *transmissivity* and their dependence on wavelength, direction, and temperature. The *greenhouse effect* is presented as an example of the consequences of the wavelength dependence of radiation properties. We end this chapter with a discussion of *atmospheric* and *solar radiation*.

### OBJECTIVES

When you finish studying this chapter, you should be able to:

- Classify electromagnetic radiation, and identify thermal radiation,
- Understand the idealized blackbody, and calculate the total and spectral blackbody emissive power,
- Calculate the fraction of radiation emitted in a specified wavelength band using the blackbody radiation functions,
- Understand the concept of radiation intensity, and define spectral directional quantities using intensity,
- Develop a clear understanding of the properties emissivity, absorptivity, reflectivity, and transmissivity on spectral, directional, and total basis,
- Apply Kirchhoff's law to determine the absorptivity of a surface when its emissivity is known,
- Model the atmospheric radiation by the use of an effective sky temperature, and appreciate the importance of greenhouse effect.

**FIGURE 12–1**

A hot object in a vacuum chamber loses heat by radiation only.

**FIGURE 12–2**

Unlike conduction and convection, heat transfer by radiation can occur between two bodies, even when they are separated by a medium colder than both.

## 12–1 ■ INTRODUCTION

Consider a hot object that is suspended in an evacuated chamber whose walls are at room temperature (Fig. 12–1). The hot object will eventually cool down and reach thermal equilibrium with its surroundings. That is, it will lose heat until its temperature reaches the temperature of the walls of the chamber. Heat transfer between the object and the chamber could not have taken place by conduction or convection, because these two mechanisms cannot occur in a vacuum. Therefore, heat transfer must have occurred through another mechanism that involves the emission of the internal energy of the object. This mechanism is *radiation*.

Radiation differs from the other two heat transfer mechanisms in that it does not require the presence of a material medium to take place. In fact, energy transfer by radiation is fastest (at the speed of light) and it suffers no attenuation in a *vacuum*. Also, radiation transfer occurs in solids as well as liquids and gases. In most practical applications, all three modes of heat transfer occur concurrently at varying degrees. But heat transfer through an evacuated space can occur only by radiation. For example, the energy of the sun reaches the earth by radiation.

You will recall that heat transfer by conduction or convection takes place in the direction of decreasing temperature; that is, from a high-temperature medium to a lower-temperature one. It is interesting that radiation heat transfer can occur between two bodies separated by a medium colder than both bodies (Fig. 12–2). For example, solar radiation reaches the surface of the earth after passing through cold air layers at high altitudes. Also, the radiation-absorbing surfaces inside a greenhouse reach high temperatures even when its plastic or glass cover remains relatively cool.

The theoretical foundation of radiation was established in 1864 by physicist James Clerk Maxwell, who postulated that accelerated charges or changing electric currents give rise to electric and magnetic fields. These rapidly moving fields are called **electromagnetic waves** or **electromagnetic radiation**, and they represent the energy emitted by matter as a result of the changes in the electronic configurations of the atoms or molecules. In 1887, Heinrich Hertz experimentally demonstrated the existence of such waves. Electromagnetic waves transport energy just like other waves, and all electromagnetic waves travel at the *speed of light* in a vacuum, which is  $c_0 = 2.9979 \times 10^8$  m/s. Electromagnetic waves are characterized by their *frequency*  $\nu$  or *wavelength*  $\lambda$ . These two properties in a medium are related by

$$\lambda = \frac{c}{\nu} \quad (12-1)$$

where  $c$  is the speed of propagation of a wave in that medium. The speed of propagation in a medium is related to the speed of light in a vacuum by  $c = c_0/n$ , where  $n$  is the *index of refraction* of that medium. The refractive index is essentially unity for air and most gases, about 1.5 for glass, and 1.33 for water. The commonly used unit of wavelength is the *micrometer* ( $\mu\text{m}$ ) or *micron*, where  $1 \mu\text{m} = 10^{-6}$  m. Unlike the wavelength and the speed of propagation, the frequency of an electromagnetic wave depends only on the source and is independent of the medium through which the wave travels. The *frequency* (the number of oscillations per second) of an electromagnetic wave

can range from less than a million Hz to a septillion Hz or higher, depending on the source. Note from Eq. 12–1 that the wavelength and the frequency of electromagnetic radiation are inversely proportional.

It has proven useful to view electromagnetic radiation as the propagation of a collection of discrete packets of energy called **photons** or **quanta**, as proposed by Max Planck in 1900 in conjunction with his *quantum theory*. In this view, each photon of frequency  $\nu$  is considered to have an energy of

$$e = h\nu = \frac{hc}{\lambda} \quad (12-2)$$

where  $h = 6.626069 \times 10^{-34}$  J·s is *Planck's constant*. Note from the second part of Eq. 12–2 that the energy of a photon is inversely proportional to its wavelength. Therefore, shorter-wavelength radiation possesses larger photon energies. It is no wonder that we try to avoid very-short-wavelength radiation such as gamma rays and X-rays since they are highly destructive.

## 12–2 • THERMAL RADIATION

Although all electromagnetic waves have the same general features, waves of different wavelength differ significantly in their behavior. The electromagnetic radiation encountered in practice covers a wide range of wavelengths, varying from less than  $10^{-10}$  μm for cosmic rays to more than  $10^{10}$  μm for electrical power waves. The **electromagnetic spectrum** also includes gamma rays, X-rays, ultraviolet radiation, visible light, infrared radiation, thermal radiation, microwaves, and radio waves, as shown in Fig. 12–3.

Different types of electromagnetic radiation are produced through various mechanisms. For example, *gamma rays* are produced by nuclear reactions, *X-rays* by the bombardment of metals with high-energy electrons, *microwaves* by special types of electron tubes such as klystrons and magnetrons, and *radio waves* by the excitation of some crystals or by the flow of alternating current through electric conductors.

The short-wavelength gamma rays and X-rays are primarily of concern to nuclear engineers, while the long-wavelength microwaves and radio waves are of concern to electrical engineers. The type of electromagnetic radiation that is pertinent to heat transfer is the **thermal radiation** emitted as a result of energy transitions of molecules, atoms, and electrons of a substance. Temperature is a measure of the strength of these activities at the microscopic level, and the rate of thermal radiation emission increases with increasing temperature. Thermal radiation is continuously emitted by all matter whose temperature is above absolute zero. That is, everything around us such as walls, furniture, and our friends constantly emits (and absorbs) radiation (Fig. 12–4). Thermal radiation is also defined as the portion of the electromagnetic spectrum that extends from about 0.1 to 100 μm, since the radiation emitted by bodies due to their temperature falls almost entirely into this wavelength range. Thus, thermal radiation includes the entire visible and infrared (IR) radiation as well as a portion of the ultraviolet (UV) radiation.

What we call **light** is simply the *visible* portion of the electromagnetic spectrum that lies between 0.40 and 0.76 μm. Light is characteristically no different than other electromagnetic radiation, except that it happens

**FIGURE 12–3**

The electromagnetic wave spectrum.

**FIGURE 12–4**

Everything around us constantly emits thermal radiation.

**TABLE 12–1**

The wavelength ranges of different colors

| Color  | Wavelength band         |
|--------|-------------------------|
| Violet | 0.40–0.44 $\mu\text{m}$ |
| Blue   | 0.44–0.49 $\mu\text{m}$ |
| Green  | 0.49–0.54 $\mu\text{m}$ |
| Yellow | 0.54–0.60 $\mu\text{m}$ |
| Orange | 0.60–0.67 $\mu\text{m}$ |
| Red    | 0.63–0.76 $\mu\text{m}$ |

**FIGURE 12–5**

Food is heated or cooked in a microwave oven by absorbing the electromagnetic radiation energy generated by the magnetron of the oven.

to trigger the sensation of seeing in the human eye. Light, or the visible spectrum, consists of narrow bands of color from violet (0.40–0.44  $\mu\text{m}$ ) to red (0.63–0.76  $\mu\text{m}$ ), as shown in Table 12–1.

A body that emits some radiation in the visible range is called a light source. The sun is obviously our primary light source. The electromagnetic radiation emitted by the sun is known as **solar radiation**, and nearly all of it falls into the wavelength band 0.3–3  $\mu\text{m}$ . Almost *half* of solar radiation is light (i.e., it falls into the visible range), with the remaining being ultraviolet and infrared.

The radiation emitted by bodies at room temperature falls into the **infrared** region of the spectrum, which extends from 0.76 to 100  $\mu\text{m}$ . Bodies start emitting noticeable visible radiation at temperatures above 800 K. The tungsten filament of a lightbulb must be heated to temperatures above 2000 K before it can emit any significant amount of radiation in the visible range.

The **ultraviolet** radiation includes the low-wavelength end of the thermal radiation spectrum and lies between the wavelengths 0.01 and 0.40  $\mu\text{m}$ . Ultraviolet rays are to be avoided since they can kill microorganisms and cause serious damage to humans and other living beings. About 12 percent of solar radiation is in the ultraviolet range, and it would be devastating if it were to reach the surface of the earth. Fortunately, the ozone ( $\text{O}_3$ ) layer in the atmosphere acts as a protective blanket and absorbs most of this ultraviolet radiation. The ultraviolet rays that remain in sunlight are still sufficient to cause serious sunburns to sun worshippers, and prolonged exposure to direct sunlight is the leading cause of skin cancer, which can be lethal. Recent discoveries of “holes” in the ozone layer have prompted the international community to ban the use of ozone-destroying chemicals such as the refrigerant Freon-12 in order to save the earth. Ultraviolet radiation is also produced artificially in fluorescent lamps for use in medicine as a bacteria killer and in tanning parlors as an artificial tanner.

Microwave ovens utilize electromagnetic radiation in the **microwave** region of the spectrum generated by microwave tubes called *magnetrons*. Microwaves in the range of  $10^2$ – $10^5 \mu\text{m}$  are very suitable for use in cooking since they are *reflected* by metals, *transmitted* by glass and plastics, and *absorbed* by food (especially water) molecules. Thus, the electric energy converted to radiation in a microwave oven eventually becomes part of the internal energy of the food. The fast and efficient cooking of microwave ovens has made them one of the essential appliances in modern kitchens (Fig. 12–5).

Radars and cordless telephones also use electromagnetic radiation in the microwave region. The wavelength of the electromagnetic waves used in radio and TV broadcasting usually ranges between 1 and 1000 m in the **radio wave** region of the spectrum.

In heat transfer studies, we are interested in the energy emitted by bodies because of their temperature only. Therefore, we limit our consideration to **thermal radiation**, which we simply call *radiation*. The relations developed below are restricted to thermal radiation only and may not be applicable to other forms of electromagnetic radiation.

The electrons, atoms, and molecules of all solids, liquids, and gases above absolute zero temperature are constantly in motion, and thus radiation is constantly emitted, as well as being absorbed or transmitted throughout the entire volume of matter. That is, radiation is a **volumetric phenomenon**. However,

for opaque (nontransparent) solids such as metals, wood, and rocks, radiation is considered to be a **surface phenomenon**, since the radiation emitted by the interior regions can never reach the surface, and the radiation incident on such bodies is usually absorbed within a few microns from the surface (Fig. 12–6). Note that the radiation characteristics of surfaces can be changed completely by applying thin layers of coatings on them.

## 12–3 ■ BLACKBODY RADIATION

A body at a thermodynamic (or absolute) temperature above zero emits radiation in all directions over a wide range of wavelengths. The amount of radiation energy emitted from a surface at a given wavelength depends on the material of the body and the condition of its surface as well as the surface temperature. Therefore, different bodies may emit different amounts of radiation per unit surface area, even when they are at the same temperature. Thus, it is natural to be curious about the *maximum* amount of radiation that can be emitted by a surface at a given temperature. Satisfying this curiosity requires the definition of an idealized body, called a *blackbody*, to serve as a standard against which the radiative properties of real surfaces may be compared.

A **blackbody** is defined as *a perfect emitter and absorber of radiation*. At a specified temperature and wavelength, no surface can emit more energy than a blackbody. A blackbody absorbs *all* incident radiation, regardless of wavelength and direction. Also, a blackbody emits radiation energy uniformly in all directions per unit area normal to direction of emission (Fig. 12–7). That is, a blackbody is a *diffuse* emitter. The term *diffuse* means “independent of direction.”

The radiation energy emitted by a blackbody per unit time and per unit surface area was determined experimentally by Joseph Stefan in 1879 and expressed as

$$E_b(T) = \sigma T^4 \quad (\text{W/m}^2) \quad (12-3)$$

where  $\sigma = 5.670 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$  is the *Stefan–Boltzmann constant* and  $T$  is the absolute temperature of the surface in K. This relation was theoretically verified in 1884 by Ludwig Boltzmann. Equation 12–3 is known as the **Stefan–Boltzmann law** and  $E_b$  is called the **blackbody emissive power**. Note that the emission of thermal radiation is proportional to the *fourth power* of the absolute temperature.

Although a blackbody would appear *black* to the eye, a distinction should be made between the idealized blackbody and an ordinary black surface. Any surface that absorbs light (the visible portion of radiation) would appear black to the eye, and a surface that reflects it completely would appear white. Considering that visible radiation occupies a very narrow band of the spectrum from 0.4 to 0.76  $\mu\text{m}$ , we cannot make any judgments about the blackness of a surface on the basis of visual observations. For example, snow and white paint reflect light and thus appear white. But they are essentially black for infrared radiation since they strongly absorb long-wavelength radiation. Surfaces coated with lampblack paint approach idealized blackbody behavior.

Another type of body that closely resembles a blackbody is a *large cavity with a small opening*, as shown in Fig. 12–8. Radiation coming in through the opening of area  $A$  undergoes multiple reflections, and thus it has several

**FIGURE 12–6**

Radiation in opaque solids is considered a surface phenomenon since the radiation emitted only by the molecules at the surface can escape the solid.

**FIGURE 12–7**

A blackbody is said to be a *diffuse* emitter since it emits radiation energy uniformly in all directions.

**FIGURE 12–8**

A large isothermal cavity at temperature  $T$  with a small opening of area  $A$  closely resembles a blackbody of surface area  $A$  at the same temperature.

chances to be absorbed by the interior surfaces of the cavity before any part of it can possibly escape. Also, if the surface of the cavity is isothermal at temperature  $T$ , the radiation emitted by the interior surfaces streams through the opening after undergoing multiple reflections, and thus it has a diffuse nature. Therefore, the cavity acts as a perfect absorber and perfect emitter, and the opening will resemble a blackbody of surface area  $A$  at temperature  $T$ , regardless of the actual radiative properties of the cavity.

The Stefan–Boltzmann law in Eq. 12–3 gives the *total* blackbody emissive power  $E_b$ , which is the sum of the radiation emitted over all wavelengths. Sometimes we need to know the **spectral blackbody emissive power**, which is *the amount of radiation energy emitted by a blackbody at a thermodynamic temperature  $T$  per unit time, per unit surface area, and per unit wavelength about the wavelength  $\lambda$* . For example, we are more interested in the amount of radiation an incandescent lightbulb emits in the visible wavelength spectrum than we are in the total amount emitted.

The relation for the spectral blackbody emissive power  $E_{b\lambda}$  was developed by Max Planck in 1901 in conjunction with his famous quantum theory. This relation is known as **Planck's law** and is expressed as

$$E_{b\lambda}(\lambda, T) = \frac{C_1}{\lambda^5 [\exp(C_2/\lambda T) - 1]} \quad (\text{W/m}^2 \cdot \mu\text{m}) \quad (12-4)$$

where

$$C_1 = 2\pi h c_0^2 = 3.74177 \times 10^8 \text{ W} \cdot \mu\text{m}^4 / \text{m}^2$$

$$C_2 = hc_0/k = 1.43878 \times 10^4 \text{ } \mu\text{m} \cdot \text{K}$$

Also,  $T$  is the absolute temperature of the surface,  $\lambda$  is the wavelength of the radiation emitted, and  $k = 1.38065 \times 10^{-23} \text{ J/K}$  is *Boltzmann's constant*. This relation is valid for a surface in a *vacuum* or a *gas*. For other mediums, it needs to be modified by replacing  $C_1$  by  $C_1/n^2$ , where  $n$  is the index of refraction of the medium. Note that the term *spectral* indicates dependence on wavelength.

The variation of the spectral blackbody emissive power with wavelength is plotted in Fig. 12–9 for selected temperatures. Several observations can be made from this figure:

1. The emitted radiation is a continuous function of *wavelength*. At any specified temperature, it increases with wavelength, reaches a peak, and then decreases with increasing wavelength.
2. At any wavelength, the amount of emitted radiation *increases* with increasing temperature.
3. As temperature increases, the curves shift to the left to the shorter-wavelength region. Consequently, a larger fraction of the radiation is emitted at *shorter wavelengths* at higher temperatures.
4. The radiation emitted by the *sun*, which is considered to be a blackbody at 5780 K (or roughly at 5800 K), reaches its peak in the visible region of the spectrum. Therefore, the sun is in tune with our eyes. On the other hand, surfaces at  $T \leq 800 \text{ K}$  emit almost entirely in the infrared region and thus are not visible to the eye unless they reflect light coming from other sources.

**FIGURE 12–9**

The variation of the blackbody emissive power with wavelength for several temperatures.

As the temperature increases, the peak of the curve in Fig. 12–9 shifts toward shorter wavelengths. The wavelength at which the peak occurs for a specified temperature is given by **Wien's displacement law** as

$$(\lambda T)_{\text{max power}} = 2897.8 \text{ } \mu\text{m} \cdot \text{K} \quad (12-5)$$

This relation was originally developed by Willy Wien in 1894 using classical thermodynamics, but it can also be obtained by differentiating Eq. 12–4 with respect to  $\lambda$  while holding  $T$  constant and setting the result equal to zero. A plot of Wien's displacement law, which is the locus of the peaks of the radiation emission curves, is also given in Fig. 12–9.

The peak of the solar radiation, for example, occurs at  $\lambda = 2897.8/5780 = 0.50 \text{ } \mu\text{m}$ , which is near the middle of the visible range. The peak of the radiation emitted by a surface at room temperature ( $T = 298 \text{ K}$ ) occurs at  $9.72 \text{ } \mu\text{m}$ , which is well into the infrared region of the spectrum.

An electrical resistance heater starts radiating heat soon after it is plugged in, and we can feel the emitted radiation energy by holding our hands against the heater. But this radiation is entirely in the infrared region and thus cannot

**FIGURE 12-10**

A surface that reflects red while absorbing the remaining parts of the incident light appears red to the eye.

**FIGURE 12-11**

On an  $E_{b\lambda}-\lambda$  chart, the area under a curve for a given temperature represents the total radiation energy emitted by a blackbody at that temperature.

be sensed by our eyes. The heater would appear dull red when its temperature reaches about 1000 K, since it starts emitting a detectable amount (about  $1 \text{ W/m}^2 \cdot \mu\text{m}$ ) of visible red radiation at that temperature. As the temperature rises even more, the heater appears bright red and is said to be *red hot*. When the temperature reaches about 1500 K, the heater emits enough radiation in the entire visible range of the spectrum to appear almost *white* to the eye, and it is called *white hot*.

Although it cannot be sensed directly by the human eye, infrared radiation can be detected by infrared cameras, which transmit the information to microprocessors to display visual images of objects at night. *Rattlesnakes* can sense the infrared radiation or the “body heat” coming off warm-blooded animals, and thus they can see at night without using any instruments. Similarly, honeybees are sensitive to ultraviolet radiation. A surface that reflects all of the light appears *white*, while a surface that absorbs all of the light incident on it appears *black*. (Then how do we see a black surface?)

It should be clear from this discussion that the color of an object is not due to emission, which is primarily in the infrared region, unless the surface temperature of the object exceeds about 1000 K. Instead, the color of a surface depends on the absorption and reflection characteristics of the surface and is due to selective absorption and reflection of the incident visible radiation coming from a light source such as the sun or an incandescent lightbulb. A piece of clothing containing a pigment that reflects red while absorbing the remaining parts of the incident light appears “red” to the eye (Fig. 12-10). Leaves appear “green” because their cells contain the pigment chlorophyll, which strongly reflects green while absorbing other colors.

It is left as an exercise to show that integration of the *spectral* blackbody emissive power  $E_{b\lambda}$  over the entire wavelength spectrum gives the *total* blackbody emissive power  $E_b$ :

$$E_b(T) = \int_0^{\infty} E_{b\lambda}(\lambda, T) d\lambda = \sigma T^4 \quad (\text{W/m}^2) \quad (12-6)$$

Thus, we obtained the Stefan–Boltzmann law (Eq. 12-3) by integrating Planck’s law (Eq. 12-4) over all wavelengths. Note that on an  $E_{b\lambda}-\lambda$  chart,  $E_{b\lambda}$  corresponds to any value on the curve, whereas  $E_b$  corresponds to the area under the entire curve for a specified temperature (Fig. 12-11). Also, the term *total* means “integrated over all wavelengths.”

### EXAMPLE 12-1 Radiation Emission from a Black Ball

Consider a 20-cm-diameter spherical ball at 800 K suspended in air as shown in Fig. 12-12. Assuming the ball closely approximates a blackbody, determine (a) the total blackbody emissive power, (b) the total amount of radiation emitted by the ball in 5 min, and (c) the spectral blackbody emissive power at a wavelength of  $3 \mu\text{m}$ .

**SOLUTION** An isothermal sphere is suspended in air. The total blackbody emissive power, the total radiation emitted in 5 min, and the spectral blackbody emissive power at  $3 \mu\text{m}$  are to be determined.

**Assumptions** The ball behaves as a blackbody.

**Analysis** (a) The total blackbody emissive power is determined from the Stefan–Boltzmann law to be

$$E_b = \sigma T^4 = (5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(800 \text{ K})^4 = 23.2 \text{ kW/m}^2$$

That is, the ball emits 23.2 kJ of energy in the form of electromagnetic radiation per second per  $\text{m}^2$  of the surface area of the ball.

(b) The total amount of radiation energy emitted from the entire ball in 5 min is determined by multiplying the blackbody emissive power obtained above by the total surface area of the ball and the given time interval:

$$A_s = \pi D^2 = \pi(0.2 \text{ m})^2 = 0.1257 \text{ m}^2$$

$$\Delta t = (5 \text{ min}) \left( \frac{60 \text{ s}}{1 \text{ min}} \right) = 300 \text{ s}$$

$$Q_{\text{rad}} = E_b A_s \Delta t = (23.2 \text{ kW/m}^2)(0.1257 \text{ m}^2)(300 \text{ s}) \left( \frac{1 \text{ kJ}}{1 \text{ kW} \cdot \text{s}} \right)$$

$$= 875 \text{ kJ}$$

That is, the ball loses 875 kJ of its internal energy in the form of electromagnetic waves to the surroundings in 5 min, which is enough energy to heat 20 kg of water from  $0^\circ\text{C}$  to  $100^\circ\text{C}$ . Note that the surface temperature of the ball cannot remain constant at 800 K unless there is an equal amount of energy flow to the surface from the surroundings or from the interior regions of the ball through some mechanisms such as chemical or nuclear reactions.

(c) The spectral blackbody emissive power at a wavelength of  $3 \mu\text{m}$  is determined from Planck's distribution law to be

$$E_{b\lambda} = \frac{C_1}{\lambda^5 \left[ \exp \left( \frac{C_2}{\lambda T} \right) - 1 \right]} = \frac{3.74177 \times 10^8 \text{ W} \cdot \mu\text{m}^4 / \text{m}^2}{(3 \mu\text{m})^5 \left[ \exp \left( \frac{1.43878 \times 10^4 \mu\text{m} \cdot \text{K}}{(3 \mu\text{m})(800 \text{ K})} \right) - 1 \right]}$$

$$= 3846 \text{ W/m}^2 \cdot \mu\text{m}$$

FIGURE 12–12

The spherical ball considered in Example 12–1.

FIGURE 12–13

On an  $E_{b\lambda}-\lambda$  chart, the area under the curve to the left of the  $\lambda = \lambda_1$  line represents the radiation energy emitted by a blackbody in the wavelength range  $0-\lambda_1$  for the given temperature.

The Stefan–Boltzmann law  $E_b(T) = \sigma T^4$  gives the *total* radiation emitted by a blackbody at all wavelengths from  $\lambda = 0$  to  $\lambda = \infty$ . But we are often interested in the amount of radiation emitted over *some wavelength band*. For example, an incandescent lightbulb is judged on the basis of the radiation it emits in the visible range rather than the radiation it emits at all wavelengths.

The radiation energy emitted by a blackbody per unit area over a wavelength band from  $\lambda = 0$  to  $\lambda$  is determined from (Fig. 12–13)

$$E_{b,0-\lambda}(T) = \int_0^\lambda E_{b\lambda}(\lambda, T) d\lambda \quad (\text{W/m}^2) \quad (12-7)$$

It looks like we can determine  $E_{b,0-\lambda}$  by substituting the  $E_{b\lambda}$  relation from Eq. 12–4 and performing this integration. But it turns out that this integration does not have a simple closed-form solution, and performing

a numerical integration each time we need a value of  $E_{b,0-\lambda}$  is not practical. Therefore, we define a dimensionless quantity  $f_\lambda$  called the **blackbody radiation function** as

$$f_\lambda(T) = \frac{\int_0^\lambda E_{b\lambda}(\lambda, T) d\lambda}{\sigma T^4} \quad (12-8)$$

The function  $f_\lambda$  represents *the fraction of radiation emitted from a blackbody at temperature T in the wavelength band from  $\lambda = 0$  to  $\lambda$* . In reference to Fig. 12–13,  $f_\lambda$  can be interpreted as the ratio of the shaded region (radiation energy emitted by the blackbody in the wavelength range  $0 - \lambda_1$ ) over the total area under the curve (total radiation energy emitted by the blackbody in the wavelength range  $0 - \infty$ ). The values of  $f_\lambda$  are listed in Table 12–2 as a function of  $\lambda T$ , where  $\lambda$  is in  $\mu\text{m}$  and  $T$  is in K.

TABLE 12–2

Blackbody radiation functions  $f_\lambda$

The fraction of radiation energy emitted by a blackbody at temperature  $T$  over a finite wavelength band from  $\lambda = \lambda_1$  to  $\lambda = \lambda_2$  is determined from (Fig. 12–14)

$$f_{\lambda_1-\lambda_2}(T) = \frac{\int_0^{\lambda_2} E_{b\lambda}(\lambda, T) d\lambda - \int_0^{\lambda_1} E_{b\lambda}(\lambda, T) d\lambda}{\sigma T^4} = f_{\lambda_2}(T) - f_{\lambda_1}(T) \quad (12-9)$$

where  $f_{\lambda_1}(T)$  and  $f_{\lambda_2}(T)$  are blackbody radiation functions corresponding to  $\lambda_1 T$  and  $\lambda_2 T$ , respectively.

### EXAMPLE 12–2 Light Emitted by the Sun and by a Lightbulb

Charge-coupled device (CCD) image sensors, that are common in modern digital cameras, respond differently to light sources with different spectral distributions. Daylight and incandescent light may be approximated as a blackbody at the effective surface temperatures of 5800 K and 2800 K, respectively. Determine the fraction of radiation emitted within the visible spectrum wavelengths, from 0.40  $\mu\text{m}$  (violet) to 0.76  $\mu\text{m}$  (red), for each of the lighting sources.

**SOLUTION** For specified blackbody temperatures, the fraction of visible radiation emitted by the sun and the filament of an incandescent lightbulb are to be determined.

**Assumptions** The sun and the incandescent light filament behave as black bodies.

**Analysis** The visible range of the electromagnetic spectrum extends from  $\lambda_1 = 0.40 \mu\text{m}$  to  $\lambda_2 = 0.76 \mu\text{m}$ . For the sun at  $T = 5800 \text{ K}$ , the blackbody radiation functions corresponding to  $\lambda_1 T$  and  $\lambda_2 T$  are determined from Table 12–2 to be (Fig. 12–15)

$$\begin{aligned}\lambda_1 T &= (0.40 \mu\text{m})(5800 \text{ K}) = 2320 \mu\text{m}\cdot\text{K} \rightarrow f_{\lambda_1, \text{daylight}} = 0.124509 \\ \lambda_2 T &= (0.76 \mu\text{m})(5800 \text{ K}) = 4408 \mu\text{m}\cdot\text{K} \rightarrow f_{\lambda_2, \text{daylight}} = 0.550015\end{aligned}$$

Then the fraction of visible radiation emitted by the sun becomes

$$f_{\lambda_1-\lambda_2, \text{daylight}} = 0.550015 - 0.124509 = \mathbf{0.426 \text{ or } 42.6 \text{ percent}}$$

For incandescent lightbulb at  $T = 2800 \text{ K}$ , the blackbody radiation functions corresponding to  $\lambda_1 T$  and  $\lambda_2 T$  are determined from Table 12–2 to be

$$\begin{aligned}\lambda_1 T &= (0.40 \mu\text{m})(2800 \text{ K}) = 1120 \mu\text{m}\cdot\text{K} \rightarrow f_{\lambda_1, \text{incandescent}} = 0.001409 \\ \lambda_2 T &= (0.76 \mu\text{m})(2800 \text{ K}) = 2128 \mu\text{m}\cdot\text{K} \rightarrow f_{\lambda_2, \text{incandescent}} = 0.088590\end{aligned}$$

Then the fraction of radiation the lightbulb emits in the visible range becomes

$$f_{\lambda_1-\lambda_2, \text{incandescent}} = 0.088590 - 0.001409 = \mathbf{0.087 \text{ or } 8.7 \text{ percent}}$$

**Discussion** Note that almost half of the radiation emitted by the sun is in the visible range, and thus the sun is a very efficient light source. But less than 10 percent of the radiation emitted by the incandescent lightbulb is in the form of visible light, and thus incandescent lightbulbs are inefficient as light sources. Consequently, they are being replaced by the highly efficient fluorescent and LED light sources.

FIGURE 12–14

Graphical representation of the fraction of radiation emitted in the wavelength band from  $\lambda_1$  to  $\lambda_2$ .

FIGURE 12–15

Graphical representation of the fraction of radiation emitted in the visible range in Example 12–2.

**FIGURE 12-16**

Radiation intensity is used to describe the variation of radiation energy with direction.

## 12-4 ■ RADIATION INTENSITY

Radiation is emitted by all parts of a plane surface in all directions into the hemisphere above the surface, and the directional distribution of emitted (or incident) radiation is usually not uniform. Therefore, we need a quantity that describes the magnitude of radiation emitted (or incident) in a specified direction in space. This quantity is *radiation intensity*, denoted by  $I$ . Before we can describe a directional quantity, we need to specify direction in space. The direction of radiation passing through a point is best described in spherical coordinates in terms of the zenith angle  $\theta$  and the azimuth angle  $\phi$ , as shown in Fig. 12-16. Radiation intensity is used to describe how the emitted radiation varies with the zenith and azimuth angles.

If all surfaces emitted radiation uniformly in all directions, the *emissive power* would be sufficient to quantify radiation, and we would not need to deal with intensity. The radiation emitted by a blackbody per unit normal area is the same in all directions, and thus there is no directional dependence. But this is not the case for real surfaces. Before we define intensity, we need to quantify the size of an opening in space.

### Solid Angle

Let us try to quantify the size of a slice of pizza. One way of doing that is to specify the arc length of the outer edge of the slice, and to form the slice by connecting the endpoints of the arc to the center. A more general approach is to specify the angle of the slice at the center, as shown in Fig. 12-17. An angle of  $90^\circ$  (or  $\pi/2$  radians), for example, always represents a quarter pizza, no matter what the radius is. For a circle of unit radius, the length of an arc is equivalent in magnitude to the *plane angle* it subtends (both are  $2\pi$  for a complete circle of radius  $r = 1$ ).

Now consider a watermelon, and let us attempt to quantify the size of a slice. Again we can do it by specifying the outer surface area of the slice (the green part), or by working with angles for generality. Connecting all points at the edges of the slice to the center in this case will form a three-dimensional body (like a cone whose tip is at the center), and thus the angle at the center in this case is properly called the **solid angle**. The solid angle is denoted by  $\omega$ , and its unit is the *steradian* (sr). In analogy to plane angle, we can say that *the area of a surface on a sphere of unit radius is equivalent in magnitude to the solid angle it subtends* (both are  $4\pi$  for a sphere of radius  $r = 1$ ).

This can be shown easily by considering a differential surface area on a sphere  $dS = r^2 \sin \theta \, d\theta \, d\phi$ , as shown in Fig. 12-18, and integrating it from  $\theta = 0$  to  $\theta = \pi$ , and from  $\phi = 0$  to  $\phi = 2\pi$ . We get

$$S = \int_{\text{sphere}} dS = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} r^2 \sin \theta \, d\theta \, d\phi = 2\pi r^2 \int_{\theta=0}^{\pi} \sin \theta \, d\theta = 4\pi r^2 \quad (12-10)$$

which is the formula for the area of a sphere. For  $r = 1$  it reduces to  $S = 4\pi$ , and thus the solid angle associated with a sphere is  $\omega = 4\pi$  sr. For a hemisphere, which is more relevant to radiation emitted or received by a surface, it is  $\omega = 2\pi$  sr.

**FIGURE 12-17**

Describing the size of a slice of pizza by a plane angle, and the size of a watermelon slice by a solid angle.

**FIGURE 12-18**

The emission of radiation from a differential surface element through a differential solid angle.

The differential solid angle  $d\omega$  subtended by a differential area  $dS$  on a sphere of radius  $r$  can be expressed as

$$d\omega = \frac{dS}{r^2} = \sin \theta d\theta d\phi \quad (12-11)$$

Note that the area  $dS$  is normal to the direction of viewing since  $dS$  is viewed from the center of the sphere. In general, the differential solid angle  $d\omega$  subtended by a differential surface area  $dA$  when viewed from a point at a distance  $r$  from  $dA$  is expressed as

$$d\omega = \frac{dA_n}{r^2} = \frac{dA \cos \alpha}{r^2} \quad (12-12)$$

where  $\alpha$  is the angle between the normal of the surface and the direction of viewing, and thus  $dA_n = dA \cos \alpha$  is the normal (or projected) area to the direction of viewing.

Small surfaces viewed from relatively large distances can approximately be treated as differential areas in solid angle calculations. For example, the solid angle subtended by a  $5 \text{ cm}^2$  plane surface when viewed from a point at a distance of 80 cm along the normal of the surface is

$$\omega \cong \frac{A_n}{r^2} = \frac{5 \text{ cm}^2}{(80 \text{ cm})^2} = 7.81 \times 10^{-4} \text{ sr}$$

If the surface is tilted so that the normal of the surface makes an angle of  $\alpha = 60^\circ$  with the line connecting the point of viewing to the center of the surface, the projected area would be  $dA_n = dA \cos \alpha = (5 \text{ cm}^2)\cos 60^\circ = 2.5 \text{ cm}^2$ , and the solid angle in this case would be half of the value just determined.

## Intensity of Emitted Radiation

Consider the emission of radiation by a differential area element  $dA$  of a surface, as shown in Fig. 12-18. Radiation is emitted in all directions into the hemispherical space, and the radiation streaming through the surface area  $dS$  is proportional to the solid angle  $d\omega$  subtended by  $dS$ . It is also proportional to the radiating area  $dA$  as seen by an observer on  $dS$ , which varies from a maximum of  $dA$  when  $dS$  is at the top directly above  $dA$  ( $\theta = 0^\circ$ ) to a minimum of zero when  $dS$  is at the bottom ( $\theta = 90^\circ$ ). Therefore, the effective area of  $dA$  for emission in the direction of  $\theta$  is the projection of  $dA$  on a plane normal to  $\theta$ ,

which is  $dA \cos \theta$ . Radiation intensity in a given direction is based on a unit area *normal* to that direction to provide a common basis for the comparison of radiation emitted in different directions.

The **radiation intensity** for emitted radiation  $I_e(\theta, \phi)$  is defined as *the rate at which radiation energy  $d\dot{Q}_e$  is emitted in the  $(\theta, \phi)$  direction per unit area normal to this direction and per unit solid angle about this direction*. That is,

$$I_e(\theta, \phi) = \frac{d\dot{Q}_e}{dA \cos \theta \cdot d\omega} = \frac{d\dot{Q}_e}{dA \cos \theta \sin \theta \, d\theta \, d\phi} \quad (\text{W/m}^2 \cdot \text{sr}) \quad (12-13)$$

The *radiation flux* for emitted radiation is the **emissive power**  $E$  (the rate at which radiation energy is emitted per unit area of the emitting surface), which can be expressed in differential form as

$$dE = \frac{d\dot{Q}_e}{dA} = I_e(\theta, \phi) \cos \theta \sin \theta \, d\theta \, d\phi \quad (12-14)$$

Noting that the hemisphere above the surface intercepts all the radiation rays emitted by the surface, the emissive power from the surface into the hemisphere surrounding it can be determined by integration as

$$E = \int_{\text{hemisphere}} dE = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_e(\theta, \phi) \cos \theta \sin \theta \, d\theta \, d\phi \quad (\text{W/m}^2) \quad (12-15)$$

The intensity of radiation emitted by a surface, in general, varies with direction (especially with the zenith angle  $\theta$ ). But many surfaces in practice can be approximated as being diffuse. For a *diffusely emitting* surface, the intensity of the emitted radiation is independent of direction and thus  $I_e = \text{constant}$ .

Noting that  $\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \cos \theta \sin \theta \, d\theta \, d\phi = \pi$ , the emissive power relation in Eq. 12-15 reduces in this case to

$$\text{Diffusely emitting surface:} \quad E = \pi I_e \quad (\text{W/m}^2) \quad (12-16)$$

Note that the factor in Eq. 12-16 is  $\pi$ . You might have expected it to be  $2\pi$  since intensity is radiation energy per unit solid angle, and the solid angle associated with a hemisphere is  $2\pi$ . The reason for the factor being  $\pi$  is that the emissive power is based on the *actual* surface area whereas the intensity is based on the *projected* area (and thus the factor  $\cos \theta$  that accompanies it), as shown in Fig. 12-19.

For a *blackbody*, which is a diffuse emitter, Eq. 12-16 can be expressed as

$$\text{Blackbody:} \quad E_b = \pi I_b \quad (12-17)$$

where  $E_b = \sigma T^4$  is the blackbody emissive power. Therefore, the intensity of the radiation emitted by a blackbody at absolute temperature  $T$  is

$$\text{Blackbody:} \quad I_b(T) = \frac{E_b(T)}{\pi} = \frac{\sigma T^4}{\pi} \quad (\text{W/m}^2 \cdot \text{sr}) \quad (12-18)$$

**FIGURE 12-19**

Radiation intensity is based on projected area, and thus the calculation of radiation emission from a surface involves the projection of the surface.

## Incident Radiation

All surfaces emit radiation, but they also receive radiation emitted or reflected by other surfaces. The intensity of incident radiation  $I_i(\theta, \phi)$  is defined as *the rate at which radiation energy  $dG$  is incident from the  $(\theta, \phi)$  direction per unit area of the receiving surface normal to this direction and per unit solid angle about this direction* (Fig. 12–20). Here  $\theta$  is the angle between the direction of incident radiation and the normal of the surface.

The radiation flux incident on a surface from *all directions* is called **irradiation**  $G$ , and is expressed as

$$G = \int_{\text{hemisphere}} dG = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_i(\theta, \phi) \cos \theta \sin \theta d\theta d\phi \quad (\text{W/m}^2) \quad (12-19)$$

Therefore irradiation represents the rate at which radiation energy is incident on a surface per unit area of the surface. When the incident radiation is diffuse and thus  $I_i = \text{constant}$ , Eq. 12–19 reduces to

$$\text{Diffusely incident radiation:} \quad G = \pi I_i \quad (\text{W/m}^2) \quad (12-20)$$

Again note that irradiation is based on the *actual* surface area (and thus the factor  $\cos \theta$ ), whereas the intensity of incident radiation is based on the *projected* area.

## Radiosity

Surfaces emit radiation as well as reflecting it, and thus the radiation leaving a surface consists of emitted and reflected components, as shown in Fig. 12–21. The calculation of radiation heat transfer between surfaces involves the *total* radiation energy streaming away from a surface, with no regard for its origin. Thus, we need to define a quantity that represents *the rate at which radiation energy leaves a unit area of a surface in all directions*. This quantity is called the **radiosity**  $J$ , and is expressed as

$$J = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_{e+r}(\theta, \phi) \cos \theta \sin \theta d\theta d\phi \quad (\text{W/m}^2) \quad (12-21)$$

where  $I_{e+r}$  is the sum of the emitted and reflected intensities. For a surface that is both a diffuse emitter and a diffuse reflector,  $I_{e+r} = \text{constant}$ , and the radiosity relation reduces to

$$\text{Diffuse emitter and reflector:} \quad J = \pi I_{e+r} \quad (\text{W/m}^2) \quad (12-22)$$

For a blackbody, radiosity  $J$  is equivalent to the emissive power  $E_b$  since a blackbody absorbs the entire radiation incident on it and there is no reflected component in radiosity.

## Spectral Quantities

So far we considered *total* radiation quantities (quantities integrated over all wavelengths), and made no reference to wavelength dependence. This lumped approach is adequate for many radiation problems encountered

**FIGURE 12-20**  
Radiation incident on a surface in the direction  $(\theta, \phi)$ .

**FIGURE 12-21**  
The three kinds of radiation flux (in  $\text{W/m}^2$ ): emissive power, irradiation, and radiosity.

in practice. But sometimes it is necessary to consider the variation of radiation with wavelength as well as direction, and to express quantities at a certain wavelength  $\lambda$  or per unit wavelength interval about  $\lambda$ . Such quantities are referred to as *spectral* quantities to draw attention to wavelength dependence. The modifier “spectral” is used to indicate “at a given wavelength.”

The *spectral radiation intensity*  $I_{\lambda}(\theta, \phi)$ , for example, is simply the total radiation intensity  $I(\theta, \phi)$  per unit wavelength interval about  $\lambda$ . The **spectral intensity** for emitted radiation  $I_{\lambda,e}(\lambda, \theta, \phi)$  can be defined as *the rate at which radiation energy  $d\dot{Q}_e$  is emitted at the wavelength  $\lambda$  in the  $(\theta, \phi)$  direction per unit area normal to this direction, per unit solid angle about this direction*, and it can be expressed as

**FIGURE 12-22**

Integration of a “spectral” quantity for all wavelengths gives the “total” quantity.

Then the *spectral emissive power* becomes

$$E_{\lambda} = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_{\lambda,e}(\lambda, \theta, \phi) \cos \theta \sin \theta d\theta d\phi \quad (\text{W/m}^2) \quad (12-24)$$

Similar relations can be obtained for spectral irradiation  $G_{\lambda}$ , and spectral radiosity  $J_{\lambda}$  by replacing  $I_{\lambda,e}$  in this equation by  $I_{\lambda,i}$  and  $I_{\lambda,e+r}$ , respectively.

When the variation of spectral radiation intensity  $I_{\lambda}$  with wavelength  $\lambda$  is known, the total radiation intensity  $I$  for emitted, incident, and emitted + reflected radiation can be determined by integration over the entire wavelength spectrum as (Fig. 12-22)

$$I_e = \int_0^{\infty} I_{\lambda,e} d\lambda, \quad I_i = \int_0^{\infty} I_{\lambda,i} d\lambda, \quad \text{and} \quad I_{e+r} = \int_0^{\infty} I_{\lambda,e+r} d\lambda \quad (12-25)$$

These intensities can then be used in Eqs. 12-15, 12-19, and 12-21 to determine the emissive power  $E$ , irradiation  $G$ , and radiosity  $J$ , respectively.

Similarly, when the variations of spectral radiation fluxes  $E_{\lambda}$ ,  $G_{\lambda}$ , and  $J_{\lambda}$  with wavelength  $\lambda$  are known, the total radiation fluxes can be determined by integration over the entire wavelength spectrum as

$$E = \int_0^{\infty} E_{\lambda} d\lambda, \quad G = \int_0^{\infty} G_{\lambda} d\lambda, \quad \text{and} \quad J = \int_0^{\infty} J_{\lambda} d\lambda \quad (12-26)$$

When the surfaces and the incident radiation are *diffuse*, the spectral radiation fluxes are related to spectral intensities as

$$E_{\lambda} = \pi I_{\lambda,e}, \quad G_{\lambda} = \pi I_{\lambda,i}, \quad \text{and} \quad J_{\lambda} = \pi I_{\lambda,e+r} \quad (12-27)$$

Note that the relations for spectral and total radiation quantities are of the same form.

The spectral intensity of radiation emitted by a blackbody at a thermodynamic temperature  $T$  at a wavelength  $\lambda$  has been determined by Max Planck, and is expressed as

$$I_{b\lambda}(\lambda, T) = \frac{2hc_0^2}{\lambda^5 [\exp(hc_0/\lambda kT) - 1]} \quad (\text{W/m}^2 \cdot \text{sr} \cdot \mu\text{m}) \quad (12-28)$$

where  $h = 6.626069 \times 10^{-34}$  J·s is the Planck constant,  $k = 1.38065 \times 10^{-23}$  J/K is the Boltzmann constant, and  $c_0 = 2.9979 \times 10^8$  m/s is the speed of light in a vacuum. Then the spectral blackbody emissive power is, from Eq. 12–27,

$$E_{b\lambda}(\lambda, T) = \pi I_{b\lambda}(\lambda, T) \quad (12-29)$$

A simplified relation for  $E_{b\lambda}$  is given by Eq. 12–4.

### EXAMPLE 12–3 Radiation Incident on a Small Surface

A small surface of area  $A_1 = 3 \text{ cm}^2$  emits radiation as a blackbody at  $T_1 = 600 \text{ K}$ . Part of the radiation emitted by  $A_1$  strikes another small surface of area  $A_2 = 5 \text{ cm}^2$  oriented as shown in Fig. 12–23. Determine the solid angle subtended by  $A_2$  when viewed from  $A_1$ , and the rate at which radiation emitted by  $A_1$  strikes  $A_2$ .

**SOLUTION** A surface is subjected to radiation emitted by another surface. The solid angle subtended and the rate at which emitted radiation is received are to be determined.

**Assumptions** 1 Surface  $A_1$  emits diffusely as a blackbody. 2 Both  $A_1$  and  $A_2$  can be approximated as differential surfaces since both are very small compared to the square of the distance between them.

**Analysis** Approximating both  $A_1$  and  $A_2$  as differential surfaces, the solid angle subtended by  $A_2$  when viewed from  $A_1$  can be determined from Eq. 12–12 to be

$$\omega_{2-1} \cong \frac{A_{n,2}}{r^2} = \frac{A_2 \cos \theta_2}{r^2} = \frac{(5 \text{ cm}^2) \cos 40^\circ}{(75 \text{ cm})^2} = 6.81 \times 10^{-4} \text{ sr}$$

since the normal of  $A_2$  makes  $40^\circ$  with the direction of viewing. Note that solid angle subtended by  $A_2$  would be maximum if  $A_2$  were positioned normal to the direction of viewing. Also, the point of viewing on  $A_1$  is taken to be a point in the middle, but it can be any point since  $A_1$  is assumed to be very small.

The radiation emitted by  $A_1$  that strikes  $A_2$  is equivalent to the radiation emitted by  $A_1$  through the solid angle  $\omega_{2-1}$ . The intensity of the radiation emitted by  $A_1$  is

$$I_1 = \frac{E_b(T_1)}{\pi} = \frac{\sigma T_1^4}{\pi} = \frac{(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(600 \text{ K})^4}{\pi} = 2339 \text{ W/m}^2 \cdot \text{sr}$$

This value of intensity is the same in all directions since a blackbody is a diffuse emitter. Intensity represents the rate of radiation emission per unit area normal to the direction of emission per unit solid angle. Therefore, the rate of radiation energy emitted by  $A_1$  in the direction of  $\theta_1$  through the solid angle  $\omega_{2-1}$  is determined by multiplying  $I_1$  by the area of  $A_1$  normal to  $\theta_1$  and the solid angle  $\omega_{2-1}$ . That is,

$$\begin{aligned} \dot{Q}_{1-2} &= I_1(A_1 \cos \theta_1)\omega_{2-1} \\ &= (2339 \text{ W/m}^2 \cdot \text{sr})(3 \times 10^{-4} \cos 55^\circ \text{ m}^2)(6.81 \times 10^{-4} \text{ sr}) \\ &= 2.74 \times 10^{-4} \text{ W} \end{aligned}$$

Therefore, the radiation emitted from surface  $A_1$  will strike surface  $A_2$  at a rate of  $2.74 \times 10^{-4} \text{ W}$ .

**FIGURE 12–23**  
Schematic for Example 12–3.

**Discussion** The total rate of radiation emission from surface  $A_1$  is  $\dot{Q}_e = A_1 \sigma T_1^4 = 2.204 \text{ W}$ . Therefore, the fraction of emitted radiation that strikes  $A_2$  is  $2.74 \times 10^{-4}/2.204 = 0.00012$  (or 0.012 percent). Noting that the solid angle associated with a hemisphere is  $2\pi$ , the fraction of the solid angle subtended by  $A_2$  is  $6.81 \times 10^{-4}/(2\pi) = 0.000108$  (or 0.0108 percent), which is 0.9 times the fraction of emitted radiation. Therefore, the fraction of the solid angle a surface occupies does not represent the fraction of radiation energy the surface will receive even when the intensity of emitted radiation is constant. This is because radiation energy emitted by a surface in a given direction is proportional to the *projected area* of the surface in that direction, and reduces from a maximum at  $\theta = 0^\circ$  (the direction normal to surface) to zero at  $\theta = 90^\circ$  (the direction parallel to surface).

## 12–5 • RADIATIVE PROPERTIES

Most materials encountered in practice, such as metals, wood, and bricks, are *opaque* to thermal radiation, and radiation is considered to be a *surface phenomenon* for such materials. That is, thermal radiation is emitted or absorbed within the first few microns of the surface, and thus we speak of radiative properties of *surfaces* for opaque materials.

Some other materials, such as glass and water, allow visible radiation to penetrate to considerable depths before any significant absorption takes place. Radiation through such *semitransparent* materials obviously cannot be considered to be a surface phenomenon since the entire volume of the material interacts with radiation. On the other hand, both glass and water are practically opaque to infrared radiation. Therefore, materials can exhibit different behavior at different wavelengths, and the dependence on wavelength is an important consideration in the study of radiative properties such as emissivity, absorptivity, reflectivity, and transmissivity of materials.

In the preceding section, we defined a *blackbody* as a perfect emitter and absorber of radiation and said that no body can emit more radiation than a blackbody at the same temperature. Therefore, a blackbody can serve as a convenient *reference* in describing the emission and absorption characteristics of real surfaces.

### Emissivity

The **emissivity** of a surface represents the *ratio of the radiation emitted by the surface at a given temperature to the radiation emitted by a blackbody at the same temperature*. The emissivity of a surface is denoted by  $\varepsilon$ , and it varies between zero and one,  $0 \leq \varepsilon \leq 1$ . Emissivity is a measure of how closely a real surface approximates a blackbody, for which  $\varepsilon = 1$ .

The emissivity of a real surface is not a constant. Rather, it varies with the *temperature* of the surface as well as the *wavelength* and the *direction* of the emitted radiation. Therefore, different emissivities can be defined for a surface, depending on the effects considered. The most elemental emissivity of a surface at a given temperature is the **spectral directional emissivity**, which is defined as the ratio of the intensity of radiation emitted by the surface at a specified wavelength in a specified direction to the intensity of radiation emitted by a blackbody at the same temperature at the same wavelength. That is,

$$\varepsilon_{\lambda, \theta}(\lambda, \theta, \phi, T) = \frac{I_{\lambda, e}(\lambda, \theta, \phi, T)}{I_{b\lambda}(\lambda, T)} \quad (12-30)$$

where the subscripts  $\lambda$  and  $\theta$  are used to designate *spectral* and *directional* quantities, respectively. Note that blackbody radiation intensity is independent of direction, and thus it has no functional dependence on  $\theta$  and  $\phi$ .

The **total directional emissivity** is defined in a like manner by using total intensities (intensities integrated over all wavelengths) as

$$\varepsilon_\theta(\theta, \phi, T) = \frac{I_e(\theta, \phi, T)}{I_b(T)} \quad (12-31)$$

In practice, it is usually more convenient to work with radiation properties averaged over all directions, called *hemispherical properties*. Noting that the integral of the rate of radiation energy emitted at a specified wavelength per unit surface area over the entire hemisphere is *spectral emissive power*, the **spectral hemispherical emissivity** can be expressed as

$$\varepsilon_\lambda(\lambda, T) = \frac{E_\lambda(\lambda, T)}{E_{b\lambda}(\lambda, T)} \quad (12-32)$$

Note that the emissivity of a surface at a given wavelength can be different at different temperatures since the spectral distribution of emitted radiation (and thus the amount of radiation emitted at a given wavelength) changes with temperature.

Finally, the **total hemispherical emissivity** is defined in terms of the radiation energy emitted over all wavelengths in all directions as

$$\varepsilon(T) = \frac{E(T)}{E_b(T)} \quad (12-33)$$

Therefore, the total hemispherical emissivity (or simply the “average emissivity”) of a surface at a given temperature represents the ratio of the total radiation energy emitted by the surface to the radiation emitted by a blackbody of the same surface area at the same temperature.

Noting from Eqs. 12–26 and 12–32 that  $E = \int_0^\infty E_\lambda d\lambda$  and  $E_\lambda(\lambda, T) = \varepsilon_\lambda(\lambda, T) E_{b\lambda}(\lambda, T)$ , and the total hemispherical emissivity can also be expressed as

$$\varepsilon(T) = \frac{E(T)}{E_b(T)} = \frac{\int_0^\infty \varepsilon_\lambda(\lambda, T) E_{b\lambda}(\lambda, T) d\lambda}{\sigma T^4} \quad (12-34)$$

since  $E_b(T) = \sigma T^4$ . To perform this integration, we need to know the variation of spectral emissivity with wavelength at the specified temperature. The integrand is usually a complicated function, and the integration has to be performed numerically. However, the integration can be performed quite easily by dividing the spectrum into a sufficient number of *wavelength bands* and assuming the emissivity to remain constant over each band; that is, by expressing the function  $\varepsilon_\lambda(\lambda, T)$  as a step function. This simplification offers great convenience for little sacrifice of accuracy, since it allows us to transform the integration into a summation in terms of blackbody emission functions.

As an example, consider the emissivity function plotted in Fig. 12–24. It seems like this function can be approximated reasonably well by a step function of the form

$$\varepsilon_\lambda = \begin{cases} \varepsilon_1 = \text{constant}, & 0 \leq \lambda < \lambda_1 \\ \varepsilon_2 = \text{constant}, & \lambda_1 \leq \lambda < \lambda_2 \\ \varepsilon_3 = \text{constant}, & \lambda_2 \leq \lambda < \infty \end{cases} \quad (12-35)$$

**FIGURE 12-24**

Approximating the actual variation of emissivity with wavelength by a step function.

*Real surface:*

$$\varepsilon_\theta \neq \text{constant}$$

$$\varepsilon_\lambda \neq \text{constant}$$

*Diffuse surface:*

$$\varepsilon_\theta = \text{constant}$$

*Gray surface:*

$$\varepsilon_\lambda = \text{constant}$$

*Diffuse, gray surface:*

$$\varepsilon = \varepsilon_\lambda = \varepsilon_\theta = \text{constant}$$

FIGURE 12-25

The effect of diffuse and gray approximations on the emissivity of a surface.

FIGURE 12-26

Typical variations of emissivity with direction for electrical conductors and nonconductors.

Then the average emissivity can be determined from Eq. 12-34 by breaking the integral into three parts and utilizing the definition of the blackbody radiation function as

$$\begin{aligned} \varepsilon(T) &= \frac{\varepsilon_1 \int_0^{\lambda_1} E_{b\lambda} d\lambda}{E_b} + \frac{\varepsilon_2 \int_{\lambda_1}^{\lambda_2} E_{b\lambda} d\lambda}{E_b} + \frac{\varepsilon_3 \int_{\lambda_2}^{\infty} E_{b\lambda} d\lambda}{E_b} \\ &= \varepsilon_1 f_{0-\lambda_1}(T) + \varepsilon_2 f_{\lambda_1-\lambda_2}(T) + \varepsilon_3 f_{\lambda_2-\infty}(T) \end{aligned} \quad (12-36)$$

Radiation is a complex phenomenon as it is, and the consideration of the wavelength and direction dependence of properties, assuming sufficient data exist, makes it even more complicated. Therefore, the *diffuse* and *gray* approximations are often utilized in radiation calculations. A surface is said to be *diffuse* if its properties are *independent of direction*, and *gray* if its properties are *independent of wavelength*. Therefore, the emissivity of a gray, diffuse surface is simply the total hemispherical emissivity of that surface because of independence of direction and wavelength (Fig. 12-25).

A few comments about the validity of the diffuse approximation are in order. Although real surfaces do not emit radiation in a perfectly diffuse manner as a blackbody does, they often come close. The variation of emissivity with direction for both electrical conductors and nonconductors is given in Fig. 12-26. Here  $\theta$  is the angle measured from the normal of the surface, and thus  $\theta = 0$  for radiation emitted in a direction normal to the surface. Note that  $\varepsilon_\theta$  remains nearly constant for about  $\theta < 40^\circ$  for conductors such as metals and for  $\theta < 70^\circ$  for nonconductors such as plastics. Therefore, the directional emissivity of a surface in the normal direction is representative of the hemispherical emissivity of the surface. In radiation analysis, it is common practice to assume the surfaces to be diffuse emitters with an emissivity equal to the value in the normal ( $\theta = 0$ ) direction.

The effect of the gray approximation on emissivity and emissive power of a real surface is illustrated in Fig. 12-27. Note that the radiation emission from a real surface, in general, differs from the Planck distribution, and the emission curve may have several peaks and valleys. A gray surface should emit as much

FIGURE 12-27

Comparison of the emissivity (a) and emissive power (b) of a real surface with those of a gray surface and a blackbody at the same temperature.

FIGURE 12-28

The variation of normal emissivity with (a) wavelength and (b) temperature for various materials.

radiation as the real surface it represents at the same temperature. Therefore, the areas under the emission curves of the real and gray surfaces must be equal.

The emissivities of common materials are listed in Tables A-18 and A-19 in the Appendix, and the variation of emissivity with wavelength and temperature is illustrated in Fig. 12-28. Typical ranges of emissivity of various materials are given in Fig. 12-29. Note that metals generally have low emissivities, as low as 0.02 for polished surfaces, and nonmetals such as ceramics and organic materials have high ones. The emissivity of metals increases with temperature. Also, oxidation causes significant increases in the emissivity of metals. Heavily oxidized metals can have emissivities comparable to those of nonmetals.

Care should be exercised in the use and interpretation of radiation property data reported in the literature, since the properties strongly depend on the surface conditions such as oxidation, roughness, type of finish, and cleanliness. Consequently, there is considerable discrepancy and uncertainty in the reported values. This uncertainty is largely due to the difficulty in characterizing and describing the surface conditions precisely.

#### EXAMPLE 12-4 Emissivity of a Surface and Emissive Power

The spectral emissivity function of an opaque surface at 800 K is approximated as (Fig. 12-30)

$$\varepsilon_\lambda = \begin{cases} \varepsilon_1 = 0.3, & 0 \leq \lambda < 3 \mu\text{m} \\ \varepsilon_2 = 0.8, & 3 \mu\text{m} \leq \lambda < 7 \mu\text{m} \\ \varepsilon_3 = 0.1, & 7 \mu\text{m} \leq \lambda < \infty \end{cases}$$

Determine the average emissivity of the surface and its emissive power.

**SOLUTION** The variation of emissivity of a surface at a specified temperature with wavelength is given. The average emissivity of the surface and its emissive power are to be determined.

FIGURE 12-29

Typical ranges of emissivity for various materials.

FIGURE 12-30

The spectral emissivity of the surface considered in Example 12-4.

**Analysis** The variation of the emissivity with wavelength is given as a step function. Therefore, the average emissivity of the surface can be determined from Eq. 12–34 by breaking the integral into three parts,

$$\begin{aligned}\varepsilon(T) &= \frac{\int_0^{\lambda_1} E_{b\lambda} d\lambda}{\sigma T^4} + \frac{\int_{\lambda_1}^{\lambda_2} E_{b\lambda} d\lambda}{\sigma T^4} + \frac{\int_{\lambda_2}^{\infty} E_{b\lambda} d\lambda}{\sigma T^4} \\ &= \varepsilon_1 f_{0-\lambda_1}(T) + \varepsilon_2 f_{\lambda_1-\lambda_2}(T) + \varepsilon_3 f_{\lambda_2-\infty}(T) \\ &= \varepsilon_1 f_{\lambda_1} + \varepsilon_2 (f_{\lambda_2} - f_{\lambda_1}) + \varepsilon_3 (1 - f_{\lambda_2})\end{aligned}$$

where  $f_{\lambda_1}$  and  $f_{\lambda_2}$  are blackbody radiation functions and are determined from Table 12–2 to be

$$\begin{aligned}\lambda_1 T &= (3 \text{ } \mu\text{m})(800 \text{ K}) = 2400 \text{ } \mu\text{m}\cdot\text{K} \rightarrow f_{\lambda_1} = 0.140256 \\ \lambda_2 T &= (7 \text{ } \mu\text{m})(800 \text{ K}) = 5600 \text{ } \mu\text{m}\cdot\text{K} \rightarrow f_{\lambda_2} = 0.701046\end{aligned}$$

Note that  $f_{0-\lambda_1} = f_{\lambda_1} - f_0 = f_{\lambda_1}$  since  $f_0 = 0$ , and  $f_{\lambda_2-\infty} = f_\infty - f_{\lambda_2} = 1 - f_{\lambda_2}$  since  $f_\infty = 1$ . Substituting,

$$\begin{aligned}\varepsilon &= 0.3 \times 0.140256 + 0.8(0.701046 - 0.140256) + 0.1(1 - 0.701046) \\ &= \mathbf{0.521}\end{aligned}$$

That is, the surface will emit as much radiation energy at 800 K as a gray surface having a constant emissivity of  $\varepsilon = 0.521$ . The emissive power of the surface is

$$E = \varepsilon \sigma T^4 = 0.521(5.67 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4)(800 \text{ K})^4 = \mathbf{12,100 \text{ W/m}^2}$$

**Discussion** Note that the surface emits 12.1 kJ of radiation energy per second per  $\text{m}^2$  area of the surface.

FIGURE 12–31

The absorption, reflection, and transmission of incident radiation by a semitransparent material.

## Absorptivity, Reflectivity, and Transmissivity

Everything around us constantly emits radiation, and the emissivity represents the emission characteristics of those bodies. This means that every body, including our own, is constantly bombarded by radiation coming from all directions over a range of wavelengths. Recall that radiation flux *incident on a surface* is called **irradiation** and is denoted by  $G$ .

When radiation strikes a surface, part of it is absorbed, part of it is reflected, and the remaining part, if any, is transmitted, as illustrated in Fig. 12–31. The fraction of irradiation absorbed by the surface is called the **absorptivity  $\alpha$** , the fraction reflected by the surface is called the **reflectivity  $\rho$** , and the fraction transmitted is called the **transmissivity  $\tau$** . That is,

$$\text{Absorptivity: } \alpha = \frac{\text{Absorbed radiation}}{\text{Incident radiation}} = \frac{G_{\text{abs}}}{G}, \quad 0 \leq \alpha \leq 1 \quad (12-37)$$

$$\text{Reflectivity: } \rho = \frac{\text{Reflected radiation}}{\text{Incident radiation}} = \frac{G_{\text{ref}}}{G}, \quad 0 \leq \rho \leq 1 \quad (12-38)$$

$$\text{Transmissivity: } \tau = \frac{\text{Transmitted radiation}}{\text{Incident radiation}} = \frac{G_{\text{tr}}}{G}, \quad 0 \leq \tau \leq 1 \quad (12-39)$$

where  $G$  is the radiation flux incident on the surface, and  $G_{\text{abs}}$ ,  $G_{\text{ref}}$ , and  $G_{\text{tr}}$  are the absorbed, reflected, and transmitted portions of it, respectively. The first

law of thermodynamics requires that the sum of the absorbed, reflected, and transmitted radiation be equal to the incident radiation. That is,

$$G_{\text{abs}} + G_{\text{ref}} + G_{\text{tr}} = G$$

Dividing each term of this relation by  $G$  yields

$$\alpha + \rho + \tau = 1 \quad (12-40)$$

For idealized blackbodies which are perfect absorbers,  $\rho = 0$  and  $\tau = 0$ , and Eq. 12-40 reduces to  $\alpha = 1$ . For opaque surfaces such as most solids and liquids,  $\tau = 0$ , and thus

$$\alpha + \rho = 1 \quad (12-41)$$

For most gases the reflectance is absent,  $\rho = 0$ , and Eq. 12-40 reduces in this case to

$$\alpha + \tau = 1 \quad (12-42)$$

The preceding two equations are important property relations since the knowledge of one property (either  $\alpha$  or  $\rho$  in Eq. 12-41 and  $\alpha$  or  $\tau$  in Eq. 12-42) implies the knowledge of the other property.

These definitions are for *total hemispherical* properties, since  $G$  represents the radiation flux incident on the surface from all directions over the hemispherical space and over all wavelengths. Thus,  $\alpha$ ,  $\rho$ , and  $\tau$  are the *average* properties of a medium for all directions and all wavelengths. However, like emissivity, these properties can also be defined for a specific wavelength and/or direction. For example, the **spectral directional absorptivity** and **spectral directional reflectivity** of a surface are defined, respectively, as the absorbed and reflected fractions of the intensity of radiation incident at a specified wavelength in a specified direction as

$$\alpha_{\lambda, \theta}(\lambda, \theta, \phi) = \frac{I_{\lambda, \text{abs}}(\lambda, \theta, \phi)}{I_{\lambda, i}(\lambda, \theta, \phi)} \quad \text{and} \quad \rho_{\lambda, \theta}(\lambda, \theta, \phi) = \frac{I_{\lambda, \text{ref}}(\lambda, \theta, \phi)}{I_{\lambda, i}(\lambda, \theta, \phi)} \quad (12-43)$$

Likewise, the **spectral hemispherical absorptivity** and **spectral hemispherical reflectivity** of a surface are defined as

$$\alpha_\lambda(\lambda) = \frac{G_{\lambda, \text{abs}}(\lambda)}{G_\lambda(\lambda)} \quad \text{and} \quad \rho_\lambda(\lambda) = \frac{G_{\lambda, \text{ref}}(\lambda)}{G_\lambda(\lambda)} \quad (12-44)$$

where  $G_\lambda$  is the spectral irradiation (in  $\text{W}/\text{m}^2 \cdot \mu\text{m}$ ) incident on the surface, and  $G_{\lambda, \text{abs}}$  and  $G_{\lambda, \text{ref}}$  are the reflected and absorbed portions of it, respectively.

Similar quantities can be defined for the transmissivity of semitransparent materials. For example, the **spectral hemispherical transmissivity** of a medium can be expressed as

$$\tau_\lambda(\lambda) = \frac{G_{\lambda, \text{tr}}(\lambda)}{G_\lambda(\lambda)} \quad (12-45)$$

The average absorptivity, reflectivity, and transmissivity of a surface can also be defined in terms of their spectral counterparts as

$$\alpha = \frac{\int_0^\infty \alpha_\lambda G_\lambda d\lambda}{\int_0^\infty G_\lambda d\lambda}, \quad \rho = \frac{\int_0^\infty \rho_\lambda G_\lambda d\lambda}{\int_0^\infty G_\lambda d\lambda}, \quad \tau = \frac{\int_0^\infty \tau_\lambda G_\lambda d\lambda}{\int_0^\infty G_\lambda d\lambda} \quad (12-46)$$

FIGURE 12-32

Different types of reflection from a surface: (a) actual or irregular, (b) diffuse, and (c) specular or mirrorlike.

The reflectivity differs somewhat from the other properties in that it is *bidirectional* in nature. That is, the value of the reflectivity of a surface depends not only on the direction of the incident radiation but also the direction of reflection. Therefore, the reflected rays of a radiation beam incident on a real surface in a specified direction forms an irregular shape, as shown in Fig. 12-32. Such detailed reflectivity data do not exist for most surfaces, and even if they did, they would be of little value in radiation calculations since this would usually add more complication to the analysis.

In practice, for simplicity, surfaces are assumed to reflect in a perfectly **specular** or **diffuse** manner. In **specular** (or *mirrorlike*) **reflection**, the angle of reflection equals the angle of incidence of the radiation beam. In **diffuse reflection**, radiation is reflected equally in all directions, as shown in Fig. 12-32. Reflection from smooth and polished surfaces approximates specular reflection, whereas reflection from rough surfaces approximates diffuse reflection. In radiation analysis, smoothness is defined relative to wavelength. A surface is said to be *smooth* if the height of the surface roughness is much smaller than the wavelength of the incident radiation.

Unlike emissivity, the absorptivity of a material is practically independent of surface temperature. However, the absorptivity depends strongly on the temperature of the source at which the incident radiation is originating. This is also evident from Fig. 12-33, which shows the absorptivities of various materials at room temperature as functions of the temperature of the radiation source. For example, the absorptivity of the concrete roof of a house is about 0.6 for solar radiation (source temperature: 5780 K) and 0.9 for radiation originating from the surrounding trees and buildings (source temperature: 300 K), as illustrated in Fig. 12-34.

Notice that the absorptivity of aluminum increases with the source temperature, a characteristic for metals, and the absorptivity of electric nonconductors, in general, decreases with temperature. This decrease is most pronounced for

FIGURE 12-33

Variation of absorptivity with the temperature of the source of irradiation for various common materials at room temperature.

FIGURE 12-34

The absorptivity of a material may be quite different for radiation originating from sources at different temperatures.

surfaces that appear white to the eye. For example, the absorptivity of a white painted surface is low for solar radiation, but it is rather high for infrared radiation.

## Kirchhoff's Law

Consider a small body of surface area  $A_s$ , emissivity  $\varepsilon$ , and absorptivity  $\alpha$  at temperature  $T$  contained in a large isothermal enclosure at the same temperature, as shown in Fig. 12–35. Recall that a large isothermal enclosure forms a blackbody cavity regardless of the radiative properties of the enclosure surface, and the body in the enclosure is too small to interfere with the blackbody nature of the cavity. Therefore, the radiation incident on any part of the surface of the small body is equal to the radiation emitted by a blackbody at temperature  $T$ . That is,  $G = E_b(T) = \sigma T^4$ , and the radiation absorbed by the small body per unit of its surface area is

$$G_{\text{abs}} = \alpha G = \alpha \sigma T^4$$

The radiation emitted by the small body is

$$E_{\text{emit}} = \varepsilon \sigma T^4$$

Considering that the small body is in thermal equilibrium with the enclosure, the net rate of heat transfer to the body must be zero. Therefore, the radiation emitted by the body must be equal to the radiation absorbed by it:

$$A_s \varepsilon \sigma T^4 = A_s \alpha \sigma T^4$$

Thus, we conclude that

$$\varepsilon(T) = \alpha(T) \quad (12-47)$$

That is, *the total hemispherical emissivity of a surface at temperature  $T$  is equal to its total hemispherical absorptivity for radiation coming from a blackbody at the same temperature*. This relation, which greatly simplifies the radiation analysis, was first developed by Gustav Kirchhoff in 1860 and is now called **Kirchhoff's law**. Note that this relation is derived under the condition that the surface temperature is equal to the temperature of the source of irradiation, and the reader is cautioned against using it when considerable difference (more than a few hundred degrees) exists between the surface temperature and the temperature of the source of irradiation.

The derivation above can also be repeated for radiation at a specified wavelength to obtain the *spectral form* of Kirchhoff's law:

$$\varepsilon_\lambda(T) = \alpha_\lambda(T) \quad (12-48)$$

This relation is valid when the irradiation or the emitted radiation is independent of direction. The form of Kirchhoff's law that involves no restrictions is the *spectral directional form* expressed as  $\varepsilon_{\lambda,\theta}(T) = \alpha_{\lambda,\theta}(T)$ . That is, the emissivity of a surface at a specified wavelength, direction, and temperature is always equal to its absorptivity at the same wavelength, direction, and temperature.

It is very tempting to use Kirchhoff's law in radiation analysis since the relation  $\varepsilon = \alpha$  together with  $\rho = 1 - \alpha$  enables us to determine all three properties of an opaque surface from a knowledge of only *one* property.

**FIGURE 12–35**

The small body contained in a large isothermal enclosure used in the development of Kirchhoff's law.

Although Eq. 12–47 gives acceptable results in most cases, in practice, care should be exercised when there is considerable difference between the surface temperature and the temperature of the source of incident radiation.

**FIGURE 12–36**

Schematic for Example 12–5.

**PtD** **EXAMPLE 12–5**

**Prevention of Thermal Burn Hazard by Using Radiation Sensors to Monitor Temperatures of Parts on a Conveyor**

Hot opaque parts ( $A_1 = 15 \text{ cm}^2$ ,  $m = 0.5 \text{ kg}$ ,  $c_v = 450 \text{ J/kg}\cdot\text{K}$ ,  $\varepsilon = 0.85$ ), coming out of a production line and on their way to packaging, are cooled in an air-chilled chamber (Fig. 12–36). One of the reasons for cooling the parts prior to the packing operation is to alleviate the risk of thermal burn hazard. For the parts to be safe for handling by the operators, each part should be cooled to below  $45^\circ\text{C}$ . To monitor the temperatures of the parts, two identical radiometers are placed at a distance of 1 m from the parts on the conveyor at the entrance and exit of the cooling chamber. Throughout the entire process, irradiation on the parts from the surroundings is estimated to be  $300 \text{ W/m}^2$ . Inside the cooling chamber, 215 W of heat is removed from each part in the duration of 1 minute. If the radiometer at the cooling chamber entrance detects an irradiation of  $0.21 \text{ W/m}^2$ , determine the irradiation that the radiometer at the cooling chamber exit would measure. Would the parts exiting the cooling chamber be safe for handling?

**SOLUTION** In this example, the concepts of Prevention through Design (PtD) are applied in conjunction with the concepts of radiation intensity and radiative properties.

**Assumptions** 1 Both part surface and radiometer can be approximated as differential surfaces since both are very small compared to the square of the distance between them. 2 Temperatures of parts are uniform. 3 Kirchhoff's law is applicable. 4 Parts are opaque and their properties are constant.

**Properties** The specific heat and the emissivity of the parts are given as  $c_v = 450 \text{ J/kg}\cdot\text{K}$  and  $\varepsilon = 0.85$ . The Stefan-Boltzmann constant is  $\sigma = 5.67 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4$ .

**Analysis** From Kirchhoff's law, the emissivity of the parts is

$$\varepsilon = \alpha = 0.85$$

The parts are opaque ( $\tau = 0$ ) and the reflectivity of the parts is

$$\rho = 1 - \alpha = 1 - 0.85 = 0.15$$

The solid angle subtended by both radiometers when viewed from the parts at the entrance and exit of the cooling chamber is

$$\omega_{2-1} \cong \frac{A_{n,2}}{L^2} = \frac{A_2 \cos \theta_2}{L^2}$$

The intensities of the radiation emitted and reflected (radiosity) by the parts  $A_1$  at the entrance and exit of the cooling chamber are

$$I_{1,\text{in}} = \frac{J_{\text{in}}}{\pi} = \frac{E_{\text{in}} + G_{\text{ref}}}{\pi} = \frac{\varepsilon \sigma T_{1,\text{in}}^4 + \rho G_1}{\pi} \quad \text{and} \quad I_{1,\text{out}} = \frac{J_{\text{out}}}{\pi} = \frac{E_{\text{out}} + G_{\text{ref}}}{\pi} = \frac{\varepsilon \sigma T_{1,\text{out}}^4 + \rho G_1}{\pi}$$

The irradiations measured by the radiometers  $A_2$  at the entrance and exit of the cooling chamber are

$$G_{2,\text{in}} = \frac{\dot{Q}_{1-2,\text{in}}}{A_2} = \frac{I_{1,\text{in}}(A_1 \cos\theta_1)\omega_{2-1}}{A_2} = \frac{(\varepsilon\sigma T_{1,\text{in}}^4 + \rho G_1)A_1(\cos\theta_1)(\cos\theta_2)}{\pi L^2}$$

and

$$G_{2,\text{out}} = \frac{\dot{Q}_{1-2,\text{out}}}{A_2} = \frac{I_{1,\text{out}}(A_1 \cos\theta_1)\omega_{2-1}}{A_2} = \frac{(\varepsilon\sigma T_{1,\text{out}}^4 + \rho G_1)A_1(\cos\theta_1)(\cos\theta_2)}{\pi L^2}$$

With both radiometers placed normal to the direction of viewing from each part that passes them ( $\theta_1 = \theta_2 = 0^\circ$ ), we have

$$G_{2,\text{in}} = \frac{(\varepsilon\sigma T_{1,\text{in}}^4 + \rho G_1)A_1}{\pi L^2} \quad \text{and} \quad G_{2,\text{out}} = \frac{(\varepsilon\sigma T_{1,\text{out}}^4 + \rho G_1)A_1}{\pi L^2}$$

From the given irradiation  $G_{2,\text{in}}$  detected by the radiometer at the cooling chamber entrance, the temperature of the parts at that location is

$$\begin{aligned} T_{1,\text{in}} &= \left[ \left( \frac{G_{2,\text{in}} \pi L^2}{A_1} - \rho G_1 \right) \left( \frac{1}{\varepsilon\sigma} \right) \right]^{1/4} \\ &= \left\{ \left[ \frac{(0.21 \text{ W/m}^2) \pi (1.5 \text{ m})^2}{15 \times 10^{-4} \text{ m}^2} - (0.15)(300 \text{ W/m}^2) R_B \frac{1}{(0.85)(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)} \right] \right\}^{1/4} \\ &= 374 \text{ K} = 101^\circ\text{C} \end{aligned}$$

The temperature of the parts at the exit of the cooling chamber can be determined from the change in the internal energy and the heat removed from the parts during the cooling process:

$$Q = \dot{Q}\Delta t = \Delta U = mc_v(T_{1,\text{in}} - T_{1,\text{out}}) \quad \text{or} \quad T_{1,\text{out}} = T_{1,\text{in}} - \frac{\dot{Q}\Delta t}{mc_v}$$

Thus,

$$T_{1,\text{out}} = 101^\circ\text{C} - \frac{(215 \text{ W})(60 \text{ s})}{(0.5 \text{ kg})(450 \text{ J/kg}\cdot\text{K})} = 43.7^\circ\text{C} < 45^\circ\text{C}$$

Finally, the irradiation  $G_{2,\text{out}}$  measured by the radiometer at the exit of the cooling chamber is

$$\begin{aligned} G_{2,\text{out}} &= \frac{(\varepsilon\sigma T_{1,\text{out}}^4 + \rho G_1)A_1}{\pi L^2} \\ &= \frac{(0.85)(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(43.7 + 273)^4 \text{ K}^4 + (0.15)(300 \text{ W/m}^2)}{\pi(1.5 \text{ m})^2} (15 \times 10^{-4} \text{ m}^2) \\ &= 0.112 \text{ W/m}^2 \end{aligned}$$

**Discussion** The temperature of the parts exiting the cooling chamber is below  $45^\circ\text{C}$ , therefore they are safe for handling in the packing operation.

Having two radiometers monitoring the temperatures of the parts entering and exiting the cooling chambers, allow the engineers to determine the cooling duration necessary for the parts. Therefore, the conveyor speed can be optimized and at the same time preventing thermal burn hazard.

**FIGURE 12-37**

The spectral transmissivity of low-iron glass at room temperature for different thicknesses.

**FIGURE 12-38**

A greenhouse traps energy by allowing the solar radiation to come in but not allowing the infrared radiation to go out.

## The Greenhouse Effect

You have probably noticed that when you leave your car under direct sunlight on a sunny day, the interior of the car gets much warmer than the air outside, and you may have wondered why the car acts like a *heat trap*. The answer lies in the spectral transmissivity curve of the *glass*, which resembles an inverted U, as shown in Fig. 12-37. We observe from this figure that glass at thicknesses encountered in practice transmits over 90 percent of radiation in the visible range and is practically opaque (nontransparent) to radiation in the longer-wavelength infrared regions of the electromagnetic spectrum (roughly  $\lambda > 3 \mu\text{m}$ ). Therefore, glass has a transparent window in the wavelength range  $0.3 \mu\text{m} < \lambda < 3 \mu\text{m}$  in which over 90 percent of solar radiation is emitted. On the other hand, the entire radiation emitted by surfaces at room temperature falls in the infrared region. Consequently, glass allows the solar radiation to enter but does not allow the infrared radiation from the interior surfaces to escape. This causes a rise in the interior temperature as a result of the energy buildup in the car. This heating effect, which is due to the nongray characteristic of glass (or clear plastics), is known as the **greenhouse effect**, since it is utilized extensively in greenhouses (Fig. 12-38).

The greenhouse effect is also experienced on a larger scale on earth. The surface of the earth, which warms up during the day as a result of the absorption of solar energy, cools down at night by radiating its energy into deep space as infrared radiation. The combustion gases such as  $\text{CO}_2$  and water vapor in the atmosphere transmit the bulk of the solar radiation but absorb the infrared radiation emitted by the surface of the earth. Thus, there is concern that the energy trapped on earth will eventually cause global warming and thus drastic changes in weather patterns.

In *humid* places such as coastal areas, there is not a large change between the daytime and nighttime temperatures, because the humidity acts as a barrier on the path of the infrared radiation coming from the earth, and thus slows down the cooling process at night. In areas with clear skies such as deserts, there is a large swing between the daytime and nighttime temperatures because of the absence of such barriers for infrared radiation.

## 12-6 • ATMOSPHERIC AND SOLAR RADIATION

The sun is our primary source of energy. The energy coming off the sun, called *solar energy*, reaches us in the form of electromagnetic waves after experiencing considerable interactions with the atmosphere. The radiation energy emitted or reflected by the constituents of the atmosphere form the *atmospheric radiation*. Here we give an overview of the solar and atmospheric radiation because of their importance and relevance to daily life. Also, our familiarity with solar energy makes it an effective tool in developing a better understanding for some of the new concepts introduced earlier. Detailed treatment of this exciting subject can be found in numerous books devoted to this topic.

The *sun* is a nearly spherical body that has a diameter of  $D \approx 1.39 \times 10^9 \text{ m}$  and a mass of  $m \approx 2 \times 10^{30} \text{ kg}$  and is located at a mean distance of  $L = 1.50 \times 10^{11} \text{ m}$  from the earth. It emits radiation energy continuously at a rate of  $E_{\text{sun}} \approx 3.8 \times 10^{26} \text{ W}$ . Less than a billionth of this energy (about  $1.7 \times 10^{17} \text{ W}$ )

strikes the earth, which is sufficient to keep the earth warm and to maintain life through the photosynthesis process. The energy of the sun is due to the continuous *fusion* reaction during which two hydrogen atoms fuse to form one atom of helium. Therefore, the sun is essentially a *nuclear reactor*, with temperatures as high as 40,000,000 K in its core region. The temperature drops to about 5800 K in the outer region of the sun, called the convective zone, as a result of the dissipation of this energy by radiation.

The solar energy reaching the earth's atmosphere is called the **total solar irradiance**  $G_s$ , whose value is

$$G_s = 1373 \text{ W/m}^2 \quad (12-49)$$

The total solar irradiance (also called the **solar constant**) represents the *rate at which solar energy is incident on a surface normal to the sun's rays at the outer edge of the atmosphere when the earth is at its mean distance from the sun* (Fig. 12-39).

The value of the total solar irradiance can be used to estimate the effective surface temperature of the sun from the requirement that

$$(4\pi L^2)G_s = (4\pi r^2) \sigma T_{\text{sun}}^4 \quad (12-50)$$

where  $L$  is the mean distance between the sun's center and the earth and  $r$  is the radius of the sun. The left-hand side of this equation represents the total solar energy passing through a spherical surface whose radius is the mean earth–sun distance, and the right-hand side represents the total energy that leaves the sun's outer surface. The conservation of energy principle requires that these two quantities be equal to each other, since the solar energy experiences no attenuation (or enhancement) on its way through the vacuum (Fig. 12-40). The **effective surface temperature** of the sun is determined from Eq. 12-50 to be  $T_{\text{sun}} = 5780$  K. That is, the sun can be treated as a blackbody at a temperature of 5780 K. This is also confirmed by the measurements of the spectral distribution of the solar radiation just outside the atmosphere plotted in Fig. 12-41, which shows only small deviations from the idealized blackbody behavior.

The spectral distribution of solar radiation on the ground plotted in Fig. 12-41 shows that the solar radiation undergoes considerable *attenuation* as it passes through the atmosphere as a result of absorption and scattering. About 99 percent of the atmosphere is contained within a distance of 30 km from the earth's surface. The several dips on the spectral distribution of radiation on the earth's surface are due to *absorption* by the gases  $O_2$ ,  $O_3$  (ozone),  $H_2O$ , and  $CO_2$ . Absorption by *oxygen* occurs in a narrow band about  $\lambda = 0.76 \mu\text{m}$ . The *ozone* absorbs *ultraviolet* radiation at wavelengths below  $0.3 \mu\text{m}$  almost completely, and radiation in the range  $0.3$ – $0.4 \mu\text{m}$  considerably. Thus, the ozone layer in the upper regions of the atmosphere protects biological systems on earth from harmful ultraviolet radiation. In turn, we must protect the ozone layer from the destructive chemicals commonly used as refrigerants, cleaning agents, and propellants in aerosol cans. The use of these chemicals is now banned. The ozone gas also absorbs some radiation in the visible range. Absorption in the infrared region is dominated by *water vapor* and *carbon dioxide*. The dust particles and other pollutants in the atmosphere also absorb radiation at various wavelengths.

**FIGURE 12-39**

Solar radiation reaching the earth's atmosphere and the total solar irradiance.

**FIGURE 12-40**

The total solar energy passing through concentric spheres remains constant, but the energy falling per unit area decreases with increasing radius.

**FIGURE 12-41**

Spectral distribution of solar radiation just outside the atmosphere, at the surface of the earth on a typical day, and comparison with blackbody radiation at 5780 K.

**FIGURE 12-42**

Air molecules scatter blue light much more than they do red light. At sunset, light travels through a thicker layer of atmosphere, which removes much of the blue from the natural light, allowing the red to dominate.

As a result of these absorptions, the solar energy reaching the earth's surface is weakened considerably, to about  $950 \text{ W/m}^2$  on a clear day and much less on cloudy or smoggy days. Also, practically all of the solar radiation reaching the earth's surface falls in the wavelength band from 0.3 to  $2.5 \mu\text{m}$ .

Another mechanism that attenuates solar radiation as it passes through the atmosphere is *scattering* or *reflection* by air molecules and the many other kinds of particles such as dust, smog, and water droplets suspended in the atmosphere. Scattering is mainly governed by the size of the particle relative to the wavelength of radiation. The oxygen and nitrogen molecules primarily scatter radiation at very short wavelengths, comparable to the size of the molecules themselves. Therefore, radiation at wavelengths corresponding to violet and blue colors is scattered the most. This molecular scattering in all directions is what gives the sky its bluish color. The same phenomenon is responsible for red sunrises and sunsets. Early in the morning and late in the afternoon, the sun's rays pass through a greater thickness of the atmosphere than they do at midday, when the sun is at the top. Therefore, the violet and blue colors of the light encounter a greater number of molecules by the time they reach the earth's surface, and thus a greater fraction of them are scattered (Fig. 12-42). Consequently, the light that reaches the earth's surface consists primarily of colors corresponding to longer wavelengths such as red, orange, and yellow. The clouds appear in reddish-orange color during sunrise and sunset because the light they reflect is reddish-orange at those times. For the same reason, a red traffic light is visible from a longer distance than is a green light under the same circumstances.

The solar energy incident on a surface on earth is considered to consist of *direct* and *diffuse* parts. The part of solar radiation that reaches the earth's surface without being scattered or absorbed by the atmosphere is called **direct solar radiation**  $G_D$ . The scattered radiation is assumed to reach the earth's surface uniformly from all directions and is called **diffuse solar radiation**  $G_d$ . Then the *total solar energy* incident on the unit area of a *horizontal surface* on the ground is (Fig. 12-43)

$$G_{\text{solar}} = G_D \cos \theta + G_d \quad (\text{W/m}^2) \quad (12-51)$$

where  $\theta$  is the angle of incidence of direct solar radiation (the angle that the sun's rays make with the normal of the surface). The diffuse radiation varies from about 10 percent of the total radiation on a clear day to nearly 100 percent on a totally cloudy day.

The gas molecules and the suspended particles in the atmosphere emit radiation as well as absorbing it. The atmospheric emission is primarily due to the  $\text{CO}_2$  and  $\text{H}_2\text{O}$  molecules and is concentrated in the regions from 5 to  $8 \mu\text{m}$  and above  $13 \mu\text{m}$ . Although this emission is far from resembling the distribution of radiation from a blackbody, it is found convenient in radiation calculations to treat the atmosphere as a blackbody at some lower fictitious temperature that emits an equivalent amount of radiation energy. This fictitious temperature is called the **effective sky temperature**  $T_{\text{sky}}$ . Then the radiation emission from the atmosphere to the earth's surface is expressed as

$$G_{\text{sky}} = \sigma T_{\text{sky}}^4 \quad (\text{W/m}^2) \quad (12-52)$$

**FIGURE 12-43**

The direct and diffuse radiation incident on a horizontal surface on earth's surface.

The value of  $T_{\text{sky}}$  depends on the atmospheric conditions. It ranges from about 230 K for cold, clear-sky conditions to about 285 K for warm, cloudy-sky conditions.

Note that the effective sky temperature does not deviate much from the room temperature. Thus, in the light of Kirchhoff's law, we can take the absorptivity of a surface to be equal to its emissivity at room temperature,  $\alpha = \varepsilon$ . Then the sky radiation absorbed by a surface can be expressed as

$$E_{\text{sky, absorbed}} = \alpha G_{\text{sky}} = \alpha \sigma T_{\text{sky}}^4 = \varepsilon \sigma T_s^4 \quad (\text{W/m}^2) \quad (12-53)$$

The net rate of radiation heat transfer to a surface exposed to solar and atmospheric radiation is determined from an energy balance (Fig. 12-44):

$$\begin{aligned} \dot{q}_{\text{net, rad}} &= \sum E_{\text{absorbed}} - \sum E_{\text{emitted}} \\ &= E_{\text{solar, absorbed}} + E_{\text{sky, absorbed}} - E_{\text{emitted}} \\ &= \alpha_s G_{\text{solar}} + \varepsilon \sigma T_{\text{sky}}^4 - \varepsilon \sigma T_s^4 \\ &= \alpha_s G_{\text{solar}} + \varepsilon \sigma (T_{\text{sky}}^4 - T_s^4) \quad (\text{W/m}^2) \end{aligned} \quad (12-54)$$

where  $T_s$  is the temperature of the surface in K and  $\varepsilon$  is its emissivity at room temperature. A positive result for  $\dot{q}_{\text{net, rad}}$  indicates a radiation heat gain by the surface and a negative result indicates a heat loss.

The absorption and emission of radiation by the *elementary gases* such as H<sub>2</sub>, O<sub>2</sub>, and N<sub>2</sub> at moderate temperatures are negligible, and a medium filled with these gases can be treated as a *vacuum* in radiation analysis. The absorption and emission of gases with *larger molecules* such as H<sub>2</sub>O and CO<sub>2</sub>, however, can be *significant* and may need to be considered when considerable amounts of such gases are present in a medium. For example, a 1-m-thick layer of water vapor at 1 atm pressure and 100°C emits more than 50 percent of the energy that a blackbody would emit at the same temperature.

In solar energy applications, the spectral distribution of incident solar radiation is very different than the spectral distribution of emitted radiation by the surfaces, since the former is concentrated in the short-wavelength region and the latter in the infrared region. Therefore, the radiation properties of surfaces are quite different for the incident and emitted radiation, and the surfaces cannot be assumed to be gray. Instead, the surfaces are assumed to have two sets of properties: one for solar radiation and another for infrared radiation at room temperature. Table 12-3 lists the *emissivity*  $\varepsilon$  and the *solar absorptivity*  $\alpha_s$  of some common materials. Surfaces that are intended to *collect solar energy*, such as the absorber surfaces of solar collectors, are desired to have high  $\alpha_s$  but low  $\varepsilon$  values to maximize the absorption of solar radiation and to minimize the emission of radiation. Surfaces that are intended to *remain cool* under the sun, such as the outer surfaces of fuel tanks and refrigerator trucks, are desired to have just the opposite properties. Surfaces are often given the desired properties by coating them with thin layers of *selective* materials. A surface can be kept cool, for example, by simply painting it white. In practice, engineers pay close attention to the ratio  $\alpha_s/\varepsilon$  when selecting appropriate materials for the purpose of heat collection or heat rejection. For heat collection, materials with

**FIGURE 12-44**

Radiation interactions of a surface exposed to solar and atmospheric radiation.

**TABLE 12-3**

Comparison of the solar absorptivity  $\alpha_s$  of some surfaces with their emissivity  $\varepsilon$  at room temperature

| Surface                | $\alpha_s$ | $\varepsilon$ |
|------------------------|------------|---------------|
| Aluminum               |            |               |

**FIGURE 12-45**

The cycle that water undergoes in a hydroelectric power plant.

large values of  $\alpha_s/\varepsilon$  (such as clean galvanized sheet metal with  $\alpha_s/\varepsilon = 5.0$ ) are required. For heat rejection, on the other hand, materials with small values of  $\alpha_s/\varepsilon$  (such as anodized aluminum with  $\alpha_s/\varepsilon = 0.17$ ) are desirable. Values of  $\alpha_s/\varepsilon$  together with solar absorptivity for selected materials are listed in Table A-19.

We close this section by pointing out that what we call *renewable energy* is usually nothing more than the manifestation of solar energy in different forms. Such energy sources include wind energy, hydroelectric power, ocean thermal energy, ocean wave energy, and wood. For example, no hydroelectric power plant can generate electricity year after year unless the water evaporates by absorbing solar energy and comes back as a rainfall to replenish the water source (Fig. 12-45). Although solar energy is sufficient to meet the entire energy needs of the world, currently it is not economical to do so because of the low concentration of solar energy on earth and the high capital cost of harnessing it.

### EXAMPLE 12-6 Selective Absorber and Reflective Surfaces

Consider a surface exposed to solar radiation. At a given time, the direct and diffuse components of solar radiation are  $G_D = 400$  and  $G_d = 300 \text{ W/m}^2$ , and the direct radiation makes a  $20^\circ$  angle with the normal of the surface. The surface temperature is observed to be  $320 \text{ K}$  at that time. Assuming an effective sky temperature of  $260 \text{ K}$ , determine the net rate of radiation heat transfer for these cases (Fig. 12-46):

- (a)  $\alpha_s = 0.9$  and  $\varepsilon = 0.9$  (gray absorber surface)
- (b)  $\alpha_s = 0.1$  and  $\varepsilon = 0.1$  (gray reflector surface)
- (c)  $\alpha_s = 0.9$  and  $\varepsilon = 0.1$  (selective absorber surface)
- (d)  $\alpha_s = 0.1$  and  $\varepsilon = 0.9$  (selective reflector surface)

**SOLUTION** A surface is exposed to solar and sky radiation. The net rate of radiation heat transfer is to be determined for four different combinations of emissivities and solar absorptivities.

**Analysis** The total solar energy incident on the surface is

$$\begin{aligned} G_{\text{solar}} &= G_D \cos \theta + G_d \\ &= (400 \text{ W/m}^2) \cos 20^\circ + (300 \text{ W/m}^2) \\ &= 676 \text{ W/m}^2 \end{aligned}$$

Then the net rate of radiation heat transfer for each of the four cases is determined from:

$$\dot{q}_{\text{net, rad}} = \alpha_s G_{\text{solar}} + \varepsilon \sigma (T_{\text{sky}}^4 - T_s^4)$$

- (a)  $\alpha_s = 0.9$  and  $\varepsilon = 0.9$  (gray absorber surface):

$$\begin{aligned} \dot{q}_{\text{net, rad}} &= 0.9(676 \text{ W/m}^2) + 0.9(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(260 \text{ K})^4 - (320 \text{ K})^4] \\ &= 307 \text{ W/m}^2 \end{aligned}$$

- (b)  $\alpha_s = 0.1$  and  $\varepsilon = 0.1$  (gray reflector surface):

$$\begin{aligned} \dot{q}_{\text{net, rad}} &= 0.1(676 \text{ W/m}^2) + 0.1(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(260 \text{ K})^4 - (320 \text{ K})^4] \\ &= 34 \text{ W/m}^2 \end{aligned}$$

(c)  $\alpha_s = 0.9$  and  $\varepsilon = 0.1$  (selective absorber surface):

$$\begin{aligned}\dot{q}_{\text{net, rad}} &= 0.9(676 \text{ W/m}^2) + 0.1(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(260 \text{ K})^4 - (320 \text{ K})^4] \\ &= 575 \text{ W/m}^2\end{aligned}$$

(d)  $\alpha_s = 0.1$  and  $\varepsilon = 0.9$  (selective reflector surface):

$$\begin{aligned}\dot{q}_{\text{net, rad}} &= 0.1(676 \text{ W/m}^2) + 0.9(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(260 \text{ K})^4 - (320 \text{ K})^4] \\ &= -234 \text{ W/m}^2\end{aligned}$$

**Discussion** Note that the surface of an ordinary gray material of high absorptivity gains heat at a rate of  $307 \text{ W/m}^2$ . The amount of heat gain increases to  $575 \text{ W/m}^2$  when the surface is coated with a selective material that has the same absorptivity for solar radiation but a low emissivity for infrared radiation. Also note that the surface of an ordinary gray material of high reflectivity still gains heat at a rate of  $34 \text{ W/m}^2$ . When the surface is coated with a selective material that has the same reflectivity for solar radiation but a high emissivity for infrared radiation, the surface loses  $234 \text{ W/m}^2$  instead. Therefore, the temperature of the surface will decrease when a selective reflector surface is used.

### TOPIC OF SPECIAL INTEREST\*

#### Solar Heat Gain through Windows

The sun is the primary heat source of the earth, and the solar irradiance on a surface normal to the sun's rays beyond the earth's atmosphere at the mean earth-sun distance of 149.5 million km is called the total solar irradiance or solar constant. The accepted value of the solar constant is  $1373 \text{ W/m}^2$  ( $435.4 \text{ Btu/h}\cdot\text{ft}^2$ ), but its value changes by 3.5 percent from a maximum of  $1418 \text{ W/m}^2$  on January 3 when the earth is closest to the sun, to a minimum of  $1325 \text{ W/m}^2$  on July 4 when the earth is farthest away from the sun. The spectral distribution of solar radiation beyond the earth's atmosphere resembles the energy emitted by a blackbody at  $5780^\circ\text{C}$ , with about 9 percent of the energy contained in the ultraviolet region (at wavelengths between  $0.29$  to  $0.4 \mu\text{m}$ ), 39 percent in the visible region ( $0.4$  to  $0.7 \mu\text{m}$ ), and the remaining 52 percent in the near-infrared region ( $0.7$  to  $3.5 \mu\text{m}$ ). The peak radiation occurs at a wavelength of about  $0.48 \mu\text{m}$ , which corresponds to the green color portion of the visible spectrum. Obviously a glazing material that transmits the visible part of the spectrum while absorbing the infrared portion is ideally suited for an application that calls for maximum daylight and minimum solar heat gain. Surprisingly, the ordinary window glass approximates this behavior remarkably well (Fig. 12-47 on the next page).

Part of the solar radiation entering the earth's atmosphere is scattered and absorbed by air and water vapor molecules, dust particles, and water droplets in the clouds, and thus the solar radiation incident on earth's surface is less than the solar constant. The extent of the attenuation of solar radiation

**FIGURE 12-48**

Direct, diffuse, and reflected components of solar radiation incident on a window.

depends on the length of the path of the rays through the atmosphere as well as the composition of the atmosphere (the clouds, dust, humidity, and smog) along the path. Most ultraviolet radiation is absorbed by the ozone in the upper atmosphere. At a solar altitude of  $41.8^\circ$ , the total energy of direct solar radiation incident at sea level on a clear day consists of about 3 percent ultraviolet, 38 percent visible, and 59 percent infrared radiation.

The part of solar radiation that reaches the earth's surface without being scattered or absorbed is the *direct radiation*. Solar radiation that is scattered or reemitted by the constituents of the atmosphere is the *diffuse radiation*. Direct radiation comes directly from the sun following a straight path, whereas diffuse radiation comes from all directions in the sky. The entire radiation reaching the ground on an overcast day is diffuse radiation. The radiation reaching a surface, in general, consists of three components: direct radiation, diffuse radiation, and radiation reflected onto the surface from surrounding surfaces (Fig. 12-48). Common surfaces such as grass, trees, rocks, and concrete reflect about 20 percent of the radiation while absorbing the rest. Snow-covered surfaces, however, reflect 70 percent of the incident radiation. Radiation incident on a surface that does not have a direct view of the sun consists of diffuse and reflected radiation. Therefore, at solar noon, solar radiations incident on the east, west, and north surfaces of a south-facing house are identical since they all consist of diffuse and reflected components. The difference between the radiations incident on the south and north walls in this case gives the magnitude of direct radiation incident on the south wall.

When solar radiation strikes a glass surface, part of it (about 8 percent for uncoated clear glass) is reflected back to outdoors, part of it (5 to 50 percent, depending on composition and thickness) is absorbed within the glass, and the remainder is transmitted indoors, as shown in Fig. 12-49. The conservation of energy principle requires that the sum of the transmitted, reflected, and absorbed solar radiations be equal to the incident solar radiation. That is,

$$\tau_s + \rho_s + \alpha_s = 1$$

where  $\tau_s$  is the transmissivity,  $\rho_s$  is the reflectivity, and  $\alpha_s$  is the absorptivity of the glass for solar energy, which are the fractions of incident solar radiation transmitted, reflected, and absorbed, respectively. The standard 3-mm-( $\frac{1}{8}$ -in)-thick single-pane double-strength clear window glass transmits 86 percent, reflects 8 percent, and absorbs 6 percent of the solar energy incident on it. The radiation properties of materials are usually given for normal incidence, but can also be used for radiation incident at other angles since the transmissivity, reflectivity, and absorptivity of the glazing materials remain essentially constant for incidence angles up to about  $60^\circ$  from the normal.

The hourly variation of solar radiation incident on the walls and windows of a house is given in Table 12-4. Solar radiation that is transmitted indoors is partially absorbed and partially reflected each time it strikes a surface, but all of it is eventually absorbed as sensible heat by the furniture, walls, people,

and so forth. Therefore, the solar energy transmitted inside a building represents a heat gain for the building. Also, the solar radiation absorbed by the glass is subsequently transferred to the indoors and outdoors by convection and radiation. The sum of the *transmitted* solar radiation and the portion of the *absorbed* radiation that flows indoors constitutes the **solar heat gain** of the building.

The fraction of incident solar radiation that enters through the glazing is called the **solar heat gain coefficient** (SHGC) and is expressed as

$$\text{SHGC} = \frac{\text{Solar heat gain through the window}}{\text{Solar radiation incident on the window}}$$

$$= \frac{\dot{q}_{\text{solar, gain}}}{\dot{q}_{\text{solar, incident}}} = \tau_s + f_i \alpha_s \quad (12-55)$$

where  $\alpha_s$  is the solar absorptivity of the glass and  $f_i$  is the inward flowing fraction of the solar radiation absorbed by the glass. Therefore, the dimensionless quantity SHGC is the sum of the fractions of the directly transmitted ( $\tau_s$ ) and the absorbed and reemitted ( $f_i \alpha_s$ ) portions of solar radiation incident on the window. The value of SHGC ranges from 0 to 1, with 1 corresponding to an opening in the wall (or the ceiling) with no glazing. When the SHGC of a window is known, the total solar heat gain through that window is determined from

$$\dot{Q}_{\text{solar, gain}} = \text{SHGC} \times A_{\text{glazing}} \times \dot{q}_{\text{solar, incident}} \quad (\text{W}) \quad (12-56)$$

where  $A_{\text{glazing}}$  is the glazing area of the window and  $\dot{q}_{\text{solar, incident}}$  is the solar heat flux incident on the outer surface of the window, in  $\text{W/m}^2$ .

Another way of characterizing the solar transmission characteristics of different kinds of glazing and shading devices is to compare them to a well-known glazing material that can serve as a base case. This is done by taking the standard 3-mm-( $\frac{1}{8}$ -in)-thick double-strength clear window glass sheet whose SHGC is 0.87 as the *reference glazing* and defining a **shading coefficient** SC as

$$\text{SC} = \frac{\text{Solar heat gain of product}}{\text{Solar heat gain of reference glazing}}$$

$$= \frac{\text{SHGC}}{\text{SHGC}_{\text{ref}}} = \frac{\text{SHGC}}{0.87} = 1.15 \times \text{SHGC} \quad (12-57)$$

Therefore, the shading coefficient of a single-pane clear glass window is  $\text{SC} = 1.0$ . The shading coefficients of other commonly used fenestration products are given in Table 12-5 for summer design conditions. The values for winter design conditions may be slightly lower because of the higher heat transfer coefficients on the outer surface due to high winds and thus higher rate of outward flow of solar heat absorbed by the glazing, but the difference is small.

Note that the larger the shading coefficient, the smaller the shading effect, and thus the larger the amount of solar heat gain. A glazing material with a large shading coefficient allows a large fraction of solar radiation to come in.

\*Multiply by 0.3171 to convert to Btu/h·ft<sup>2</sup>.

Values given are for the 21st of the month for average days with no clouds. The values can be up to 15 percent higher at high elevations under very clear skies and up to 30 percent lower at very humid locations with very dusty industrial atmospheres. Daily totals are obtained using Simpson's rule for integration with 10-min time intervals. Solar reflectance of the ground is assumed to be 0.2, which is valid for old concrete, crushed rock, and bright green grass. For a specified location, use solar radiation data obtained for that location. The direction of a surface indicates the direction a vertical surface is facing. For example, W represents the solar radiation incident on a west-facing wall per unit area of the wall.

Solar time may deviate from the local time. Solar noon at a location is the time when the sun is at the highest location (and thus when the shadows are shortest). Solar radiation data are symmetric about the solar noon: the value on a west wall before the solar noon is equal to the value on an east wall two hours after the solar noon.

<sup>c</sup>Refers to gray-, bronze-, and green-tinted heat-absorbing float glass.

Shading devices are classified as *internal shading* and *external shading*, depending on whether the shading device is placed *inside* or *outside*. External shading devices are more effective in reducing the solar heat gain since they intercept the sun's rays before they reach the glazing. The solar heat gain through a window can be reduced by as much as 80 percent by exterior shading. Roof overhangs have long been used for exterior shading of windows. The sun is high in the horizon in summer and low in winter. A properly sized roof overhang or a horizontal projection blocks off the sun's rays completely in summer while letting in most of them in winter, as shown in Figure 12-50. Such shading structures can reduce the solar heat gain on the south, southeast, and southwest windows in the northern hemisphere considerably. A window can also be shaded from outside by vertical or horizontal architectural projections, insect or shading screens, and sun screens. To be effective, air must be able to move freely around the exterior device to carry away the heat absorbed by the shading and the glazing materials.

Some type of internal shading is used in most windows to provide privacy and aesthetic effects as well as some control over solar heat gain. Internal shading devices reduce solar heat gain by reflecting transmitted solar radiation back through the glazing before it can be absorbed and converted into heat in the building.

*Drapery* reduce the annual heating and cooling loads of a building by 5 to 20 percent, depending on the type and the user habits. In summer, they reduce heat gain primarily by reflecting back direct solar radiation (Fig. 12-51). The semiclosed air space formed by the draperies serves as an additional barrier against heat transfer, resulting in a lower *U*-factor for the window and thus a lower rate of heat transfer in summer and winter. The solar optical properties of draperies can be measured accurately, or they can be obtained directly from the manufacturers. The shading coefficient of draperies depends on the openness factor, which is the ratio of the open area between the fibers that permits the sun's rays to pass freely, to the total area of the fabric. Tightly woven fabrics allow little direct radiation to pass through, and thus they have a small openness factor. The *reflectance* of the surface of the drapery facing the glazing has a major effect on the amount of solar heat gain. *Light-colored* draperies made of closed or tightly woven fabrics maximize the back reflection and thus minimize the solar gain. *Dark-colored* draperies made of open or semi-open woven fabrics, on the other hand, minimize the back reflection and thus maximize the solar gain.

The shading coefficients of drapes also depend on the way they are hung. Usually, the width of drapery used is twice the width of the draped area to allow folding of the drapes and to give them their characteristic "full" or "wavy" appearance. A flat drape behaves like an ordinary window shade. A flat drape has a higher reflectance and thus a lower shading coefficient than a full drape.

*External shading devices* such as overhangs and tinted glazings do not require operation, and provide reliable service over a long time without significant degradation during their service life. Their operation does not depend on a person or an automated system, and these passive shading devices are considered fully effective when determining the peak cooling load and the

**FIGURE 12-50**

A properly sized overhang blocks off the sun's rays completely in summer while letting them in in winter.

**FIGURE 12-51**

Draperies reduce heat gain in summer by reflecting back solar radiation, and reduce heat loss in winter by forming an air space before the window.

annual energy use. The effectiveness of manually operated shading devices, on the other hand, varies greatly depending on the user habits, and this variation should be considered when evaluating performance.

The primary function of an indoor shading device is to provide *thermal comfort* for the occupants. An unshaded window glass allows most of the incident solar radiation in, and also dissipates part of the solar energy it absorbs by emitting infrared radiation to the room. The emitted radiation and the transmitted direct sunlight may bother the occupants near the window. In winter, the temperature of the glass is lower than the room air temperature, causing excessive heat loss by radiation from the occupants. A shading device allows the control of direct solar and infrared radiation while providing various degrees of privacy and outward vision. The shading device is also at a higher temperature than the glass in winter, and thus reduces radiation loss from occupants. *Glare* from draperies can be minimized by using off-white colors. Indoor shading devices, especially draperies made of a closed-weave fabric, are effective in reducing *sounds* that originate in the room, but they are not as effective against the sounds coming from outside.

The type of climate in an area usually dictates the type of windows to be used in buildings. In *cold climates* where the heating load is much larger than the cooling load, the windows should have the highest transmissivity for the entire solar spectrum, and a high reflectivity (or low emissivity) for the far infrared radiation emitted by the walls and furnishings of the room. Low-e windows are well suited for such heating-dominated buildings. Properly designed and operated windows allow more heat into the building over a heating season than it loses, making them energy contributors rather than energy losers. In *warm climates* where the cooling load is much larger than the heating load, the windows should allow the visible solar radiation (light) in, but should block off the infrared solar radiation. Such windows can reduce the solar heat gain by 60 percent with no appreciable loss in daylighting. This behavior is approximated by window glazings that are coated with a heat-absorbing film outside and a low-e film inside (Fig. 12-52). Properly selected windows can reduce the cooling load by 15 to 30 percent compared to windows with clear glass.

Note that radiation heat transfer between a room and its windows is proportional to the emissivity of the glass surface facing the room,  $\varepsilon_{\text{glass}}$ , and can be expressed as

$$\dot{Q}_{\text{rad, room-window}} = \varepsilon_{\text{glass}} A_{\text{glass}} \sigma (T_{\text{room}}^4 - T_{\text{glass}}^4) \quad (12-58)$$

Therefore, a low-e interior glass will reduce the heat loss by radiation in winter ( $T_{\text{glass}} < T_{\text{room}}$ ) and heat gain by radiation in summer ( $T_{\text{glass}} > T_{\text{room}}$ ).

Tinted glass and glass coated with reflective films reduce solar heat gain in summer and heat loss in winter. The conductive heat gains or losses can be minimized by using multiple-pane windows. Double-pane windows are usually called for in climates where the winter design temperature is less than 7°C (45°F). Double-pane windows with tinted or reflective films are commonly used in buildings with large window areas. Clear glass is preferred for showrooms since it affords maximum visibility from outside, but bronze-, gray-, and green-colored glass are preferred in office buildings since they provide considerable privacy while reducing glare.

**EXAMPLE 12–7** Installing Reflective Films on Windows

A manufacturing facility located at 40° N latitude has a glazing area of 40 m<sup>2</sup> that consists of double-pane windows made of clear glass (SHGC = 0.766). To reduce the solar heat gain in summer, a reflective film that reduces the SHGC to 0.261 is considered. The cooling season consists of June, July, August, and September, and the heating season October through April. The average daily solar heat fluxes incident on the west side at this latitude are 1.86, 2.66, 3.43, 4.00, 4.36, 5.13, 4.31, 3.93, 3.28, 2.80, 1.84, and 1.54 kWh/day·m<sup>2</sup> for January through December, respectively. Also, the unit cost of electricity and natural gas are \$0.08/kWh and \$0.50/therm, respectively. If the coefficient of performance of the cooling system is 2.5 and efficiency of the furnace is 0.8, determine the net annual cost savings due to installing reflective coating on the windows. Also, determine the simple payback period if the installation cost of reflective film is \$20/m<sup>2</sup> (Fig. 12–53).

**SOLUTION** The net annual cost savings due to installing reflective film on the west windows of a building and the simple payback period are to be determined.

**Assumptions** 1 The calculations given below are for an average year. 2 The unit costs of electricity and natural gas remain constant.

**Analysis** Using the daily averages for each month and noting the number of days of each month, the total solar heat flux incident on the glazing during summer and winter months are determined to be

$$\begin{aligned} Q_{\text{solar, summer}} &= 5.13 \times 30 + 4.31 \times 31 + 3.93 \times 31 + 3.28 \times 30 = 508 \text{ kWh/year} \\ Q_{\text{solar, winter}} &= 2.80 \times 31 + 1.84 \times 30 + 1.54 \times 31 + 1.86 \times 31 \\ &\quad + 2.66 \times 28 + 3.43 \times 31 + 4.00 \times 30 \\ &= 548 \text{ kWh/year} \end{aligned}$$

Then the decrease in the annual cooling load and the increase in the annual heating load due to the reflective film become

$$\begin{aligned} \text{Cooling load decrease} &= Q_{\text{solar, summer}} A_{\text{glazing}} (\text{SHGC}_{\text{without film}} - \text{SHGC}_{\text{with film}}) \\ &= (508 \text{ kWh/year})(40 \text{ m}^2)(0.766 - 0.261) \\ &= 10,262 \text{ kWh/year} \end{aligned}$$

$$\begin{aligned} \text{Heating load increase} &= Q_{\text{solar, winter}} A_{\text{glazing}} (\text{SHGC}_{\text{without film}} - \text{SHGC}_{\text{with film}}) \\ &= (548 \text{ kWh/year})(40 \text{ m}^2)(0.766 - 0.261) \\ &= 11,070 \text{ kWh/year} = 377.7 \text{ therms/year} \end{aligned}$$

since 1 therm = 29.31 kWh. The corresponding decrease in cooling costs and the increase in heating costs are

$$\begin{aligned} \text{Decrease in cooling costs} &= (\text{Cooling load decrease})(\text{Unit cost of electricity})/\text{COP} \\ &= (10,262 \text{ kWh/year})(\$0.08/\text{kWh})/2.5 = \$328/\text{year} \end{aligned}$$

$$\begin{aligned} \text{Increase in heating costs} &= (\text{Heating load increase})(\text{Unit cost of fuel})/\text{Efficiency} \\ &= (377.7 \text{ therms/year})(\$0.50/\text{therm})/0.80 = \$236/\text{year} \end{aligned}$$

Then the net annual cost savings due to the reflective film become

$$\begin{aligned} \text{Cost savings} &= \text{Decrease in cooling costs} - \text{Increase in heating costs} \\ &= \$328 - \$236 = \$92/\text{year} \end{aligned}$$

(a) Cold climates

(b) Warm climates

**FIGURE 12–52**

Radiation heat transfer between a room and its windows is proportional to the emissivity of the glass surface, and low-e coatings on the inner surface of the windows reduce heat loss in winter and heat gain in summer.

**FIGURE 12–53**

Schematic for Example 12–7.

The implementation cost of installing films is

$$\text{Implementation cost} = (\$20/\text{m}^2)(40 \text{ m}^2) = \$800$$

This gives a simple payback period of

$$\text{Simple payback period} = \frac{\text{Implementation cost}}{\text{Annual cost savings}} = \frac{\$800}{\$92/\text{year}} = \mathbf{8.7 \text{ years}}$$

**Discussion** The reflective film will pay for itself in about nine years. This may be unacceptable to most manufacturers since they are not usually interested in any energy conservation measure that does not pay for itself within three years. But the enhancement in thermal comfort and thus the resulting increase in productivity often makes it worthwhile to install reflective film.

## SUMMARY

Radiation propagates in the form of electromagnetic waves. The frequency  $\nu$  and wavelength  $\lambda$  of electromagnetic waves in a medium are related by  $\lambda = c/\nu$ , where  $c$  is the speed of propagation in that medium. All matter continuously emits *thermal radiation* as a result of vibrational and rotational motions of molecules, atoms, and electrons of a substance.

A *blackbody* is defined as a perfect emitter and absorber of radiation. At a specified temperature and wavelength, no surface can emit more energy than a blackbody. A blackbody absorbs *all* incident radiation, regardless of wavelength and direction. The radiation energy emitted by a blackbody per unit time and per unit surface area is called the *blackbody emissive power*  $E_b$  and is expressed by the *Stefan–Boltzmann law* as

$$E_b(T) = \sigma T^4$$

where  $\sigma = 5.670 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4$  is the *Stefan–Boltzmann constant* and  $T$  is the absolute temperature of the surface in K. At any specified temperature, the spectral blackbody emissive power  $E_{b\lambda}$  increases with wavelength, reaches a peak, and then decreases with increasing wavelength. The wavelength at which the peak occurs for a specified temperature is given by *Wien's displacement law* as

$$(\lambda T)_{\text{max power}} = 2897.8 \mu\text{m}\cdot\text{K}$$

The *blackbody radiation function*  $f_\lambda$  represents the fraction of radiation emitted by a blackbody at temperature  $T$  in the wavelength band from  $\lambda = 0$  to  $\lambda$ . The fraction of radiation energy emitted by a blackbody at temperature  $T$  over a finite wavelength band from  $\lambda = \lambda_1$  to  $\lambda = \lambda_2$  is determined from

$$f_{\lambda_1-\lambda_2}(T) = f_{\lambda_2}(T) - f_{\lambda_1}(T)$$

where  $f_{\lambda_1}(T)$  and  $f_{\lambda_2}(T)$  are the blackbody radiation functions corresponding to  $\lambda_1 T$  and  $\lambda_2 T$ , respectively.

The magnitude of a viewing angle in space is described by solid angle expressed as  $d\omega = dA_n/r^2$ . The *radiation intensity* for emitted radiation  $I_e(\theta, \phi)$  is defined as the rate at which radiation energy is emitted in the  $(\theta, \phi)$  direction per unit area normal to this direction and per unit solid angle about this direction. The *radiation flux* for emitted radiation is the *emissive power*  $E$ , and is expressed as

$$E = \int dE = \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_e(\theta, \phi) \cos \theta \sin \theta d\theta d\phi$$

For a *diffusely emitting* surface, intensity is independent of direction and thus

$$E = \pi I_e$$

For a blackbody, we have

$$E_b = \pi I_b \quad \text{and} \quad I_b(T) = \frac{E_b(T)}{\pi} = \frac{\sigma T^4}{\pi}$$

The radiation flux incident on a surface from all directions is *irradiation*  $G$ , and for diffusely incident radiation of intensity  $I_i$  it is expressed as

$$G = \pi I_i$$

The rate at which radiation energy leaves a unit area of a surface in all directions is *radiosity*  $J$ , and for a surface that is both a diffuse emitter and a diffuse reflector it is expressed as

$$J = \pi I_{e+r}$$

where  $I_{e+r}$  is the sum of the emitted and reflected intensities. The spectral emitted quantities are related to total quantities as

$$I_e = \int_0^\infty I_{\lambda,e} d\lambda \quad \text{and} \quad E = \int_0^\infty E_\lambda d\lambda$$

They reduce for a diffusely emitting surface and for a blackbody to

$$E_\lambda = \pi I_{\lambda, e} \quad \text{and} \quad E_{b\lambda}(\lambda, T) = \pi I_{b\lambda}(\lambda, T)$$

The *emissivity* of a surface represents the ratio of the radiation emitted by the surface at a given temperature to the radiation emitted by a blackbody at the same temperature. Different emissivities are defined as

*Spectral directional emissivity*:

$$\varepsilon_{\lambda, \theta}(\lambda, \theta, \phi, T) = \frac{I_{\lambda, e}(\lambda, \theta, \phi, T)}{I_{b\lambda}(\lambda, T)}$$

*Total directional emissivity*:

$$\varepsilon_\theta(\theta, \phi, T) = \frac{I_e(\theta, \phi, T)}{I_b(T)}$$

*Spectral hemispherical emissivity*:

$$\varepsilon_\lambda(\lambda, T) = \frac{E_\lambda(\lambda, T)}{E_{b\lambda}(\lambda, T)}$$

*Total hemispherical emissivity*:

$$\varepsilon(T) = \frac{E(T)}{E_b(T)} = \frac{\int_0^\infty \varepsilon_\lambda(\lambda, T) E_{b\lambda}(\lambda, T) d\lambda}{\sigma T^4}$$

Emissivity can also be expressed as a step function by dividing the spectrum into a sufficient number of *wavelength bands* of constant emissivity as, for example,

$$\varepsilon(T) = \varepsilon_1 f_{0-\lambda_1}(T) + \varepsilon_2 f_{\lambda_1-\lambda_2}(T) + \varepsilon_3 f_{\lambda_2-\infty}(T)$$

The *total hemispherical emissivity*  $\varepsilon$  of a surface is the average emissivity over all directions and wavelengths.

When radiation strikes a surface, part of it is absorbed, part of it is reflected, and the remaining part, if any, is transmitted. The fraction of incident radiation (intensity  $I_i$  or irradiation  $G$ ) absorbed by the surface is called the *absorptivity*, the fraction reflected by the surface is called the *reflectivity*, and the fraction transmitted is called the *transmissivity*. Various absorptivities, reflectivities, and transmissivities for a medium are expressed as

$$\alpha_{\lambda, \theta}(\lambda, \theta, \phi) = \frac{I_{\lambda, \text{abs}}(\lambda, \theta, \phi)}{I_{\lambda, i}(\lambda, \theta, \phi)} \text{ and } \rho_{\lambda, \theta}(\lambda, \theta, \phi) = \frac{I_{\lambda, \text{ref}}(\lambda, \theta, \phi)}{I_{\lambda, i}(\lambda, \theta, \phi)}$$

$$\alpha_\lambda(\lambda) = \frac{G_{\lambda, \text{abs}}(\lambda)}{G_\lambda(\lambda)}, \rho_\lambda(\lambda) = \frac{G_{\lambda, \text{ref}}(\lambda)}{G_\lambda(\lambda)}, \text{ and } \tau_\lambda(\lambda) = \frac{G_{\lambda, \text{tr}}(\lambda)}{G_\lambda(\lambda)}$$

$$\alpha = \frac{G_{\text{abs}}}{G}, \rho = \frac{G_{\text{ref}}}{G}, \text{ and } \tau = \frac{G_{\text{tr}}}{G}$$

The consideration of wavelength and direction dependence of properties makes radiation calculations very complicated. Therefore, the *gray* and *diffuse* approximations are commonly utilized in radiation calculations. A surface is said to be *diffuse* if its properties are independent of direction and *gray* if its properties are independent of wavelength.

The sum of the absorbed, reflected, and transmitted fractions of radiation energy must be equal to unity,

$$\alpha + \rho + \tau = 1$$

For *opaque* surfaces ( $\tau = 0$ ):  $\alpha + \rho = 1$

For surfaces with *no reflectance* ( $\rho = 0$ ):  $\alpha + \tau = 1$

Surfaces are usually assumed to reflect in a perfectly *specular* or *diffuse* manner for simplicity. In *specular* (or *mirrorlike*) *reflection*, the angle of reflection equals the angle of incidence of the radiation beam. In *diffuse reflection*, radiation is reflected equally in all directions. Reflection from smooth and polished surfaces approximates specular reflection, whereas reflection from rough surfaces approximates diffuse reflection. *Kirchhoff's law* of radiation is expressed as

$$\varepsilon_{\lambda, \theta}(T) = \alpha_{\lambda, \theta}(T), \quad \varepsilon_\lambda(T) = \alpha_\lambda(T), \quad \text{and} \quad \varepsilon(T) = \alpha(T)$$

Gas molecules and the suspended particles in the atmosphere emit radiation as well as absorbing it. The atmosphere can be treated as a blackbody at some lower fictitious temperature, called the *effective sky temperature*  $T_{\text{sky}}$  that emits an equivalent amount of radiation energy,

$$G_{\text{sky}} = \sigma T_{\text{sky}}^4$$

The net rate of radiation heat transfer to a surface exposed to solar and atmospheric radiation is determined from an energy balance expressed as

$$\dot{q}_{\text{net, rad}} = \alpha_s G_{\text{solar}} + \varepsilon \sigma (T_{\text{sky}}^4 - T_s^4)$$

where  $T_s$  is the surface temperature in K, and  $\varepsilon$  is the surface emissivity at room temperature.

## PROBLEMS\*

### Electromagnetic and Thermal Radiation

**12–1C** What is an electromagnetic wave? How does it differ from a sound wave?

**12–2C** By what properties is an electromagnetic wave characterized? How are these properties related to each other?

**12–3C** What is thermal radiation? How does it differ from the other forms of electromagnetic radiation?

**12–4C** How does microwave cooking differ from conventional cooking?

**12–5C** What is visible light? How does it differ from the other forms of electromagnetic radiation?

**12–6C** What is the cause of color? Why do some objects appear blue to the eye while others appear red? Is the color of a surface at room temperature related to the radiation it emits?

**12–7C** Why do skiers get sunburned so easily?

**12–8C** How do ultraviolet and infrared radiation differ? Do you think your body emits any radiation in the ultraviolet range? Explain.

**12–9C** Why is radiation usually treated as a surface phenomenon?

**12–10** A cordless telephone is designed to operate at a frequency of  $8.5 \times 10^8$  Hz. Determine the wavelength of these telephone waves.

**12–11** Electricity is generated and transmitted in power lines at a frequency of 60 Hz (1 Hz = 1 cycle per second). Determine the wavelength of the electromagnetic waves generated by the passage of electricity in power lines.

**12–12** The speed of light in vacuum is given to be  $3.0 \times 10^8$  m/s. Determine the speed of light in air ( $n = 1$ ), in water ( $n = 1.33$ ), and in glass ( $n = 1.5$ ).

\*Problems designated by a “C” are concept questions, and students are encouraged to answer them all. Problems designated by an “E” are in English units, and the SI users can ignore them. Problems with the icon are solved using EES, and complete solutions together with parametric studies are included on the text website. Problems with the icon are comprehensive in nature, and are intended to be solved with an equation solver such as ESS. Problems with the icon are Prevention through Design problems.

**12–13** A radio station is broadcasting radio waves at a wavelength of 200 m. Determine the frequency of these waves.

**12–14** A microwave oven is designed to operate at a frequency of  $2.2 \times 10^9$  Hz. Determine the wavelength of these microwaves and the energy of each microwave.

**12–15** Consider a radio wave with a wavelength of  $10^7$   $\mu\text{m}$  and a  $\gamma$ -ray with a wavelength of  $10^{-7}$   $\mu\text{m}$ . Determine the photon energies of the radio wave and the  $\gamma$ -ray, and the photon energy ratio of the  $\gamma$ -ray to the radio wave.

**12–16** An electromagnetic wave with a wavelength of 0.5  $\mu\text{m}$  is being propagated in different mediums: air, water, and glass. The refractive index of air, water, and glass are 1, 1.33, and 1.5 respectively. Determine the photon energy, in eV, of the electromagnetic wave in each medium (1 eV =  $1.6022 \times 10^{-19}$  J).

**12–17** The electromagnetic spectrum that lies between 0.40 and 0.76  $\mu\text{m}$  is what we call visible light. Within this spectrum, the color violet has the shortest wavelength while the color red has the longest wavelength. Determine which of these colors, violet ( $\lambda = 0.40$   $\mu\text{m}$ ) or red ( $\lambda = 0.76$   $\mu\text{m}$ ), propagates more photon energy.

### Blackbody Radiation

**12–18C** What is a blackbody? Does a blackbody actually exist?

**12–19C** Define the total and spectral blackbody emissive powers. How are they related to each other? How do they differ?

**12–20C** Why did we define the blackbody radiation function? What does it represent? For what is it used?

**12–21C** Consider two identical bodies, one at 1000 K and the other at 1500 K. Which body emits more radiation in the shorter-wavelength region? Which body emits more radiation at a wavelength of 20  $\mu\text{m}$ ?

**12–22** Consider a surface at a uniform temperature of 800 K. Determine the maximum rate of thermal radiation that can be emitted by this surface, in  $\text{W}/\text{m}^2$ .

**12–23** Consider a 20-cm  $\times$  20-cm  $\times$  20-cm cubical body at 750 K suspended in the air. Assuming the body closely approximates a blackbody, determine (a) the rate at which the cube emits radiation energy, in W and (b) the spectral blackbody emissive power at a wavelength of 4  $\mu\text{m}$ .

**12-24** A flame from a match may be approximated as a blackbody at the effective surface temperature of 1700 K, while moonlight may be approximated as a blackbody at the effective surface temperature of 4000 K, respectively. Determine the peak spectral blackbody emissive power for both lighting sources (match flame and moonlight).

**12-25** At a wavelength of 0.7  $\mu\text{m}$ , the black body emissive power is equal to  $10^8 \text{ W/m}^3$ . Determine (a) the temperature of the blackbody and (b) the total emissive power at this temperature.

**12-26** The sun can be treated as a blackbody at 5780 K. Using EES (or other) software, calculate and plot the spectral blackbody emissive power  $E_{b\lambda}$  of the sun versus wavelength in the range of 0.01  $\mu\text{m}$  to 1000  $\mu\text{m}$ . Discuss the results.

**12-27** A small body is placed inside of a spherical stainless steel chamber with a diameter of 3 m. The chamber is evacuated and has a constant surface temperature of 500 K. Determine the radiation incident on the surface of the small body inside the chamber if the interior surface of the chamber is (a) coated black and (b) well-polished.

**12-28** Consider a black spherical ball, with a diameter of 25 cm, is being suspended in air. Determine the surface temperature of the ball that should be maintained in order to heat 10 kg of air from 20 to 30°C in the duration of 5 minutes.

**12-29** A thin vertical copper plate is subjected to a uniform heat flux of  $1000 \text{ W/m}^2$  on one side, while the other side is exposed to ambient surrounding at 5°C. The surface of the plate is oxidized black and can be treated as a blackbody. The heat transfer coefficient due to natural convection on the plate surface is  $5.3 \text{ W/m}^2\cdot\text{K}$ . Determine the surface temperature of the plate. Discuss the contribution of the net radiation heat transfer on the total heat loss from the plate.

FIGURE P12-29

**12-30** A circular ceramic plate that can be modeled as a blackbody is being heated by an electrical heater. The plate is 30 cm in diameter and is situated in a surrounding ambient temperature of 15°C where the natural convection heat transfer coefficient is  $12 \text{ W/m}^2\cdot\text{K}$ . If the efficiency of the electrical heater to transfer heat to the plate is 80%, determine the electric power that the heater needs to keep the surface temperature of the plate at 200°C.

FIGURE P12-30

**12-31** An incandescent lightbulb is desired to emit at least 15 percent of its energy at wavelengths shorter than 0.8  $\mu\text{m}$ . Determine the minimum temperature to which the filament of the lightbulb must be heated.

**12-32** The temperature of the filament of an incandescent lightbulb is 2500 K. Assuming the filament to be a blackbody, determine the fraction of the radiant energy emitted by the filament that falls in the visible range. Also, determine the wavelength at which the emission of radiation from the filament peaks.

**12-33** The temperature of the filament of an incandescent lightbulb is 3000 K. Treating the filament as a blackbody, determine the fraction of the radiant energy emitted by the filament that falls in the visible range. Also, determine the wavelength at which the emission of radiation from the filament peaks.

**12-34** Reconsider Prob. 12-33. Using EES (or other) software, investigate the effect of temperature on the fraction of radiation emitted in the visible range. Let the surface temperature vary from 1000 K to 4000 K, and plot fraction of radiation emitted in the visible range versus the surface temperature.

**12-35E** Consider a black surface at 2060°F. Determine the radiation energy emitted by the black surface per unit area (in  $\text{Btu/h}\cdot\text{ft}^2$ ) for  $\lambda \geq 4 \mu\text{m}$ .

**12-36** It is desired that the radiation energy emitted by a light source reach a maximum in the blue range ( $\lambda = 0.47 \mu\text{m}$ ). Determine the temperature of this light source and the fraction of radiation it emits in the visible range ( $\lambda = 0.40\text{--}0.76 \mu\text{m}$ ).

**12-37E** The sun can be treated as a blackbody at an effective surface temperature of 10,400 R. Determine the rate at which infrared radiation energy ( $\lambda = 0.76\text{--}100 \mu\text{m}$ ) is emitted by the sun, in  $\text{Btu/h}\cdot\text{ft}^2$ .

**12-38** A 3-mm-thick glass window transmits 90 percent of the radiation between  $\lambda = 0.3$  and  $3.0 \mu\text{m}$  and is essentially opaque for radiation at other wavelengths. Determine the rate of radiation transmitted through a  $2\text{-m} \times 2\text{-m}$  glass window from blackbody sources at (a) 5800 K and (b) 1000 K.

**12-39** Daylight and candlelight may be approximated as a blackbody at the effective surface temperatures of 5800 K and 1800 K, respectively. Determine the radiation energy (in  $\text{W/m}^2$ ) emitted by both lighting sources (daylight and candlelight) within the visible light region (0.40 to 0.76  $\mu\text{m}$ ).

**12-40** Consider the sun, which is considered to be a blackbody with a surface temperature of roughly 5800 K. Determine the percentage of solar energy (a) in the visible range, (b) at wavelengths shorter than the visible range, and (c) at wavelengths longer than the visible range.

### Radiation Intensity

**12-41C** What does a solid angle represent, and how does it differ from a plane angle? What is the value of a solid angle associated with a sphere?

**12-42C** For a surface, how is irradiation defined? For diffusely incident radiation, how is irradiation on a surface related to the intensity of incident radiation?

**12-43C** For a surface, how is radiosity defined? For diffusely emitting and reflecting surfaces, how is radiosity related to the intensities of emitted and reflected radiation?

**12-44C** When the variation of spectral radiation quantity with wavelength is known, how is the corresponding total quantity determined?

**12-45C** How is the intensity of emitted radiation defined? For a diffusely emitting surface, how is the emissive power related to the intensity of emitted radiation?

**12-46** A small surface of area  $A_1 = 3 \text{ cm}^2$  emits radiation as a blackbody, and part of the radiation emitted by  $A_1$  strikes another small surface of area  $A_2 = 8 \text{ cm}^2$  oriented as shown in the figure. If the rate at which radiation emitted by  $A_1$  that strikes  $A_2$  is measured to be  $274 \times 10^{-6} \text{ W}$ , determine the intensity of the radiation emitted by  $A_1$ , and the temperature of  $A_1$ .

FIGURE P12-46

**12-47** A small circular surface of area  $A_1 = 2 \text{ cm}^2$  located at the center of a 2-m-diameter sphere emits radiation as a blackbody at  $T_1 = 1000 \text{ K}$ . Determine the rate at which radiation energy is streaming through a  $D_2 = 1\text{-cm-diameter}$  hole located (a) on top of the sphere directly above  $A_1$  and (b) on the side of sphere such that the line that connects the centers of  $A_1$  and  $A_2$  makes  $45^\circ$  with surface  $A_1$ .

**12-48** Repeat Prob. 12-47 for a 4-m-diameter sphere.

**12-49** A small surface of area  $A_1 = 8 \text{ cm}^2$  emits radiation as a blackbody at  $T_1 = 800 \text{ K}$ . Part of the radiation emitted by  $A_1$  strikes another small surface of area  $A_2 = 8 \text{ cm}^2$  oriented as

shown in the figure. Determine the solid angle subtended by  $A_2$  when viewed from  $A_1$ , and the rate at which radiation emitted by  $A_1$  strikes  $A_2$  directly. What would your answer be if  $A_2$  were directly above  $A_1$  at a distance of 80 cm?

FIGURE P12-49

**12-50** A small surface of area  $A = 1 \text{ cm}^2$  emits radiation as a blackbody at 1800 K. Determine the rate at which radiation energy is emitted through a band defined by  $0 \leq \phi \leq 2\pi$  and  $45^\circ \leq \theta \leq 60^\circ$ , where  $\theta$  is the angle a radiation beam makes with the normal of the surface and  $\phi$  is the azimuth angle.

**12-51** Consider the intensity of solar radiation incident on earth's surface can be expressed as  $I_i = 100 \cos \theta$ , where  $I_i$  has the units of  $\text{W/m}^2\cdot\text{sr}$ . Determine the peak value for the intensity of incident solar radiation, and the solar irradiation on earth's surface.

**12-52** A small surface of area  $A_1 = 3 \text{ cm}^2$  emits radiation as a blackbody with total emissive power of  $E_b = 5.67 \times 10^4 \text{ W/m}^2$ . Part of the radiation emitted by  $A_1$  strikes another small surface of area  $A_2 = 8 \text{ cm}^2$  oriented as shown in the figure. Determine the rate at which radiation emitted by  $A_1$  strikes  $A_2$ , and the irradiation on  $A_2$ .

FIGURE P12-52

**12-53** A small surface of area  $A_1 = 3 \text{ cm}^2$  emits radiation as a blackbody at  $T_1 = 1000 \text{ K}$ . A radiation detector ( $A_2$ ) is placed normal to the direction of viewing from surface  $A_1$  at a distance  $L$ , as shown in the figure. If the radiation detector is measuring an irradiation of  $100 \text{ W/m}^2$ , determine the distance between the radiation detector and surface  $A_1$ .

FIGURE P12-53

**12-54** A small surface of area  $A = 1 \text{ cm}^2$  is subjected to incident radiation of constant intensity  $I_i = 2.2 \times 10^4 \text{ W/m}^2 \cdot \text{sr}$  over the entire hemisphere. Determine the rate at which radiation energy is incident on the surface through (a)  $0 \leq \theta \leq 45^\circ$  and (b)  $45^\circ \leq \theta \leq 90^\circ$ , where  $\theta$  is the angle a radiation beam makes with the normal of the surface.

**12-55** Consider an aperture of 10-mm diameter through which radiation is emitted as a blackbody with an emissive power of  $2.87 \times 10^5 \text{ W/m}^2$ . A radiation sensor is positioned with a  $30^\circ$  tilt off the normal direction of viewing, as shown in the figure. If the sensor is sensing an irradiation of  $50 \text{ W/m}^2$ , determine the distance between the aperture and the sensor.

FIGURE P12-55

**12-56** A small circular plate has a diameter of 2 cm and can be approximated as a blackbody. To determine the radiation from the plate, a radiometer is placed normal to the direction of viewing from the plate at a distance of 50 cm. If the radiometer measured an irradiation of  $85 \text{ W/m}^2$  from the plate, determine the temperature of the plate.

**12-57** **PtD** Heat dissipated from an engine in operation can cause hot spots on its surface. If the outer surface of an engine is situated in a place where oil leakage is possible, then when the leaked oil comes in contact with hot spots above the oil's autoignition temperature, it can ignite spontaneously. Consider an engine outer surface that can be approximated as a blackbody. To prevent fire hazard in the event of oil leak on the engine surface, the surface temperature of the engine should be kept below  $180^\circ\text{C}$ . A radiometer is placed normal to and at a distance of 1 m from the engine surface to monitor the surface temperature. The radiometer receives radiation from a target area of  $1 \text{ cm}^2$  of the engine surface. If the radiometer detects an irradiation of  $0.1 \text{ W/m}^2$ , would there be any risk of fire hazard?

**12-58** A radiometer can be used to determine the position of an approaching hot object by measuring the amount of irradiation it detects. Consider a radiometer placed at a distance

$H = 0.5 \text{ m}$  from the  $x$ -axis is used to measure the position of an approaching small blackbody object. If the radiometer is measuring 80% of the irradiation corresponding to the position of the object directly under the radiometer ( $x = 0$ ), determine the position of the object  $L$ .

FIGURE P12-58

**12-59** **EES** Reconsider Prob. 12-58. Using the EES (or other) software, evaluate the effect of the position of the approaching object on the irradiation ratio  $G_{2,x}/G_{2,0}$ , where  $G_{2,x}$  and  $G_{2,0}$  are the irradiation on the radiometer when the object is at position  $x$  and at  $x = 0$ , respectively. By varying  $x$  from 0 to 3 m with 0.2 m increments, plot irradiation ratio  $G_{2,x}/G_{2,0}$  as a function of the approaching object position  $x$  for the placement of the radiometer at  $H = 0.5, 1.0$ , and  $1.5 \text{ m}$ .

**12-60** A small circular plate with a surface  $A_1$  can be approximated as a blackbody. A radiometer with a surface  $A_2$  is placed normal to the direction of viewing from the plate at a distance  $L$ . Would the irradiation on the radiometer from the plate decrease if the distance  $L$  is doubled, and if so, by how much?

**12-61** A blackbody plate ( $A_1 = 5 \text{ cm}^2$ ) is subjected to a uniform heat flux of  $1000 \text{ W/m}^2$  on the bottom, while the top surface is exposed to an ambient surrounding at  $5^\circ\text{C}$ . The heat transfer coefficient due to natural convection on the plate surface is  $5 \text{ W/m}^2 \cdot \text{K}$ . A radiometer is placed 1 m above the plate normal to the direction of viewing from the plate. Determine the irradiation that the radiometer would detect.

**12-62** **PtD** A long metal sheet that can be approximated as a blackbody is being conveyed through a water bath to be cooled. In order to prevent thermal burn on people handling the sheet, it must exit the water bath at a temperature below  $45^\circ\text{C}$ . A radiometer is placed normal to and at a distance of 0.5 m from the sheet surface to monitor the exit temperature. The radiometer receives radiation from a target area of  $1 \text{ cm}^2$  of the metal sheet surface. When the radiometer detects that the metal sheet temperature is not below  $45^\circ\text{C}$ , an alarm will go off to warn that the sheet is not safe to touch. Determine the irradiation on the radiometer that the warning alarm should be triggered.

**12–63** **PtD** A radiometer is employed to monitor the temperature of manufactured parts ( $A_1 = 10 \text{ cm}^2$ ) on a conveyor. The radiometer is placed at a distance of 1 m from and normal to the manufactured parts. When a part moves to the position normal to the radiometer, the sensor measures the radiation emitted from the part. In order to prevent thermal burn on people handling the manufactured parts at the end of the conveyor, the temperature of the parts should be below  $45^\circ\text{C}$ . An array of spray heads is programmed to discharge mist to cool the parts when the radiometer detects a temperature of  $45^\circ\text{C}$  or higher on a part. If the manufactured parts can be approximated as blackbody, determine the irradiation on the radiometer that should trigger the spray heads to release cooling mist when the temperature is not below  $45^\circ\text{C}$ .

FIGURE P12–63

**12–64** **PtD** A long metal bar ( $c_p = 450 \text{ J/kg}\cdot\text{K}$ ,  $\rho = 7900 \text{ kg/m}^3$ ) is being conveyed through a water bath to be quenched. The metal bar has a cross section of  $30 \text{ mm} \times 15 \text{ mm}$ , and it enters the water bath at  $700^\circ\text{C}$ . During the quenching process,  $500 \text{ kW}$  of heat is released from the bar in the water bath. In order to prevent thermal burn on people handling the metal bar, it must exit the water bath at a temperature below  $45^\circ\text{C}$ . A radiometer is placed normal to and at a distance of 1 m from the bar to monitor the exit temperature. The radiometer receives radiation from a target area of  $1 \text{ cm}^2$  of the bar surface. Irradiation signal detected by the radiometer is used to control the speed of the bar being conveyed through the water bath so that the exit temperature is safe for handling. If the radiometer detects an irradiation of  $0.015 \text{ W/m}^2$ , determine the speed of the bar being conveyed through the water bath. Assume that the metal bar can be approximated as a blackbody.

FIGURE P12–64

## Radiation Properties

**12–65C** What is a graybody? How does it differ from a blackbody? What is a diffuse gray surface?

**12–66C** Define the properties emissivity and absorptivity. When are these two properties equal to each other?

**12–67C** Define the properties reflectivity and transmissivity and discuss the different forms of reflection.

**12–68C** What is the greenhouse effect? Why is it a matter of great concern among atmospheric scientists?

**12–69C** We can see the inside of a microwave oven during operation through its glass door, which indicates that visible radiation is escaping the oven. Do you think that the harmful microwave radiation might also be escaping?

**12–70E** A 5-in-diameter spherical ball is known to emit radiation at a rate of  $550 \text{ Btu/h}$  when its surface temperature is  $950 \text{ R}$ . Determine the average emissivity of the ball at this temperature.

**12–71** A small surface of area  $A_1 = 5 \text{ cm}^2$  emits radiation as a blackbody at  $T_1 = 1000 \text{ K}$ . A radiation sensor of area  $A_2 = 3 \text{ cm}^2$  is placed normal to the direction of viewing from surface  $A_1$  at a distance  $L$ . An optical filter with the following spectral transmissivity is placed in front of the sensor:

$$\tau_\lambda = \begin{cases} \tau_1 = 0, & 0 \leq \lambda < 2 \mu\text{m} \\ \tau_2 = 0.5, & 2 \mu\text{m} \leq \lambda < \infty \end{cases}$$

If the distance between the radiation sensor and surface  $A_1$  is  $L = 0.5 \text{ m}$ , determine the irradiation measured by the sensor.

**12–72** **PtD** A tank is filled with chemicals undergoing an exothermic reaction. The reaction heats up the tank wall, and to prevent thermal burn on individuals, the tank's outer surface temperature should be below  $45^\circ\text{C}$ . The emissivity of the tank surface is 0.85, and irradiation on the tank surface from the surroundings is estimated to be  $390 \text{ W/m}^2$ . A radiometer is placed normal to and at a distance of 0.5 m from the tank surface to monitor the surface temperature. The radiometer receives radiation from a target area of  $1 \text{ cm}^2$  of the tank surface. If the irradiation measured by the radiometer is  $0.085 \text{ W/m}^2$ , determine whether or not the tank surface is safe to touch.

**12–73** A furnace that has a  $40\text{-cm} \times 40\text{-cm}$  glass window can be considered to be a blackbody at  $1200 \text{ K}$ . If the transmissivity of the glass is 0.7 for radiation at wavelengths less than  $3 \mu\text{m}$  and zero for radiation at wavelengths greater than  $3 \mu\text{m}$ , determine the fraction and the rate of radiation coming from the furnace and transmitted through the window.

**12–74** The spectral emissivity function of an opaque surface at  $1000 \text{ K}$  is approximated as

$$\varepsilon_\lambda = \begin{cases} \varepsilon_1 = 0.4, & 0 \leq \lambda < 2 \mu\text{m} \\ \varepsilon_2 = 0.7, & 2 \mu\text{m} \leq \lambda < 6 \mu\text{m} \\ \varepsilon_3 = 0.3, & 6 \mu\text{m} \leq \lambda < \infty \end{cases}$$

Determine the average emissivity of the surface and the rate of radiation emission from the surface, in  $\text{W/m}^2$ .

**12–75** The emissivity of a tungsten filament can be approximated to be 0.5 for radiation at wavelengths less than  $1 \mu\text{m}$  and 0.15 for radiation at greater than  $1 \mu\text{m}$ . Determine the average emissivity of the filament at (a) 2000 K and (b) 3000 K. Also, determine the absorptivity and reflectivity of the filament at both temperatures.

**12–76** The variations of the spectral emissivity of two surfaces are as given in Fig. P12–76. Determine the average emissivity of each surface at  $T = 3000 \text{ K}$ . Also, determine the average absorptivity and reflectivity of each surface for radiation coming from a source at 3000 K. Which surface is more suitable to serve as a solar absorber?

FIGURE P12–76

**12–77** The emissivity of a surface coated with aluminum oxide can be approximated to be 0.15 for radiation at wavelengths less than  $5 \mu\text{m}$  and 0.9 for radiation at wavelengths greater than  $5 \mu\text{m}$ . Determine the average emissivity of this surface at (a) 5800 K and (b) 300 K. What can you say about the absorptivity of this surface for radiation coming from sources at 5800 K and 300 K? *Answers: (a) 0.154, (b) 0.89*

**12–78** The variation of the spectral absorptivity of a surface is as given in Fig. P12–78. Determine the average absorptivity and reflectivity of the surface for radiation that originates from a source at  $T = 2500 \text{ K}$ . Also, determine the average emissivity of this surface at 3000 K.

FIGURE P12–78

**12–79** The reflectivity of aluminum coated with lead sulfate is 0.35 for radiation at wavelengths less than  $3 \mu\text{m}$  and 0.95 for radiation greater than  $3 \mu\text{m}$ . Determine the average reflectivity

of this surface for solar radiation ( $T \approx 5800 \text{ K}$ ) and radiation coming from surfaces at room temperature ( $T \approx 300 \text{ K}$ ). Also, determine the emissivity and absorptivity of this surface at both temperatures. Do you think this material is suitable for use in solar collectors?

**12–80** The variation of the spectral transmissivity of a 0.6-cm-thick glass window is as given in Fig. P12–80. Determine the average transmissivity of this window for solar radiation ( $T \approx 5800 \text{ K}$ ) and radiation coming from surfaces at room temperature ( $T \approx 300 \text{ K}$ ). Also, determine the amount of solar radiation transmitted through the window for incident solar radiation of  $650 \text{ W/m}^2$ . *Answers: 0.870, 0.00016, 566 \text{ W/m}^2*

FIGURE P12–80

**12–81** Consider an opaque horizontal plate that is well insulated on the edges and the lower surface. The plate is maintained at  $500 \text{ K}$ , has a total hemispherical absorptivity of 0.51 and the following spectral emissivity function:

$$\varepsilon_\lambda = \begin{cases} \varepsilon_1 = 0.4, & 0 \leq \lambda < 4 \mu\text{m} \\ \varepsilon_2 = 0.8, & 4 \mu\text{m} \leq \lambda < \infty \end{cases}$$

If the plate is subjected to an irradiation of  $5600 \text{ W/m}^2$ , determine (a) the total hemispherical emissivity and (b) the radiosity of the plate surface.

**12–82** An opaque horizontal plate is well insulated on the edges and the lower surface. The irradiation on the plate is  $3000 \text{ W/m}^2$ , of which  $500 \text{ W/m}^2$  is reflected. The plate has a uniform temperature of  $700 \text{ K}$  and has an emissive power of  $5000 \text{ W/m}^2$ . Determine the total emissivity and absorptivity of the plate.

FIGURE P12–82

**12–83** Irradiation on a semi-transparent medium is at a rate of  $520 \text{ W/m}^2$ . If  $160 \text{ W/m}^2$  of the irradiation is reflected from the medium and  $130 \text{ W/m}^2$  is transmitted through the medium, determine the medium's absorptivity, reflectivity, transmissivity, and emissivity.

**12–84** Consider an opaque horizontal plate that is well insulated on the edges and the lower surface. The plate is uniformly irradiated from above while air at  $T_{\infty} = 300\text{ K}$  flows over the surface providing a uniform convection heat transfer coefficient of  $40\text{ W/m}^2\cdot\text{K}$ . Under steady state conditions the surface has a radiosity of  $4000\text{ W/m}^2$ , and the plate temperature is maintained uniformly at  $350\text{ K}$ . If the total absorptivity of the plate is 0.40, determine (a) the irradiation on the plate, (b) the total reflectivity of the plate, (c) the emissive power of the plate, and (d) the total emissivity of the plate.

FIGURE P12–84

**12–85** Consider an opaque plate that is well insulated on the edges and it is heated at the bottom with an electric heater. The plate has an emissivity of 0.67, and is situated in an ambient surrounding temperature of  $7^\circ\text{C}$  where the natural convection heat transfer coefficient is  $7\text{ W/m}^2\cdot\text{K}$ . To maintain a surface temperature of  $80^\circ\text{C}$ , the electric heater supplies  $1000\text{ W/m}^2$  of uniform heat flux to the plate. Determine the radiosity of the plate under these conditions.

**12–86** A horizontal plate is experiencing uniform irradiation on the both upper and lower surfaces. The ambient air temperature surrounding the plate is  $290\text{ K}$  with a convection heat transfer coefficient of  $30\text{ W/m}^2\cdot\text{K}$ . Both upper and lower surfaces of the plate have a radiosity of  $4000\text{ W/m}^2$ , and the plate temperature is maintained uniformly at  $390\text{ K}$ . If the plate is not opaque and has an absorptivity of 0.527, determine the irradiation and emissivity of the plate.

FIGURE P12–86

**12–87** A semi-transparent plate ( $A_1 = 2\text{ cm}^2$ ) has an irradiation of  $500\text{ W/m}^2$ , where 30% of the irradiation is reflected away from the plate and 50% of the irradiation is transmitted through the plate. A radiometer is placed 0.5 m above the plate normal to the direction of viewing from the plate. If the temperature of

the plate is uniform at  $350\text{ K}$ , determine the irradiation that the radiometer would detect.

### Atmospheric and Solar Radiation

**12–88C** When the earth is closest to the sun, we have winter in the northern hemisphere. Explain why. Also explain why we have summer in the northern hemisphere when the earth is farthest away from the sun.

**12–89C** Explain why surfaces usually have quite different absorptivities for solar radiation and for radiation originating from the surrounding bodies.

**12–90C** You have probably noticed warning signs on the highways stating that bridges may be icy even when the roads are not. Explain how this can happen.

**12–91C** What changes would you notice if the sun emitted radiation at an effective temperature of  $2000\text{ K}$  instead of  $5762\text{ K}$ ?

**12–92C** What is the solar constant? How is it used to determine the effective surface temperature of the sun? How would the value of the solar constant change if the distance between the earth and the sun doubled?

**12–93C** Explain why the sky is blue and the sunset is yellow-orange.

**12–94C** What is the effective sky temperature?

**12–95E** Solar radiation is incident on the outer surface of a spaceship at a rate of  $400\text{ Btu/h}\cdot\text{ft}^2$ . The surface has an absorptivity of  $\alpha_s = 0.10$  for solar radiation and an emissivity of  $\varepsilon = 0.6$  at room temperature. The outer surface radiates heat into space at  $0\text{ R}$ . If there is no net heat transfer into the spaceship, determine the equilibrium temperature of the surface. *Answer: 444 R*

**12–96** The air temperature on a clear night is observed to remain at about  $4^\circ\text{C}$ . Yet water is reported to have frozen that night due to radiation effect. Taking the convection heat transfer coefficient to be  $18\text{ W/m}^2\cdot\text{K}$ , determine the value of the maximum effective sky temperature that night.

**12–97** A surface has an absorptivity of  $\alpha_s = 0.72$  for solar radiation and an emissivity of  $\varepsilon = 0.6$  at room temperature. The surface temperature is observed to be  $350\text{ K}$  when the direct and the diffuse components of solar radiation are  $G_D = 350$  and  $G_d = 400\text{ W/m}^2$ , respectively, and the direct radiation makes a  $30^\circ$  angle with the normal of the surface. Taking the effective sky temperature to be  $280\text{ K}$ , determine the net rate of radiation heat transfer to the surface at that time.

**12–98** The absorber surface of a solar collector is made of aluminum coated with black chrome ( $\alpha_s = 0.87$  and  $\varepsilon = 0.09$ ). Solar radiation is incident on the surface at a rate of  $600\text{ W/m}^2$ . The air and the effective sky temperatures are  $25^\circ\text{C}$  and  $15^\circ\text{C}$ , respectively, and the convection heat transfer coefficient is  $10\text{ W/m}^2\cdot\text{K}$ . For an absorber surface temperature of  $70^\circ\text{C}$ , determine the net rate of solar energy delivered by the absorber plate to the water circulating behind it.

FIGURE P12-98

**12-99** Determine the equilibrium temperature of the absorber surface in Prob. 12-98 if the back side of the absorber is insulated.

**12-100** Reconsider Prob. 12-98. Using EES (or other) software, plot the net rate of solar energy transferred to water as a function of the absorptivity of the absorber plate. Let the absorptivity vary from 0.5 to 1.0, and discuss the results.

#### Special Topic: Solar Heat Gain through Windows

**12-101C** What fraction of the solar energy is in the visible range (*a*) outside the earth's atmosphere and (*b*) at sea level on earth? Answer the same question for infrared radiation.

**12-102C** Describe the solar radiation properties of a window that is ideally suited for minimizing the air-conditioning load.

**12-103C** What is the effect of a low-e coating on the inner surface of a window glass on the (*a*) heat loss in winter and (*b*) heat gain in summer through the window?

**12-104C** What is a shading device? Is an internal or external shading device more effective in reducing the solar heat gain through a window? How does the color of the surface of a shading device facing outside affect the solar heat gain?

**12-105C** What does the SC (shading coefficient) of a device represent? How do the SCs of clear glass and heat-absorbing glass compare?

**12-106C** Define the SHGC (solar heat gain coefficient), and explain how it differs from the SC (shading coefficient). What are the values of the SHGC and SC of a single-pane clear-glass window?

**12-107** Consider a building in New York (40° N latitude) that has 130 m<sup>2</sup> of window area on its south wall. The windows are double-pane heat-absorbing type, and are equipped with light-colored venetian blinds with a shading coefficient of SC = 0.30. Determine the total solar heat gain of the building through the south windows at solar noon in April. What would your answer be if there were no blinds at the windows?

FIGURE P12-107

**12-108** A typical winter day in Reno, Nevada (39° N latitude), is cold but sunny, and thus the solar heat gain through the windows can be more than the heat loss through them during daytime. Consider a house with double-door-type windows that are double paned with 3-mm-thick glasses and 6.4 mm of air space and have aluminum frames and spacers. The house is maintained at 22°C at all times. Determine if the house is losing more or less heat than it is gaining from the sun through an east window on a typical day in January for a 24-h period if the average outdoor temperature is 10°C. *Answer: less*

FIGURE P12-108

**12-109** Repeat Prob. 12-108 for a south window.

**12-110** Consider a building located near  $40^\circ$  N latitude that has equal window areas on all four sides. The building owner is considering coating the south-facing windows with reflective film to reduce the solar heat gain and thus the cooling load. But someone suggests that the owner will reduce the cooling load even more if she coats the west-facing windows instead. What do you think?

**12-111E** Determine the rate of net heat gain (or loss) through a 9-ft-high, 15-ft-wide, fixed  $\frac{1}{8}$ -in single-glass window with aluminum frames on the west wall at 3 PM solar time during a typical day in January at a location near  $40^\circ$  N latitude when the indoor and outdoor temperatures are  $70^\circ\text{F}$  and  $20^\circ\text{F}$ , respectively.

**12-112** A manufacturing facility located at  $32^\circ$  N latitude has a glazing area of  $60 \text{ m}^2$  facing west that consists of double-pane windows made of clear glass ( $\text{SHGC} = 0.766$ ). To reduce the solar heat gain in summer, a reflective film that will reduce the SHGC to 0.35 is considered. The cooling season consists of June, July, August, and September, and the heating season, October through April. The average daily solar heat fluxes incident on the west side at this latitude are 2.35, 3.03, 3.62, 4.00, 4.20, 4.24, 4.16, 3.93, 3.48, 2.94, 2.33, and  $2.07 \text{ kWh/day}\cdot\text{m}^2$  for January through December, respectively. Also, the unit costs of electricity and natural gas are  $\$0.09/\text{kWh}$  and  $\$0.45/\text{therm}$ , respectively. If the coefficient of performance of the cooling system is 3.2 and the efficiency of the furnace is 0.90, determine the net annual cost savings due to installing reflective coating on the windows. Also, determine the simple payback period if the installation cost of reflective film is  $\$20/\text{m}^2$ .

**12-113** A house located in Boulder, Colorado ( $40^\circ$  N latitude), has ordinary double-pane windows with 6-mm-thick glasses and the total window areas are 8, 6, 6, and  $4 \text{ m}^2$  on the south, west, east, and north walls, respectively. Determine the total solar heat gain of the house at 9:00, 12:00, and 15:00 solar time in July. Also, determine the total amount of solar heat gain per day for an average day in January.

**12-114** Repeat Prob. 11-113 for double-pane windows that are gray-tinted.

### Review Problems

**12-115** A 1-m-diameter spherical cavity is maintained at a uniform temperature of 600 K. Now a 5-mm-diameter hole is drilled. Determine the maximum rate of radiation energy streaming through the hole. What would your answer be if the diameter of the cavity were 3 m?

**12-116** Daylight and incandescent light may be approximated as a blackbody at the effective surface temperatures of 5800 K and 2800 K, respectively. Determine the wavelength at maximum emission of radiation for each of the lighting sources.

**12-117** The human skin is “selective” when it comes to the absorption of the solar radiation that strikes it perpendicularly. The skin absorbs only 50 percent of the incident radiation with wavelengths between  $\lambda_1 = 0.517 \mu\text{m}$  and  $\lambda_2 = 1.552 \mu\text{m}$ . The radiation with wavelengths shorter than  $\lambda_1$  and longer than  $\lambda_2$  is fully absorbed. The solar surface may be modeled as a blackbody with effective surface temperature of 5800 K. Calculate the fraction of the incident solar radiation that is absorbed by the human skin.

**12-118** Consider a small black surface of area  $A = 3.5 \text{ cm}^2$  maintained at 600 K. Determine the rate at which radiation energy is emitted by the surface through a ring-shaped opening defined by  $0 \leq \phi \leq 2\pi$  and  $40^\circ \leq \theta \leq 50^\circ$ , where  $\phi$  is the azimuth angle and  $\theta$  is the angle a radiation beam makes with the normal of the surface.

**12-119** A small surface of area  $A = 3 \text{ cm}^2$  emits radiation with an intensity of radiation that can be expressed as  $I_e(\theta, \phi) = 100 \phi \cos\theta$ , where  $I_e$  has the units of  $\text{W}/\text{m}^2\cdot\text{sr}$ . Determine the emissive power from the surface into the hemisphere surrounding it, and the rate of radiation emission from the surface.

**12-120** A radiation sensor and a small surface of area  $A_1$  that emits radiation as a blackbody are oriented as shown in the figure. Determine the distance  $L$  at which the sensor is measuring two-thirds of the radiation rate emitted from surface  $A_1$  corresponding to the position directly under the sensor at  $L = 0$ .

FIGURE P12-120

**12-121** The spectral emissivity of an opaque surface at 1500 K is approximated as

$$\begin{aligned}\varepsilon_1 &= 0 && \text{for } \lambda < 2 \mu\text{m} \\ \varepsilon_2 &= 0.85 && \text{for } 2 \leq \lambda \leq 6 \mu\text{m} \\ \varepsilon_3 &= 0 && \text{for } \lambda > 6 \mu\text{m}\end{aligned}$$

Determine the total emissivity and the emissive flux of the surface.

**12-122** The spectral absorptivity of an opaque surface is as shown on the graph. Determine the absorptivity of the surface for radiation emitted by a source at (a) 1000 K and (b) 3000 K.

FIGURE P12-122

**12-123** The surface in Prob. 12-122 receives solar radiation at a rate of  $470 \text{ W/m}^2$ . Determine the solar absorptivity of the surface and the rate of absorption of solar radiation.

**12-124** The spectral transmissivity of a 3-mm-thick regular glass can be expressed as

$$\begin{aligned}\tau_1 &= 0 && \text{for } \lambda < 0.35 \mu\text{m} \\ \tau_2 &= 0.85 && \text{for } 0.35 < \lambda < 2.5 \mu\text{m} \\ \tau_3 &= 0 && \text{for } \lambda > 2.5 \mu\text{m}\end{aligned}$$

Determine the transmissivity of this glass for solar radiation. What is the transmissivity of this glass for light?

**12-125** The spectral transmissivity of a glass cover used in a solar collector is given as

$$\begin{aligned}\tau_1 &= 0 && \text{for } \lambda < 0.3 \mu\text{m} \\ \tau_2 &= 0.9 && \text{for } 0.3 < \lambda < 3 \mu\text{m} \\ \tau_3 &= 0 && \text{for } \lambda > 3 \mu\text{m}\end{aligned}$$

Solar radiation is incident at a rate of  $950 \text{ W/m}^2$ , and the absorber plate, which can be considered to be black, is maintained at  $340 \text{ K}$  by the cooling water. Determine (a) the solar flux incident on the absorber plate, (b) the transmissivity of the glass cover for radiation emitted by the absorber plate, and (c) the rate of heat transfer to the cooling water if the glass cover temperature is also  $340 \text{ K}$ .

**12-126** A small surface of area  $A_1 = 3 \text{ cm}^2$  and a radiation sensor of area  $A_2 = 1 \text{ cm}^2$  are oriented as shown in the figure. Surface  $A_1$  is opaque (diffuse emitter and reflector) and maintains a constant temperature of  $T_1 = 400 \text{ K}$ . The absorptivity and emissivity of surface  $A_1$  are 0.5 and 0.7, respectively. If surface  $A_1$  is experiencing  $2000 \text{ W/m}^2$  of irradiation, determine the rate at which radiation emitted from  $A_1$  is intercepted by the sensor.

FIGURE P12-126

**12-127** Solar radiation is incident on the front surface of a thin plate with direct and diffuse components of  $300$  and  $250 \text{ W/m}^2$ , respectively. The direct radiation makes a  $30^\circ$  angle with the normal of the surface. The plate surfaces have a solar absorptivity of  $0.63$  and an emissivity of  $0.93$ . The air temperature is  $5^\circ\text{C}$  and the convection heat transfer coefficient is  $20 \text{ W/m}^2\cdot\text{K}$ . The effective sky temperature for the front surface is  $-33^\circ\text{C}$  while the surrounding surfaces are at  $5^\circ\text{C}$  for the back surface. Determine the equilibrium temperature of the plate.

FIGURE P12-127

**12-128** A horizontal opaque flat plate is well insulated on the edges and the lower surface. The top surface has an area of  $5 \text{ m}^2$ , and it experiences uniform irradiation at a rate of  $5000 \text{ W}$ . The plate absorbs  $4000 \text{ W}$  of the irradiation, and the surface is losing heat at a rate of  $500 \text{ W}$  by convection. If the plate maintains a uniform temperature of  $350 \text{ K}$ , determine the absorptivity, reflectivity, and emissivity of the plate.

FIGURE P12-128

### Fundamentals of Engineering (FE) Exam Problems

**12-129** Consider a surface at  $-5^\circ\text{C}$  in an environment at  $25^\circ\text{C}$ . The maximum rate of heat that can be emitted from this surface by radiation is

- (a)  $0 \text{ W/m}^2$       (b)  $155 \text{ W/m}^2$       (c)  $293 \text{ W/m}^2$   
 (d)  $354 \text{ W/m}^2$       (e)  $567 \text{ W/m}^2$

**12-130** Consider a surface at  $500 \text{ K}$ . The spectral blackbody emissive power at a wavelength of  $50 \mu\text{m}$  is

- (a)  $1.54 \text{ W/m}^2\cdot\mu\text{m}$       (b)  $26.3 \text{ W/m}^2\cdot\mu\text{m}$   
 (c)  $108.4 \text{ W/m}^2\cdot\mu\text{m}$       (d)  $2750 \text{ W/m}^2\cdot\mu\text{m}$       (e)  $8392 \text{ W/m}^2\cdot\mu\text{m}$

**12-131** The wavelength at which the blackbody emissive power reaches its maximum value at  $300 \text{ K}$  is

- (a)  $5.1 \mu\text{m}$       (b)  $9.7 \mu\text{m}$       (c)  $15.5 \mu\text{m}$   
 (d)  $38.0 \mu\text{m}$       (e)  $73.1 \mu\text{m}$

**12-132** A surface absorbs 10 percent of radiation at wavelengths less than  $3 \mu\text{m}$  and 50 percent of radiation at wavelengths greater than  $3 \mu\text{m}$ . The average absorptivity of this surface for radiation emitted by a source at 3000 K is

- (a) 0.14    (b) 0.22    (c) 0.30    (d) 0.38    (e) 0.42

**12-133** A surface at  $300^\circ\text{C}$  has an emissivity of 0.7 in the wavelength range of  $0\text{--}4.4 \mu\text{m}$  and 0.3 over the rest of the wavelength range. At a temperature of  $300^\circ\text{C}$ , 19 percent of the blackbody emissive power is in wavelength range up to  $4.4 \mu\text{m}$ . The total emissivity of this surface is

- (a) 0.300    (b) 0.376    (c) 0.624  
 (d) 0.70    (e) 0.50

**12-134** Consider a 4-cm-diameter and 6-cm-long cylindrical rod at 1000 K. If the emissivity of the rod surface is 0.75, the total amount of radiation emitted by all surfaces of the rod in 20 min is

- (a) 43 kJ    (b) 385 kJ    (c) 434 kJ  
 (d) 513 kJ    (e) 684 kJ

**12-135** Solar radiation is incident on a semi-transparent body at a rate of  $500 \text{ W/m}^2$ . If  $150 \text{ W/m}^2$  of this incident radiation is reflected back and  $225 \text{ W/m}^2$  is transmitted across the body, the absorptivity of the body is

- (a) 0    (b) 0.25    (c) 0.30    (d) 0.45    (e) 1

**12-136** Solar radiation is incident on an opaque surface at a rate of  $400 \text{ W/m}^2$ . The emissivity of the surface is 0.65 and the absorptivity to solar radiation is 0.85. The convection coefficient between the surface and the environment at  $25^\circ\text{C}$  is

$6 \text{ W/m}^2\text{-K}$ . If the surface is exposed to atmosphere with an effective sky temperature of 250 K, the equilibrium temperature of the surface is

- |           |           |           |
|-----------|-----------|-----------|
| (a) 281 K | (b) 298 K | (c) 303 K |
| (d) 317 K | (e) 339 K |           |

**12-137** A surface is exposed to solar radiation. The direct and diffuse components of solar radiation are  $350$  and  $250 \text{ W/m}^2$ , and the direct radiation makes a  $35^\circ$  angle with the normal of the surface. The solar absorptivity and the emissivity of the surface are 0.24 and 0.41, respectively. If the surface is observed to be at 315 K and the effective sky temperature is 256 K, the net rate of radiation heat transfer to the surface is

- |                          |                         |                       |
|--------------------------|-------------------------|-----------------------|
| (a) $-129 \text{ W/m}^2$ | (b) $-44 \text{ W/m}^2$ | (c) $0 \text{ W/m}^2$ |
| (d) $129 \text{ W/m}^2$  | (e) $537 \text{ W/m}^2$ |                       |

### Design and Essay Problems

**12-138** Write an essay on the radiation properties of selective surfaces used on the absorber plates of solar collectors. Find out about the various kinds of such surfaces, and discuss the performance and cost of each type. Recommend a selective surface that optimizes cost and performance.

**12-139** According to an Atomic Energy Commission report, a hydrogen bomb can be approximated as a large fireball at a temperature of 7200 K. You are to assess the impact if such a bomb exploded 5 km above a city. Assume the diameter of the fireball to be 1 km, and the blast to last 15 s. Investigate the level of radiation energy people, plants, and houses will be exposed to, and how adversely they will be affected by the blast.

## RADIATION HEAT TRANSFER

In Chapter 12, we considered the fundamental aspects of radiation and the radiation properties of surfaces. We are now in a position to consider radiation exchange between two or more surfaces, which is the primary quantity of interest in most radiation problems.

We start this chapter with a discussion of view factors and the rules associated with them. View factor expressions and charts for some common configurations are given, and the crossed-strings method is presented. We then discuss radiation heat transfer, first between black surfaces and then between nonblack surfaces using the radiation network approach. We continue with radiation shields and discuss the radiation effect on temperature measurements and comfort. Finally, we consider gas radiation, and discuss the effective emissivities and absorptivities of gas bodies of various shapes. We also discuss radiation exchange between the walls of combustion chambers and the high-temperature emitting and absorbing combustion gases inside.

### OBJECTIVES

When you finish studying this chapter, you should be able to:

- Define view factor, and understand its importance in radiation heat transfer calculations,
- Develop view factor relations, and calculate the unknown view factors in an enclosure by using these relations,
- Calculate radiation heat transfer between black surfaces,
- Determine radiation heat transfer between diffuse and gray surfaces in an enclosure using the concept of radiosity,
- Obtain relations for net rate of radiation heat transfer between the surfaces of a two-zone enclosure, including two large parallel plates, two long concentric cylinders, and two concentric spheres,
- Quantify the effect of radiation shields on the reduction of radiation heat transfer between two surfaces, and become aware of the importance of radiation effect in temperature measurements.

**FIGURE 13-1**

Radiation heat exchange between surfaces depends on the *orientation* of the surfaces relative to each other, and this dependence on orientation is accounted for by the *view factor*.

## 13-1 ■ THE VIEW FACTOR

Radiation heat transfer between surfaces depends on the *orientation* of the surfaces relative to each other as well as their radiation properties and temperatures, as illustrated in Fig. 13-1. For example, a camper can make the most use of a campfire on a cold night by standing as close to the fire as possible and by blocking as much of the radiation coming from the fire by turning his or her front to the fire instead of the side. Likewise, a person can maximize the amount of solar radiation incident on him or her and take a sunbath by lying down on his or her back instead of standing.

To account for the effects of orientation on radiation heat transfer between two surfaces, we define a new parameter called the *view factor*, which is a purely geometric quantity and is independent of the surface properties and temperature. It is also called the *shape factor*, *configuration factor*, and *angle factor*. The view factor based on the assumption that the surfaces are diffuse emitters and diffuse reflectors is called the *diffuse view factor*, and the view factor based on the assumption that the surfaces are diffuse emitters but specular reflectors is called the *specular view factor*. In this book, we consider radiation exchange between diffuse surfaces only, and thus the term *view factor* simply means *diffuse view factor*.

The view factor from a surface  $i$  to a surface  $j$  is denoted by  $F_{i \rightarrow j}$  or just  $F_{ij}$  and is defined as

$$F_{ij} = \text{the fraction of the radiation leaving surface } i \text{ that strikes surface } j \text{ directly}$$

The notation  $F_{i \rightarrow j}$  is instructive for beginners, since it emphasizes that the view factor is for radiation that travels from surface  $i$  to surface  $j$ . However, this notation becomes rather awkward when it has to be used many times in a problem. In such cases, it is convenient to replace it by its *shorthand* version  $F_{ij}$ .

The view factor  $F_{12}$  represents the fraction of radiation leaving surface 1 that strikes surface 2 directly, and  $F_{21}$  represents the fraction of radiation leaving surface 2 that strikes surface 1 directly. Note that the radiation that strikes a surface does not need to be absorbed by that surface. Also, radiation that strikes a surface after being reflected by other surfaces is not considered in the evaluation of view factors.

To develop a general expression for the view factor, consider two differential surfaces  $dA_1$  and  $dA_2$  on two arbitrarily oriented surfaces  $A_1$  and  $A_2$ , respectively, as shown in Fig. 13-2. The distance between  $dA_1$  and  $dA_2$  is  $r$ , and the angles between the normals of the surfaces and the line that connects  $dA_1$  and  $dA_2$  are  $\theta_1$  and  $\theta_2$ , respectively. Surface 1 emits and reflects radiation diffusely in all directions with a constant intensity of  $I_1$ , and the solid angle subtended by  $dA_2$  when viewed by  $dA_1$  is  $d\omega_{21}$ .

The rate at which radiation leaves  $dA_1$  in the direction of  $\theta_1$  is  $I_1 \cos \theta_1 dA_1$ . Noting that  $d\omega_{21} = dA_2 \cos \theta_2 / r^2$ , the portion of this radiation that strikes  $dA_2$  is

$$\dot{Q}_{dA_1 \rightarrow dA_2} = I_1 \cos \theta_1 dA_1 d\omega_{21} = I_1 \cos \theta_1 dA_1 \frac{dA_2 \cos \theta_2}{r^2} \quad (13-1)$$

The total rate at which radiation leaves  $dA_1$  (via emission and reflection) in all directions is the radiosity (which is  $J_1 = \pi I_1$ ) times the surface area,

$$\dot{Q}_{dA_1} = J_1 dA_1 = \pi I_1 dA_1 \quad (13-2)$$

**FIGURE 13-2**

Geometry for the determination of the view factor between two surfaces.

Then the *differential view factor*  $dF_{dA_1 \rightarrow dA_2}$ , which is the fraction of radiation leaving  $dA_1$  that strikes  $dA_2$  directly, becomes

$$dF_{dA_1 \rightarrow dA_2} = \frac{\dot{Q}_{dA_1 \rightarrow dA_2}}{\dot{Q}_{dA_1}} = \frac{\cos \theta_1 \cos \theta_2}{\pi r^2} dA_2 \quad (13-3)$$

The differential view factor  $dF_{dA_2 \rightarrow dA_1}$  can be determined from Eq. 13-3 by interchanging the subscripts 1 and 2.

The view factor from a differential area  $dA_1$  to a finite area  $A_2$  can be determined from the fact that the fraction of radiation leaving  $dA_1$  that strikes  $A_2$  is the sum of the fractions of radiation striking the differential areas  $dA_2$ . Therefore, the view factor  $F_{dA_1 \rightarrow A_2}$  is determined by integrating  $dF_{dA_1 \rightarrow dA_2}$  over  $A_2$ ,

$$F_{dA_1 \rightarrow A_2} = \int_{A_2} \frac{\cos \theta_1 \cos \theta_2}{\pi r^2} dA_2 \quad (13-4)$$

The total rate at which radiation leaves the entire  $A_1$  (via emission and reflection) in all directions is

$$\dot{Q}_{A_1} = J_1 A_1 = \pi I_1 A_1 \quad (13-5)$$

The portion of this radiation that strikes  $dA_2$  is determined by considering the radiation that leaves  $dA_1$  and strikes  $dA_2$  (given by Eq. 13-1), and integrating it over  $A_1$ ,

$$\dot{Q}_{A_1 \rightarrow dA_2} = \int_{A_1} \dot{Q}_{dA_1 \rightarrow dA_2} = \int_{A_1} \frac{I_1 \cos \theta_1 \cos \theta_2 dA_2}{r^2} dA_1 \quad (13-6)$$

Integration of this relation over  $A_2$  gives the radiation that strikes the entire  $A_2$ ,

$$\dot{Q}_{A_1 \rightarrow A_2} = \int_{A_2} \dot{Q}_{A_1 \rightarrow dA_2} = \int_{A_2} \int_{A_1} \frac{I_1 \cos \theta_1 \cos \theta_2}{r^2} dA_1 dA_2 \quad (13-7)$$

Dividing this by the total radiation leaving  $A_1$  (from Eq. 13-5) gives the fraction of radiation leaving  $A_1$  that strikes  $A_2$ , which is the view factor  $F_{A_1 \rightarrow A_2}$  (or  $F_{12}$  for short),

$$F_{12} = F_{A_1 \rightarrow A_2} = \frac{\dot{Q}_{A_1 \rightarrow A_2}}{\dot{Q}_{A_1}} = \frac{1}{A_1} \int_{A_2} \int_{A_1} \frac{\cos \theta_1 \cos \theta_2}{\pi r^2} dA_1 dA_2 \quad (13-8)$$

The view factor  $F_{A_2 \rightarrow A_1}$  is readily determined from Eq. 13-8 by interchanging the subscripts 1 and 2,

$$F_{21} = F_{A_2 \rightarrow A_1} = \frac{\dot{Q}_{A_2 \rightarrow A_1}}{\dot{Q}_{A_2}} = \frac{1}{A_2} \int_{A_1} \int_{A_2} \frac{\cos \theta_1 \cos \theta_2}{\pi r^2} dA_1 dA_2 \quad (13-9)$$

Note that  $I_1$  is constant but  $r$ ,  $\theta_1$ , and  $\theta_2$  are variables. Also, integrations can be performed in any order since the integration limits are constants. These relations confirm that the view factor between two surfaces depends on their relative orientation and the distance between them.

**FIGURE 13-3**

The view factor from a surface to itself is *zero* for *plane* or *convex* surfaces and *nonzero* for *concave* surfaces.

**FIGURE 13-4**

In a geometry that consists of two concentric spheres, the view factor  $F_{1 \rightarrow 2} = 1$  since the entire radiation leaving the surface of the smaller sphere is intercepted by the larger sphere.

Combining Eqs. 13-8 and 13-9 after multiplying the former by  $A_1$  and the latter by  $A_2$  gives

$$A_1 F_{12} = A_2 F_{21} \quad (13-10)$$

which is known as the **reciprocity relation** for view factors. It allows the calculation of a view factor from a knowledge of the other.

The view factor relations developed above are applicable to any two surfaces  $i$  and  $j$  provided that the surfaces are diffuse emitters and diffuse reflectors (so that the assumption of constant intensity is valid). For the special case of  $j = i$ , we have

$$F_{i \rightarrow i} = \text{the fraction of radiation leaving surface } i \text{ that strikes itself directly}$$

Noting that in the absence of strong electromagnetic fields radiation beams travel in straight paths, the view factor from a surface to itself is zero unless the surface “sees” itself. Therefore,  $F_{i \rightarrow i} = 0$  for *plane* or *convex* surfaces and  $F_{i \rightarrow i} \neq 0$  for *concave* surfaces, as illustrated in Fig. 13-3.

The value of the view factor ranges between *zero* and *one*. The limiting case  $F_{i \rightarrow j} = 0$  indicates that the two surfaces do not have a direct view of each other, and thus radiation leaving surface  $i$  cannot strike surface  $j$  directly. The other limiting case  $F_{i \rightarrow j} = 1$  indicates that surface  $j$  completely surrounds surface  $i$ , so that the entire radiation leaving surface  $i$  is intercepted by surface  $j$ . For example, in a geometry consisting of two concentric spheres, the entire radiation leaving the surface of the smaller sphere (surface 1) strikes the larger sphere (surface 2), and thus  $F_{1 \rightarrow 2} = 1$ , as illustrated in Fig. 13-4.

The view factor has proven to be very useful in radiation analysis because it allows us to express the *fraction of radiation* leaving a surface that strikes another surface in terms of the orientation of these two surfaces relative to each other. The underlying assumption in this process is that the radiation a surface receives from a source is directly proportional to the angle the surface subtends when viewed from the source. This would be the case only if the radiation coming off the source is *uniform* in all directions throughout its surface and the medium between the surfaces does not *absorb*, *emit*, or *scatter* radiation. That is, it is the case when the surfaces are *isothermal* and *diffuse* emitters and reflectors and the surfaces are separated by a *nonparticipating* medium such as a vacuum or air.

The view factor  $F_{1 \rightarrow 2}$  between two surfaces  $A_1$  and  $A_2$  can be determined in a systematic manner first by expressing the view factor between two differential areas  $dA_1$  and  $dA_2$  in terms of the spatial variables and then by performing the necessary integrations. However, this approach is not practical, since, even for simple geometries, the resulting integrations are usually very complex and difficult to perform.

View factors for hundreds of common geometries are evaluated and the results are given in analytical, graphical, and tabular form in several publications. View factors for selected geometries are given in Tables 13-1 and 13-2 in *analytical* form and in Figs. 13-5 to 13-8 in *graphical* form. The view factors in Table 13-1 are for three-dimensional geometries. The view factors in Table 13-2, on the other hand, are for geometries that are *infinitely long* in the direction perpendicular to the plane of the paper and are therefore two-dimensional.

**TABLE 13-1**

View factor expressions for some common geometries of finite size (3-D)

| Geometry                                    | Relation  |
|---|---|
| Aligned parallel rectangles                 | $\bar{X} = X/L$ and $\bar{Y} = Y/L$ $F_{i \rightarrow j} = \frac{2}{\pi \bar{X} \bar{Y}} \left\{ \ln \left[ \frac{(1 + \bar{X}^2)(1 + \bar{Y}^2)}{1 + \bar{X}^2 + \bar{Y}^2} \right]^{1/2} + \bar{X}(1 + \bar{Y}^2)^{1/2} \tan^{-1} \frac{\bar{X}}{(1 + \bar{Y}^2)^{1/2}} \right. \\ \left. + \bar{Y}(1 + \bar{X}^2)^{1/2} \tan^{-1} \frac{\bar{Y}}{(1 + \bar{X}^2)^{1/2}} - \bar{X} \tan^{-1} \bar{X} - \bar{Y} \tan^{-1} \bar{Y} \right\}$                           |
| Coaxial parallel disks                      | $R_i = r_i/L$ and $R_j = r_j/L$ $S = 1 + \frac{1 + R_j^2}{R_i^2}$ $F_{i \rightarrow j} = \frac{1}{2} \left\{ S - \left[ S^2 - 4 \left( \frac{r_j}{r_i} \right)^2 \right]^{1/2} \right\}$ For $r_i = r_j = r$ and $R = r/L$ : $F_{i \rightarrow j} = F_{j \rightarrow i} = 1 + \frac{1 - \sqrt{4R^2 + 1}}{2R^2}$    |
| Perpendicular rectangles with a common edge | $H = Z/X$ and $W = Y/X$ $F_{i \rightarrow j} = \frac{1}{\pi W} \left( W \tan^{-1} \frac{1}{W} + H \tan^{-1} \frac{1}{H} - (H^2 + W^2)^{1/2} \tan^{-1} \frac{1}{(H^2 + W^2)^{1/2}} \right. \\ \left. + \frac{1}{4} \ln \left\{ \frac{(1 + W^2)(1 + H^2)}{1 + W^2 + H^2} \left[ \frac{W^2(1 + W^2 + H^2)}{(1 + W^2)(W^2 + H^2)} \right]^{W^2} \right. \right. \\ \left. \times \left[ \frac{H^2(1 + H^2 + W^2)}{(1 + H^2)(H^2 + W^2)} \right]^{H^2} \right\} \right)$  |

## 13-2 • VIEW FACTOR RELATIONS

Radiation analysis on an enclosure consisting of  $N$  surfaces requires the evaluation of  $N^2$  view factors, and this evaluation process is probably the most time-consuming part of a radiation analysis. However, it is neither practical nor necessary to evaluate all of the view factors directly. Once a sufficient number of view factors are available, the rest of them can be determined by utilizing some fundamental relations for view factors, as discussed next.

TABLE 13–2

View factor expressions for some infinitely long (2-D) geometries

| Geometry  | Relation   |
|---|--|
| Parallel plates with midlines connected by perpendicular line | $W_i = w_i/L$ and $W_j = w_j/L$<br>$F_{i \rightarrow j} = \frac{[(W_i + W_j)^2 + 4]^{1/2} - (W_j - W_i)^2 + 4]^{1/2}}{2W_i}$                         |
| Inclined plates of equal width and with a common edge         | $F_{i \rightarrow j} = 1 - \sin \frac{1}{2}\alpha$   |
| Perpendicular plates with a common edge                       | $F_{i \rightarrow j} = \frac{1}{2} \left\{ 1 + \frac{w_j}{w_i} - \left[ 1 + \left( \frac{w_j}{w_i} \right)^2 \right]^{1/2} \right\}$                 |
| Three-sided enclosure   | $F_{i \rightarrow j} = \frac{w_i + w_j - w_k}{2w_i}$   |
| Infinite plane and row of cylinders                           | $F_{i \rightarrow j} = 1 - \left[ 1 - \left( \frac{D}{s} \right)^2 \right]^{1/2} + \frac{D}{s} \tan^{-1} \left( \frac{s^2 - D^2}{D^2} \right)^{1/2}$ |

## 1 The Reciprocity Relation

The view factors  $F_{i \rightarrow j}$  and  $F_{j \rightarrow i}$  are *not* equal to each other unless the areas of the two surfaces are. That is,

$$F_{j \rightarrow i} = F_{i \rightarrow j} \quad \text{when } A_i = A_j$$

$$F_{j \rightarrow i} \neq F_{i \rightarrow j} \quad \text{when } A_i \neq A_j$$

**FIGURE 13-5**

View factor between two aligned parallel rectangles of equal size.

**FIGURE 13-6**

View factor between two perpendicular rectangles with a common edge.

**FIGURE 13-7**

View factor between two coaxial parallel disks.

**FIGURE 13-8**

View factors for two concentric cylinders of finite length: (a) outer cylinder to inner cylinder; (b) outer cylinder to itself.

We have shown earlier that the pair of view factors  $F_{i \rightarrow j}$  and  $F_{j \rightarrow i}$  are related to each other by

$$A_i F_{i \rightarrow j} = A_j F_{j \rightarrow i} \quad (13-11)$$

This relation is referred to as the **reciprocity relation** or the **reciprocity rule**, and it enables us to determine the counterpart of a view factor from a knowledge of the view factor itself and the areas of the two surfaces. When determining the pair of view factors  $F_{i \rightarrow j}$  and  $F_{j \rightarrow i}$ , it makes sense to evaluate first the easier one directly and then the more difficult one by applying the reciprocity relation.

## 2 The Summation Rule

The radiation analysis of a surface normally requires the consideration of the radiation coming in or going out in all directions. Therefore, most radiation problems encountered in practice involve enclosed spaces. When formulating a radiation problem, we usually form an *enclosure* consisting of the surfaces interacting radiatively. Even openings are treated as imaginary surfaces with radiation properties equivalent to those of the opening.

The conservation of energy principle requires that the entire radiation leaving any surface  $i$  of an enclosure be intercepted by the surfaces of the enclosure. Therefore, *the sum of the view factors from surface  $i$  of an enclosure to all surfaces of the enclosure, including to itself, must equal unity*. This is known as the **summation rule** for an enclosure and is expressed as (Fig. 13–9)

$$\sum_{j=1}^N F_{i \rightarrow j} = 1 \quad (13-12)$$

where  $N$  is the number of surfaces of the enclosure. For example, applying the summation rule to surface 1 of a three-surface enclosure yields

$$\sum_{j=1}^3 F_{1 \rightarrow j} = F_{1 \rightarrow 1} + F_{1 \rightarrow 2} + F_{1 \rightarrow 3} = 1$$

The summation rule can be applied to each surface of an enclosure by varying  $i$  from 1 to  $N$ . Therefore, the summation rule applied to each of the  $N$  surfaces of an enclosure gives  $N$  relations for the determination of the view factors. Also, the reciprocity rule gives  $\frac{1}{2}N(N - 1)$  additional relations. Then the total number of view factors that need to be evaluated directly for an  $N$ -surface enclosure becomes

$$N^2 - [N + \frac{1}{2}N(N - 1)] = \frac{1}{2}N(N - 1)$$

For example, for a six-surface enclosure, we need to determine only  $\frac{1}{2} \times 6(6 - 1) = 15$  of the  $6^2 = 36$  view factors directly. The remaining 21 view factors can be determined from the 21 equations that are obtained by applying the reciprocity and the summation rules.

**FIGURE 13–9**

Radiation leaving any surface  $i$  of an enclosure must be intercepted completely by the surfaces of the enclosure. Therefore, the sum of the view factors from surface  $i$  to each one of the surfaces of the enclosure must be unity.

**FIGURE 13–10**

The geometry considered in Example 13–1.

### EXAMPLE 13–1 View Factors Associated with Two Concentric Spheres

Determine the view factors associated with an enclosure formed by two concentric spheres, shown in Fig. 13–10.

**SOLUTION** The view factors associated with two concentric spheres are to be determined.

**Assumptions** The surfaces are diffuse emitters and reflectors.

**Analysis** The outer surface of the smaller sphere (surface 1) and inner surface of the larger sphere (surface 2) form a two-surface enclosure. Therefore,  $N = 2$  and this enclosure involves  $N^2 = 2^2 = 4$  view factors, which are  $F_{11}$ ,  $F_{12}$ ,  $F_{21}$ , and  $F_{22}$ . In this two-surface enclosure, we need to determine only

$$\frac{1}{2}N(N - 1) = \frac{1}{2} \times 2(2 - 1) = 1$$

view factor directly. The remaining three view factors can be determined by the application of the summation and reciprocity rules. But it turns out that we can determine not only one but *two* view factors directly in this case by a simple *inspection*:

$$\begin{aligned} F_{11} &= 0, && \text{since no radiation leaving surface 1 strikes itself} \\ F_{12} &= 1, && \text{since all radiation leaving surface 1 strikes surface 2} \end{aligned}$$

Actually it would be sufficient to determine only one of these view factors by inspection, since we could always determine the other one from the summation rule applied to surface 1 as  $F_{11} + F_{12} = 1$ .

The view factor  $F_{21}$  is determined by applying the reciprocity relation to surfaces 1 and 2:

$$A_1 F_{12} = A_2 F_{21}$$

which yields

$$F_{21} = \frac{A_1}{A_2} F_{12} = \frac{4\pi r_1^2}{4\pi r_2^2} \times 1 = \left(\frac{r_1}{r_2}\right)^2$$

Finally, the view factor  $F_{22}$  is determined by applying the summation rule to surface 2:

$$F_{21} + F_{22} = 1$$

and thus

$$F_{22} = 1 - F_{21} = 1 - \left(\frac{r_1}{r_2}\right)^2$$

**Discussion** Note that when the outer sphere is much larger than the inner sphere ( $r_2 \gg r_1$ ),  $F_{22}$  approaches one. This is expected, since the fraction of radiation leaving the outer sphere that is intercepted by the inner sphere will be negligible in that case. Also note that the two spheres considered above do not need to be concentric. However, the radiation analysis will be most accurate for the case of concentric spheres, since the radiation is most likely to be uniform on the surfaces in that case.

### 3 The Superposition Rule

Sometimes the view factor associated with a given geometry is not available in standard tables and charts. In such cases, it is desirable to express the given geometry as the sum or difference of some geometries with known view factors, and then to apply the **superposition rule**, which can be expressed as *the view factor from a surface i to a surface j is equal to the sum of the view factors from surface i to the parts of surface j*. Note that the reverse of this is not true. That is, the view factor from a surface j to a surface i is *not* equal to the sum of the view factors from the parts of surface j to surface i.

Consider the geometry in Fig. 13–11, which is infinitely long in the direction perpendicular to the plane of the paper. The radiation that leaves surface 1 and strikes the combined surfaces 2 and 3 is equal to the sum of the radiation that strikes surfaces 2 and 3. Therefore, the view factor from surface 1 to the combined surfaces of 2 and 3 is

$$F_{1 \rightarrow (2,3)} = F_{1 \rightarrow 2} + F_{1 \rightarrow 3} \quad (13-13)$$

Suppose we need to find the view factor  $F_{1 \rightarrow 3}$ . A quick check of the view factor expressions and charts in this section reveals that such a view factor cannot be evaluated directly. However, the view factor  $F_{1 \rightarrow 3}$  can be determined from Eq. 13–13 after determining both  $F_{1 \rightarrow 2}$  and  $F_{1 \rightarrow (2,3)}$  from the chart in Table 13–2. Therefore, it may be possible to determine some difficult view factors with relative ease by expressing one or both of the areas as the sum or differences of areas and then applying the superposition rule.

To obtain a relation for the view factor  $F_{(2,3) \rightarrow 1}$ , we multiply Eq. 13–13 by  $A_1$ ,

$$A_1 F_{1 \rightarrow (2,3)} = A_1 F_{1 \rightarrow 2} + A_1 F_{1 \rightarrow 3}$$

and apply the reciprocity relation to each term to get

$$(A_2 + A_3) F_{(2,3) \rightarrow 1} = A_2 F_{2 \rightarrow 1} + A_3 F_{3 \rightarrow 1}$$

or

$$F_{(2,3) \rightarrow 1} = \frac{A_2 F_{2 \rightarrow 1} + A_3 F_{3 \rightarrow 1}}{A_2 + A_3} \quad (13-14)$$

Areas that are expressed as the sum of more than two parts can be handled in a similar manner.

#### EXAMPLE 13–2 Fraction of Radiation Leaving through an Opening

Determine the fraction of the radiation leaving the base of the cylindrical enclosure shown in Fig. 13–12 that escapes through a coaxial ring opening at its top surface. The radius and the length of the enclosure are  $r_1 = 10$  cm and  $L = 10$  cm, while the inner and outer radii of the ring are  $r_2 = 5$  cm and  $r_3 = 8$  cm, respectively.

**FIGURE 13-11**

The view factor from a surface to a composite surface is equal to the sum of the view factors from the surface to the parts of the composite surface.

**FIGURE 13-12**

The cylindrical enclosure considered in Example 13–2.

**SOLUTION** The fraction of radiation leaving the base of a cylindrical enclosure through a coaxial ring opening at its top surface is to be determined.

**Assumptions** The base surface is a diffuse emitter and reflector.

**Analysis** We are asked to determine the fraction of the radiation leaving the base of the enclosure that escapes through an opening at the top surface. Actually, what we are asked to determine is simply the view factor  $F_{1 \rightarrow \text{ring}}$  from the base of the enclosure to the ring-shaped surface at the top.

We do not have an analytical expression or chart for view factors between a circular area and a coaxial ring, and so we cannot determine  $F_{1 \rightarrow \text{ring}}$  directly. However, we do have a chart for view factors between two coaxial parallel disks, and we can always express a ring in terms of disks.

Let the base surface of radius  $r_1 = 10 \text{ cm}$  be surface 1, the circular area of  $r_2 = 5 \text{ cm}$  at the top be surface 2, and the circular area of  $r_3 = 8 \text{ cm}$  be surface 3. Using the superposition rule, the view factor from surface 1 to surface 3 can be expressed as

$$F_{1 \rightarrow 3} = F_{1 \rightarrow 2} + F_{1 \rightarrow \text{ring}}$$

since surface 3 is the sum of surface 2 and the ring area. The view factors  $F_{1 \rightarrow 2}$  and  $F_{1 \rightarrow 3}$  are determined from the chart in Fig. 13–7.

$$\frac{L}{r_1} = \frac{10 \text{ cm}}{10 \text{ cm}} = 1 \quad \text{and} \quad \frac{r_2}{L} = \frac{5 \text{ cm}}{10 \text{ cm}} = 0.5 \xrightarrow{\text{(Fig. 13-7)}} = 0.11$$

$$\frac{L}{r_1} = \frac{10 \text{ cm}}{10 \text{ cm}} = 1 \quad \text{and} \quad \frac{r_3}{L} = \frac{8 \text{ cm}}{10 \text{ cm}} = 0.8 \xrightarrow{\text{(Fig. 13-7)}} = 0.28$$

Therefore,

$$F_{1 \rightarrow \text{ring}} = F_{1 \rightarrow 3} - F_{1 \rightarrow 2} = 0.28 - 0.11 = 0.17$$

which is the desired result. Note that  $F_{1 \rightarrow 2}$  and  $F_{1 \rightarrow 3}$  represent the fractions of radiation leaving the base that strike the circular surfaces 2 and 3, respectively, and their difference gives the fraction that strikes the ring area.

## 4 The Symmetry Rule

The determination of the view factors in a problem can be simplified further if the geometry involved possesses some sort of symmetry. Therefore, it is good practice to check for the presence of any *symmetry* in a problem before attempting to determine the view factors directly. The presence of symmetry can be determined by *inspection*, keeping the definition of the view factor in mind. Identical surfaces that are oriented in an identical manner with respect to another surface will intercept identical amounts of radiation leaving that surface. Therefore, the **symmetry rule** can be expressed as *two (or more) surfaces that possess symmetry about a third surface will have identical view factors from that surface* (Fig. 13–13).

The symmetry rule can also be expressed as *if the surfaces j and k are symmetric about the surface i then  $F_{i \rightarrow j} = F_{i \rightarrow k}$* . Using the reciprocity rule, we can show that the relation  $F_{j \rightarrow i} = F_{k \rightarrow i}$  is also true in this case.

FIGURE 13–13

Two surfaces that are symmetric about a third surface will have the same view factor from the third surface.

**EXAMPLE 13–3** View Factors Associated with a Tetragon

Determine the view factors from the base of the pyramid shown in Fig. 13–14 to each of its four side surfaces. The base of the pyramid is a square, and its side surfaces are isosceles triangles.

**SOLUTION** The view factors from the base of a pyramid to each of its four side surfaces for the case of a square base are to be determined.

**Assumptions** The surfaces are diffuse emitters and reflectors.

**Analysis** The base of the pyramid (surface 1) and its four side surfaces (surfaces 2, 3, 4, and 5) form a five-surface enclosure. The first thing we notice about this enclosure is its symmetry. The four side surfaces are symmetric about the base surface. Then, from the *symmetry rule*, we have

$$F_{12} = F_{13} = F_{14} = F_{15}$$

Also, the *summation rule* applied to surface 1 yields

$$\sum_{j=1}^5 F_{1j} = F_{11} + F_{12} + F_{13} + F_{14} + F_{15} = 1$$

However,  $F_{11} = 0$ , since the base is a *flat* surface. Then the two relations above yield

$$F_{12} = F_{13} = F_{14} = F_{15} = 0.25$$

**Discussion** Note that each of the four side surfaces of the pyramid receive one-fourth of the entire radiation leaving the base surface, as expected. Also note that the presence of symmetry greatly simplified the determination of the view factors.

**FIGURE 13–14**

The pyramid considered in Example 13–3.

**EXAMPLE 13–4** View Factors Associated with a Triangular Duct

Determine the view factor from any one side to any other side of the infinitely long triangular duct whose cross section is given in Fig. 13–15.

**SOLUTION** The view factors associated with an infinitely long triangular duct are to be determined.

**Assumptions** The surfaces are diffuse emitters and reflectors.

**Analysis** The widths of the sides of the triangular cross section of the duct are  $L_1$ ,  $L_2$ , and  $L_3$ , and the surface areas corresponding to them are  $A_1$ ,  $A_2$ , and  $A_3$ , respectively. Since the duct is infinitely long, the fraction of radiation leaving any surface that escapes through the ends of the duct is negligible. Therefore, the infinitely long duct can be considered to be a three-surface enclosure,  $N = 3$ .

This enclosure involves  $N^2 = 3^2 = 9$  view factors, and we need to determine

$$\frac{1}{2}N(N - 1) = \frac{1}{2} \times 3(3 - 1) = 3$$

of these view factors directly. Fortunately, we can determine all three of them by inspection to be

$$F_{11} = F_{22} = F_{33} = 0$$

since all three surfaces are flat. The remaining six view factors can be determined by the application of the summation and reciprocity rules.

**FIGURE 13–15**

The infinitely long triangular duct considered in Example 13–4.

Applying the summation rule to each of the three surfaces gives

$$F_{11} + F_{12} + F_{13} = 1$$

$$F_{21} + F_{22} + F_{23} = 1$$

$$F_{31} + F_{32} + F_{33} = 1$$

Noting that  $F_{11} = F_{22} = F_{33} = 0$  and multiplying the first equation by  $A_1$ , the second by  $A_2$ , and the third by  $A_3$  gives

$$A_1 F_{12} + A_1 F_{13} = A_1$$

$$A_2 F_{21} + A_2 F_{23} = A_2$$

$$A_3 F_{31} + A_3 F_{32} = A_3$$

Finally, applying the three reciprocity relations  $A_1 F_{12} = A_2 F_{21}$ ,  $A_1 F_{13} = A_3 F_{31}$ , and  $A_2 F_{23} = A_3 F_{32}$  gives

$$A_1 F_{12} + A_1 F_{13} = A_1$$

$$A_1 F_{12} + A_2 F_{23} = A_2$$

$$A_1 F_{13} + A_2 F_{23} = A_3$$

This is a set of three algebraic equations with three unknowns, which can be solved to obtain

$$\begin{aligned} F_{12} &= \frac{A_1 + A_2 - A_3}{2A_1} = \frac{\underline{L_1 + L_2 - L_3}}{2\underline{L_1}} \\ F_{13} &= \frac{A_1 + A_3 - A_2}{2A_1} = \frac{\underline{L_1 + L_3 - L_2}}{2\underline{L_1}} \\ F_{23} &= \frac{A_2 + A_3 - A_1}{2A_2} = \frac{\underline{L_2 + L_3 - L_1}}{2\underline{L_2}} \end{aligned} \quad (13-15)$$

**Discussion** Note that we have replaced the areas of the side surfaces by their corresponding widths for simplicity, since  $A = Ls$  and the length  $s$  can be factored out and canceled. We can generalize this result as *the view factor from a surface of a very long triangular duct to another surface is equal to the sum of the widths of these two surfaces minus the width of the third surface, divided by twice the width of the first surface.*

FIGURE 13–16

Determination of the view factor  $F_{1 \rightarrow 2}$  by the application of the crossed-strings method.

## View Factors between Infinitely Long Surfaces: The Crossed-Strings Method

Many problems encountered in practice involve geometries of constant cross section such as channels and ducts that are *very long* in one direction relative to the other directions. Such geometries can conveniently be considered to be *two-dimensional*, since any radiation interaction through their end surfaces is negligible. These geometries can subsequently be modeled as being *infinitely long*, and the view factor between their surfaces can be determined by the amazingly simple *crossed-strings method* developed by H. C. Hottel in the 1950s. The surfaces of the geometry do not need to be flat; they can be convex, concave, or any irregular shape.

To demonstrate this method, consider the geometry shown in Fig. 13–16, and let us try to find the view factor  $F_{1 \rightarrow 2}$  between surfaces 1 and 2. The first thing we do is identify the endpoints of the surfaces (the points A, B, C, and D) and

connect them to each other with tightly stretched strings, which are indicated by dashed lines. Hottel has shown that the view factor  $F_{1 \rightarrow 2}$  can be expressed in terms of the lengths of these stretched strings, which are straight lines, as

$$F_{1 \rightarrow 2} = \frac{(L_5 + L_6) - (L_3 + L_4)}{2L_1} \quad (13-16)$$

Note that  $L_5 + L_6$  is the sum of the lengths of the *crossed strings*, and  $L_3 + L_4$  is the sum of the lengths of the *uncrossed strings* attached to the endpoints. Therefore, Hottel's crossed-strings method can be expressed verbally as

$$F_{i \rightarrow j} = \frac{\sum(\text{Crossed strings}) - \sum(\text{Uncrossed strings})}{2 \times (\text{String on surface } i)} \quad (13-17)$$

The crossed-strings method is applicable even when the two surfaces considered share a common edge, as in a triangle. In such cases, the common edge can be treated as an imaginary string of zero length. The method can also be applied to surfaces that are partially blocked by other surfaces by allowing the strings to bend around the blocking surfaces.

### EXAMPLE 13-5 The Crossed-Strings Method for View Factors

Two infinitely long parallel plates of widths  $a = 12$  cm and  $b = 5$  cm are located a distance  $c = 6$  cm apart, as shown in Fig. 13-17. (a) Determine the view factor  $F_{1 \rightarrow 2}$  from surface 1 to surface 2 by using the crossed-strings method. (b) Derive the crossed-strings formula by forming triangles on the given geometry and using Eq. 13-15 for view factors between the sides of triangles.

**SOLUTION** The view factors between two infinitely long parallel plates are to be determined using the crossed-strings method, and the formula for the view factor is to be derived.

**Assumptions** The surfaces are diffuse emitters and reflectors.

**Analysis** (a) First we label the endpoints of both surfaces and draw straight dashed lines between the endpoints, as shown in Fig. 13-17. Then we identify the crossed and uncrossed strings and apply the crossed-strings method (Eq. 13-17) to determine the view factor  $F_{1 \rightarrow 2}$ :

$$F_{1 \rightarrow 2} = \frac{\sum(\text{Crossed strings}) - \sum(\text{Uncrossed strings})}{2 \times (\text{String on surface 1})} = \frac{(L_5 + L_6) - (L_3 + L_4)}{2L_1}$$

where

$$\begin{aligned} L_1 &= a = 12 \text{ cm} & L_4 &= \sqrt{7^2 + 6^2} = 9.22 \text{ cm} \\ L_2 &= b = 5 \text{ cm} & L_5 &= \sqrt{5^2 + 6^2} = 7.81 \text{ cm} \\ L_3 &= c = 6 \text{ cm} & L_6 &= \sqrt{12^2 + 6^2} = 13.42 \text{ cm} \end{aligned}$$

Substituting,

$$F_{1 \rightarrow 2} = \frac{[(7.81 + 13.42) - (6 + 9.22)] \text{ cm}}{2 \times 12 \text{ cm}} = 0.250$$

(b) The geometry is infinitely long in the direction perpendicular to the plane of the paper, and thus the two plates (surfaces 1 and 2) and the two openings

FIGURE 13-17

The two infinitely long parallel plates considered in Example 13-5.

(imaginary surfaces 3 and 4) form a four-surface enclosure. Then applying the summation rule to surface 1 yields

$$F_{11} + F_{12} + F_{13} + F_{14} = 1$$

But  $F_{11} = 0$  since it is a flat surface. Therefore,

$$F_{12} = 1 - F_{13} - F_{14}$$

where the view factors  $F_{13}$  and  $F_{14}$  can be determined by considering the triangles  $ABC$  and  $ABD$ , respectively, and applying Eq. 13–15 for view factors between the sides of triangles. We obtain

$$F_{13} = \frac{L_1 + L_3 - L_6}{2L_1}, \quad F_{14} = \frac{L_1 + L_4 - L_5}{2L_1}$$

Substituting,

$$\begin{aligned} F_{12} &= 1 - \frac{L_1 + L_3 - L_6}{2L_1} - \frac{L_1 + L_4 - L_5}{2L_1} \\ &= \frac{(L_5 + L_6) - (L_3 + L_4)}{2L_1} \end{aligned}$$

which is the desired result. This is also a miniproof of the crossed-strings method for the case of two infinitely long plain parallel surfaces.

### 13–3 • RADIATION HEAT TRANSFER: BLACK SURFACES

So far, we have considered the nature of radiation, the radiation properties of materials, and the view factors, and we are now in a position to consider the rate of heat transfer between surfaces by radiation. The analysis of radiation exchange between surfaces, in general, is complicated because of reflection: a radiation beam leaving a surface may be reflected several times, with partial reflection occurring at each surface, before it is completely absorbed. The analysis is simplified greatly when the surfaces involved can be approximated as blackbodies because of the absence of reflection. In this section, we consider radiation exchange between *black surfaces* only; we extend the analysis to reflecting surfaces in the next section.

Consider two black surfaces of arbitrary shape maintained at uniform temperatures  $T_1$  and  $T_2$ , as shown in Fig. 13–18. Recognizing that radiation leaves a black surface at a rate of  $E_b = \sigma T^4$  per unit surface area and that the view factor  $F_{1 \rightarrow 2}$  represents the fraction of radiation leaving surface 1 that strikes surface 2, the *net* rate of radiation heat transfer from surface 1 to surface 2 can be expressed as

$$\begin{aligned} \dot{Q}_{1 \rightarrow 2} &= \left( \begin{array}{l} \text{Radiation leaving} \\ \text{the entire surface 1} \\ \text{that strikes surface 2} \end{array} \right) - \left( \begin{array}{l} \text{Radiation leaving} \\ \text{the entire surface 2} \\ \text{that strikes surface 1} \end{array} \right) \\ &= A_1 E_{b1} F_{1 \rightarrow 2} - A_2 E_{b2} F_{2 \rightarrow 1} \quad (\text{W}) \end{aligned} \quad (13-18)$$

Applying the reciprocity relation  $A_1 F_{1 \rightarrow 2} = A_2 F_{2 \rightarrow 1}$  yields

$$\dot{Q}_{1 \rightarrow 2} = A_1 F_{1 \rightarrow 2} \sigma (T_1^4 - T_2^4) \quad (\text{W}) \quad (13-19)$$

**FIGURE 13–18**

Two general black surfaces maintained at uniform temperatures  $T_1$  and  $T_2$ .

which is the desired relation. A negative value for  $\dot{Q}_{1 \rightarrow 2}$  indicates that net radiation heat transfer is from surface 2 to surface 1.

Now consider an *enclosure* consisting of  $N$  black surfaces maintained at specified temperatures. The *net* radiation heat transfer from any surface  $i$  of this enclosure is determined by adding up the net radiation heat transfers from surface  $i$  to each of the surfaces of the enclosure:

$$\dot{Q}_i = \sum_{j=1}^N \dot{Q}_{i \rightarrow j} = \sum_{j=1}^N A_i F_{i \rightarrow j} \sigma (T_i^4 - T_j^4) \quad (\text{W}) \quad (13-20)$$

Again a negative value for  $\dot{Q}$  indicates that net radiation heat transfer is *to* surface  $i$  (i.e., surface  $i$  *gains* radiation energy instead of losing). Also, the net heat transfer from a surface to itself is zero, regardless of the shape of the surface.

### EXAMPLE 13-6 Radiation Heat Transfer in a Black Furnace

Consider the 5-m  $\times$  5-m  $\times$  5-m cubical furnace shown in Fig. 13-19, whose surfaces closely approximate black surfaces. The base, top, and side surfaces of the furnace are maintained at uniform temperatures of 800 K, 1500 K, and 500 K, respectively. Determine (a) the net rate of radiation heat transfer between the base and the side surfaces, (b) the net rate of radiation heat transfer between the base and the top surface, and (c) the net radiation heat transfer from the base surface.

**SOLUTION** The surfaces of a cubical furnace are black and are maintained at uniform temperatures. The net rate of radiation heat transfer between the base and side surfaces, between the base and the top surface, and from the base surface are to be determined.

**Assumptions** The surfaces are black and isothermal.

**Analysis** (a) The geometry involves six surfaces, and thus we may be tempted at first to treat the furnace as a six-surface enclosure. However, the four side surfaces possess the same properties, and thus we can treat them as a single side surface in radiation analysis. We consider the base surface to be surface 1, the top surface to be surface 2, and the side surfaces to be surface 3. Then the problem reduces to determining  $\dot{Q}_{1 \rightarrow 3}$ ,  $\dot{Q}_{1 \rightarrow 2}$ , and  $\dot{Q}_1$ .

The net rate of radiation heat transfer  $\dot{Q}_{1 \rightarrow 3}$  from surface 1 to surface 3 can be determined from Eq. 13-19, since both surfaces involved are black, by replacing the subscript 2 by 3:

$$\dot{Q}_{1 \rightarrow 3} = A_1 F_{1 \rightarrow 3} \sigma (T_1^4 - T_3^4)$$

But first we need to evaluate the view factor  $F_{1 \rightarrow 3}$ . After checking the view factor charts and tables, we realize that we cannot determine this view factor directly. However, we can determine the view factor  $F_{1 \rightarrow 2}$  from Fig. 13-5 to be  $F_{1 \rightarrow 2} = 0.2$ , and we know that  $F_{1 \rightarrow 1} = 0$  since surface 1 is a plane. Then applying the summation rule to surface 1 yields

$$F_{1 \rightarrow 1} + F_{1 \rightarrow 2} + F_{1 \rightarrow 3} = 1$$

or

$$F_{1 \rightarrow 3} = 1 - F_{1 \rightarrow 1} - F_{1 \rightarrow 2} = 1 - 0 - 0.2 = 0.8$$

Substituting,

$$\begin{aligned} \dot{Q}_{1 \rightarrow 3} &= (25 \text{ m}^2)(0.8)(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(800 \text{ K})^4 - (500 \text{ K})^4] \\ &= 394 \text{ kW} \end{aligned}$$

FIGURE 13-19

The cubical furnace of black surfaces considered in Example 13-6.

(b) The net rate of radiation heat transfer  $\dot{Q}_{1 \rightarrow 2}$  from surface 1 to surface 2 is determined in a similar manner from Eq. 13–19 to be

$$\begin{aligned}\dot{Q}_{1 \rightarrow 2} &= A_1 F_{1 \rightarrow 2} \sigma (T_1^4 - T_2^4) \\ &= (25 \text{ m}^2)(0.2)(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(800 \text{ K})^4 - (1500 \text{ K})^4] \\ &= -1319 \text{ kW}\end{aligned}$$

The negative sign indicates that net radiation heat transfer is from surface 2 to surface 1.

(c) The net radiation heat transfer from the base surface  $\dot{Q}_1$  is determined from Eq. 13–20 by replacing the subscript  $i$  by 1 and taking  $N = 3$ :

$$\begin{aligned}\dot{Q}_1 &= \sum_{j=1}^3 \dot{Q}_{1 \rightarrow j} = \dot{Q}_{1 \rightarrow 1} + \dot{Q}_{1 \rightarrow 2} + \dot{Q}_{1 \rightarrow 3} \\ &= 0 + (-1319 \text{ kW}) + (394 \text{ kW}) \\ &= -925 \text{ kW}\end{aligned}$$

Again the negative sign indicates that net radiation heat transfer is to surface 1. That is, the base of the furnace is gaining net radiation at a rate of 925 kW.

## 13–4 ■ RADIATION HEAT TRANSFER: DIFFUSE, GRAY SURFACES

The analysis of radiation transfer in enclosures consisting of black surfaces is relatively easy, as we have seen, but most enclosures encountered in practice involve nonblack surfaces, which allow multiple reflections to occur. Radiation analysis of such enclosures becomes very complicated unless some simplifying assumptions are made.

To make a simple radiation analysis possible, it is common to assume the surfaces of an enclosure to be *opaque, diffuse, and gray*. That is, the surfaces are nontransparent, they are diffuse emitters and diffuse reflectors, and their radiation properties are independent of wavelength. Also, each surface of the enclosure is *isothermal*, and both the incoming and outgoing radiation are *uniform* over each surface. But first we review the concept of radiosity introduced in Chap. 12.

### Radiosity

Surfaces emit radiation as well as reflect it, and thus the radiation leaving a surface consists of emitted and reflected parts. The calculation of radiation heat transfer between surfaces involves the *total radiation energy streaming away from a surface per unit time and per unit area* is the **radiosity** and is denoted by  $J$  (Fig. 13–20).

For a surface  $i$  that is *gray and opaque* ( $\varepsilon_i = \alpha_i$  and  $\alpha_i + \rho_i = 1$ ), the radiosity can be expressed as

$$\begin{aligned}J_i &= \left( \begin{array}{l} \text{Radiation emitted} \\ \text{by surface } i \end{array} \right) + \left( \begin{array}{l} \text{Radiation reflected} \\ \text{by surface } i \end{array} \right) \\ &= \varepsilon_i E_{bi} + \rho_i G_i \\ &= \varepsilon_i E_{bi} + (1 - \varepsilon_i) G_i \quad (\text{W/m}^2)\end{aligned} \tag{13–21}$$

**FIGURE 13–20**

Radiosity represents the sum of the radiation energy emitted and reflected by a surface.

where  $E_{bi} = \sigma T_i^4$  is the blackbody emissive power of surface  $i$  and  $G_i$  is irradiation (i.e., the radiation energy incident on surface  $i$  per unit time per unit area).

For a surface that can be approximated as a *blackbody* ( $\varepsilon_i = 1$ ), the radiosity relation reduces to

$$J_i = E_{bi} = \sigma T_i^4 \quad (\text{blackbody}) \quad (13-22)$$

That is, *the radiosity of a blackbody is equal to its emissive power*. This is expected, since a blackbody does not reflect any radiation, and thus radiation coming from a blackbody is due to emission only.

## Net Radiation Heat Transfer to or from a Surface

During a radiation interaction, a surface *loses* energy by emitting radiation and *gains* energy by absorbing radiation emitted by other surfaces. A surface experiences a net gain or a net loss of energy, depending on which quantity is larger. The *net* rate of radiation heat transfer from a surface  $i$  of surface area  $A_i$  is denoted by  $\dot{Q}_i$  and is expressed as

$$\begin{aligned} \dot{Q}_i &= \left( \begin{array}{l} \text{Radiation leaving} \\ \text{entire surface } i \end{array} \right) - \left( \begin{array}{l} \text{Radiation incident} \\ \text{on entire surface } i \end{array} \right) \\ &= A_i(J_i - G_i) \quad (\text{W}) \end{aligned} \quad (13-23)$$

Solving for  $G_i$  from Eq. 13-21 and substituting into Eq. 13-23 yields

$$\dot{Q}_i = A_i \left( J_i - \frac{J_i - \varepsilon_i E_{bi}}{1 - \varepsilon_i} \right) = \frac{A_i \varepsilon_i}{1 - \varepsilon_i} (E_{bi} - J_i) \quad (\text{W}) \quad (13-24)$$

In an electrical analogy to Ohm's law, this equation can be rearranged as

$$\dot{Q}_i = \frac{E_{bi} - J_i}{R_i} \quad (\text{W}) \quad (13-25)$$

where

$$R_i = \frac{1 - \varepsilon_i}{A_i \varepsilon_i} \quad (13-26)$$

is the **surface resistance** to radiation. The quantity  $E_{bi} - J_i$  corresponds to a *potential difference* and the net rate of radiation heat transfer corresponds to *current* in the electrical analogy, as illustrated in Fig. 13-21.

The direction of the net radiation heat transfer depends on the relative magnitudes of  $J_i$  (the radiosity) and  $E_{bi}$  (the emissive power of a blackbody at the temperature of the surface). It is *from* the surface if  $E_{bi} > J_i$  and *to* the surface if  $J_i > E_{bi}$ . A negative value for  $\dot{Q}_i$  indicates that heat transfer is *to* the surface. All of this radiation energy gained must be removed from the other side of the surface through some mechanism if the surface temperature is to remain constant.

The surface resistance to radiation for a *blackbody* is *zero* since  $\varepsilon_i = 1$  and  $J_i = E_{bi}$ . The net rate of radiation heat transfer in this case is determined directly from Eq. 13-23.

Some surfaces encountered in numerous practical heat transfer applications are modeled as being *adiabatic* since their back sides are well insulated and the net heat transfer through them is zero. When the convection effects on the front (heat transfer) side of such a surface is negligible and steady-state

**FIGURE 13-21**  
Electrical analogy of surface resistance to radiation.

conditions are reached, the surface must lose as much radiation energy as it gains, and thus  $\dot{Q}_i = 0$ . In such cases, the surface is said to *reradiate* all the radiation energy it receives, and such a surface is called a **reradiating surface**. Setting  $\dot{Q}_i = 0$  in Eq. 13–25 yields

$$J_i = E_{bi} = \sigma T_i^4 \quad (\text{W/m}^2) \quad (13-27)$$

Therefore, the *temperature* of a reradiating surface under steady conditions can easily be determined from the equation above once its radiosity is known. Note that the temperature of a reradiating surface is *independent of its emissivity*. In radiation analysis, the surface resistance of a reradiating surface is disregarded since there is no net heat transfer through it. (This is like the fact that there is no need to consider a resistance in an electrical network if no current is flowing through it.)

## Net Radiation Heat Transfer between Any Two Surfaces

Consider two diffuse, gray, and opaque surfaces of arbitrary shape maintained at uniform temperatures, as shown in Fig. 13–22. Recognizing that the radiosity  $J$  represents the rate of radiation leaving a surface per unit surface area and that the view factor  $F_{i \rightarrow j}$  represents the fraction of radiation leaving surface  $i$  that strikes surface  $j$ , the *net rate of radiation heat transfer* from surface  $i$  to surface  $j$  can be expressed as

$$\begin{aligned} \dot{Q}_{i \rightarrow j} &= \left( \begin{array}{l} \text{Radiation leaving} \\ \text{the entire surface } i \\ \text{that strikes surface } j \end{array} \right) - \left( \begin{array}{l} \text{Radiation leaving} \\ \text{the entire surface } j \\ \text{that strikes surface } i \end{array} \right) \\ &= A_i J_i F_{i \rightarrow j} - A_j J_j F_{j \rightarrow i} \quad (\text{W}) \end{aligned} \quad (13-28)$$

Applying the reciprocity relation  $A_i F_{i \rightarrow j} = A_j F_{j \rightarrow i}$  yields

$$\dot{Q}_{i \rightarrow j} = A_i F_{i \rightarrow j} (J_i - J_j) \quad (\text{W}) \quad (13-29)$$

Again in analogy to Ohm's law, this equation can be rearranged as

$$\dot{Q}_{i \rightarrow j} = \frac{J_i - J_j}{R_{i \rightarrow j}} \quad (\text{W}) \quad (13-30)$$

where

$$R_{i \rightarrow j} = \frac{1}{A_i F_{i \rightarrow j}} \quad (13-31)$$

is the **space resistance** to radiation. Again the quantity  $J_i - J_j$  corresponds to a *potential difference*, and the net rate of heat transfer between two surfaces corresponds to *current* in the electrical analogy, as illustrated in Fig. 13–22.

The direction of the net radiation heat transfer between two surfaces depends on the relative magnitudes of  $J_i$  and  $J_j$ . A positive value for  $\dot{Q}_{i \rightarrow j}$  indicates that net heat transfer is *from* surface  $i$  to surface  $j$ . A negative value indicates the opposite.

In an  $N$ -surface enclosure, the conservation of energy principle requires that the net heat transfer from surface  $i$  be equal to the sum of the net heat transfers from surface  $i$  to each of the  $N$  surfaces of the enclosure. That is,

**FIGURE 13–22**

Electrical analogy of space resistance to radiation.

$$\dot{Q}_i = \sum_{j=1}^N \dot{Q}_{i \rightarrow j} = \sum_{j=1}^N A_i F_{i \rightarrow j} (J_i - J_j) = \sum_{j=1}^N \frac{J_i - J_j}{R_{i \rightarrow j}} \quad (\text{W}) \quad (13-32)$$

The network representation of net radiation heat transfer from surface  $i$  to the remaining surfaces of an  $N$ -surface enclosure is given in Fig. 13–23. Note that  $\dot{Q}_{i \rightarrow i}$  (the net rate of heat transfer from a surface to itself) is zero regardless of the shape of the surface. Combining Eqs. 13–25 and 13–32 gives

$$\frac{E_{bi} - J_i}{R_i} = \sum_{j=1}^N \frac{J_i - J_j}{R_{i \rightarrow j}} \quad (\text{W}) \quad (13-33)$$

which has the electrical analogy interpretation that *the net radiation flow from a surface through its surface resistance is equal to the sum of the radiation flows from that surface to all other surfaces through the corresponding space resistances.*

## Methods of Solving Radiation Problems

In the radiation analysis of an enclosure, either the temperature or the net rate of heat transfer must be given for each of the surfaces to obtain a unique solution for the unknown surface temperatures and heat transfer rates. There are two methods commonly used to solve radiation problems. In the first method, Eqs. 13–32 (for surfaces with specified heat transfer rates) and 13–33 (for surfaces with specified temperatures) are simplified and rearranged as

*Surfaces with specified net heat transfer rate  $\dot{Q}$*        $\dot{Q}_i = A_i \sum_{j=1}^N F_{i \rightarrow j} (J_i - J_j) \quad (13-34)$

*Surfaces with specified temperature  $T_i$*        $\sigma T_i^4 = J_i + \frac{1 - \varepsilon_i}{\varepsilon_i} \sum_{j=1}^N F_{i \rightarrow j} (J_i - J_j) \quad (13-35)$

Note that  $\dot{Q}_i = 0$  for insulated (or reradiating) surfaces, and  $\sigma T_i^4 = J_i$  for black surfaces since  $\varepsilon_i = 1$  in that case. Also, the term corresponding to  $j = i$  drops out from either relation since  $J_i - J_j = J_i - J_i = 0$  in that case.

The equations above give  $N$  linear algebraic equations for the determination of the  $N$  unknown radiosities for an  $N$ -surface enclosure. Once the radiosities  $J_1, J_2, \dots, J_N$  are available, the unknown heat transfer rates can be determined from Eq. 13–34 while the unknown surface temperatures can be determined from Eq. 13–35. The temperatures of insulated or reradiating surfaces can be determined from  $\sigma T_i^4 = J_i$ . A positive value for  $\dot{Q}_i$  indicates net radiation heat transfer *from* surface  $i$  to other surfaces in the enclosure while a negative value indicates net radiation heat transfer *to* the surface.

The systematic approach described above for solving radiation heat transfer problems is very suitable for use with today's popular equation solvers such as EES, Mathcad, and Matlab, especially when there are a large number of surfaces, and is known as the **direct method** (formerly, the *matrix method*, since it resulted in matrices and the solution required a knowledge of linear algebra). The second method described below, called the **network method**, is based on the electrical network analogy.

The network method was first introduced by A. K. Oppenheim in the 1950s and found widespread acceptance because of its simplicity and emphasis on

FIGURE 13-23

Network representation of net radiation heat transfer from surface  $i$  to the remaining surfaces of an  $N$ -surface enclosure.

the physics of the problem. The application of the method is straightforward: draw a surface resistance associated with each surface of an enclosure and connect them with space resistances. Then solve the radiation problem by treating it as an electrical network problem where the radiation heat transfer replaces the current and radiosity replaces the potential.

The network method is not practical for enclosures with more than three or four surfaces, however, because of the increased complexity of the network. Next we apply the method to solve radiation problems in two- and three-surface enclosures.

## Radiation Heat Transfer in Two-Surface Enclosures

Consider an enclosure consisting of two opaque surfaces at specified temperatures  $T_1$  and  $T_2$ , as shown in Fig. 13–24, and try to determine the net rate of radiation heat transfer between the two surfaces with the network method. Surfaces 1 and 2 have emissivities  $\varepsilon_1$  and  $\varepsilon_2$  and surface areas  $A_1$  and  $A_2$  and are maintained at uniform temperatures  $T_1$  and  $T_2$ , respectively. There are only two surfaces in the enclosure, and thus we can write

$$\dot{Q}_{12} = \dot{Q}_1 = -\dot{Q}_2$$

That is, the net rate of radiation heat transfer from surface 1 to surface 2 must equal the net rate of radiation heat transfer *from* surface 1 and the net rate of radiation heat transfer *to* surface 2.

The radiation network of this two-surface enclosure consists of two surface resistances and one space resistance, as shown in Fig. 13–24. In an electrical network, the electric current flowing through these resistances connected in series would be determined by dividing the potential difference between points A and B by the total resistance between the same two points. The net rate of radiation transfer is determined in the same manner and is expressed as

**FIGURE 13–24**

Schematic of a two-surface enclosure and the radiation network associated with it.

$$\dot{Q}_{12} = \frac{E_{b1} - E_{b2}}{R_1 + R_{12} + R_2} = \dot{Q}_1 = -\dot{Q}_2$$

or

$$\dot{Q}_{12} = \frac{\sigma(T_1^4 - T_2^4)}{\frac{1 - \varepsilon_1}{A_1 \varepsilon_1} + \frac{1}{A_1 F_{12}} + \frac{1 - \varepsilon_2}{A_2 \varepsilon_2}} \quad (\text{W}) \quad (13-36)$$

This important result is applicable to any two gray, diffuse, and opaque surfaces that form an enclosure. The view factor  $F_{12}$  depends on the geometry and must be determined first. Simplified forms of Eq. 13–36 for some familiar arrangements that form a two-surface enclosure are given in Table 13–3. Note that  $F_{12} = 1$  for all of these special cases.

**FIGURE 13–25**

The two parallel plates considered in Example 13–7.

### EXAMPLE 13–7 Radiation Heat Transfer between Parallel Plates

Two very large parallel plates are maintained at uniform temperatures  $T_1 = 800 \text{ K}$  and  $T_2 = 500 \text{ K}$  and have emissivities  $\varepsilon_1 = 0.2$  and  $\varepsilon_2 = 0.7$ , respectively, as shown in Fig. 13–25. Determine the net rate of radiation heat transfer between the two surfaces per unit surface area of the plates.

**SOLUTION** Two large parallel plates are maintained at uniform temperatures. The net rate of radiation heat transfer between the plates is to be determined.

**Assumptions** Both surfaces are opaque, diffuse, and gray.

**Analysis** The net rate of radiation heat transfer between the two plates per unit area is readily determined from Eq. 13-38 to be

$$\begin{aligned}\dot{q}_{12} &= \frac{\dot{Q}_{12}}{A} = \frac{\sigma(T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1} = \frac{(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(800 \text{ K})^4 - (500 \text{ K})^4]}{\frac{1}{0.2} + \frac{1}{0.7} - 1} \\ &= 3625 \text{ W/m}^2\end{aligned}$$

**Discussion** Note that heat at a net rate of 3625 W is transferred from plate 1 to plate 2 by radiation per unit surface area of either plate.

**TABLE 13-3**

Radiation heat transfer relations for some familiar two-surface arrangements

Small object in a large cavity

$$\begin{aligned}\frac{A_1}{A_2} &\approx 0 \\ F_{12} &= 1\end{aligned}\quad \dot{Q}_{12} = A_1 \sigma \varepsilon_1 (T_1^4 - T_2^4) \quad (13-37)$$

Infinitely large parallel plates

$$\begin{array}{c} \hline A_1, T_1, \varepsilon_1 \\ \hline A_1 = A_2 = A & \dot{Q}_{12} = \frac{A \sigma (T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1} \\ F_{12} = 1 & \hline A_2, T_2, \varepsilon_2 \end{array} \quad (13-38)$$

Infinitely long concentric cylinders

$$\begin{aligned}\frac{A_1}{A_2} &= \frac{r_1}{r_2} \\ F_{12} &= 1\end{aligned}\quad \dot{Q}_{12} = \frac{A_1 \sigma (T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1 - \varepsilon_2}{\varepsilon_2} \left(\frac{r_1}{r_2}\right)^2} \quad (13-39)$$

Concentric spheres

$$\begin{aligned}\frac{A_1}{A_2} &= \left(\frac{r_1}{r_2}\right)^2 \\ F_{12} &= 1\end{aligned}\quad \dot{Q}_{12} = \frac{A_1 \sigma (T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1 - \varepsilon_2}{\varepsilon_2} \left(\frac{r_1}{r_2}\right)^2} \quad (13-40)$$

FIGURE 13-26

Schematic of a three-surface enclosure and the radiation network associated with it.

FIGURE 13-27

The cylindrical furnace considered in Example 13-8.

## Radiation Heat Transfer in Three-Surface Enclosures

We now consider an enclosure consisting of three opaque, diffuse, and gray surfaces, as shown in Fig. 13-26. Surfaces 1, 2, and 3 have surface areas  $A_1$ ,  $A_2$ , and  $A_3$ ; emissivities  $\varepsilon_1$ ,  $\varepsilon_2$ , and  $\varepsilon_3$ ; and uniform temperatures  $T_1$ ,  $T_2$ , and  $T_3$ , respectively. The radiation network of this geometry is constructed by following the standard procedure: draw a surface resistance associated with each of the three surfaces and connect these surface resistances with space resistances, as shown in the figure. Relations for the surface and space resistances are given by Eqs. 13-26 and 13-31. The three endpoint potentials  $E_{b1}$ ,  $E_{b2}$ , and  $E_{b3}$  are considered known, since the surface temperatures are specified. Then all we need to find are the radiosities  $J_1$ ,  $J_2$ , and  $J_3$ . The three equations for the determination of these three unknowns are obtained from the requirement that *the algebraic sum of the currents (net radiation heat transfer) at each node must equal zero*. That is,

$$\begin{aligned}\frac{E_{b1} - J_1}{R_1} + \frac{J_2 - J_1}{R_{12}} + \frac{J_3 - J_1}{R_{13}} &= 0 \\ \frac{J_1 - J_2}{R_{12}} + \frac{E_{b2} - J_2}{R_2} + \frac{J_3 - J_2}{R_{23}} &= 0 \\ \frac{J_1 - J_3}{R_{13}} + \frac{J_2 - J_3}{R_{23}} + \frac{E_{b3} - J_3}{R_3} &= 0\end{aligned}\quad (13-41)$$

Once the radiosities  $J_1$ ,  $J_2$ , and  $J_3$  are available, the net rate of radiation heat transfers at each surface can be determined from Eq. 13-32.

The set of equations above simplify further if one or more surfaces are “special” in some way. For example,  $J_i = E_{bi} = \sigma T_i^4$  for a *black* or *reradiating* surface. Also,  $\dot{Q}_i = 0$  for a reradiating surface. Finally, when the net rate of radiation heat transfer  $\dot{Q}_i$  is specified at surface  $i$  instead of the temperature, the term  $(E_{bi} - J_i)/R_i$  should be replaced by the specified  $\dot{Q}_i$ .

### EXAMPLE 13-8 Radiation Heat Transfer in a Cylindrical Furnace

Consider a cylindrical furnace with  $r_o = H = 1\text{ m}$ , as shown in Fig. 13-27. The top (surface 1) and the base (surface 2) of the furnace have emissivities  $\varepsilon_1 = 0.8$  and  $\varepsilon_2 = 0.4$ , respectively, and are maintained at uniform temperatures  $T_1 = 700\text{ K}$  and  $T_2 = 500\text{ K}$ . The side surface closely approximates a black-body and is maintained at a temperature of  $T_3 = 400\text{ K}$ . Determine the net rate of radiation heat transfer at each surface during steady operation and explain how these surfaces can be maintained at specified temperatures.

**SOLUTION** The surfaces of a cylindrical furnace are maintained at uniform temperatures. The net rate of radiation heat transfer at each surface during steady operation is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The surfaces are opaque, diffuse, and gray. 3 Convection heat transfer is not considered.

**Analysis** We will solve this problem systematically using the direct method to demonstrate its use. The cylindrical furnace can be considered to be a three-surface enclosure with surface areas of

$$A_1 = A_2 = \pi r_o^2 = \pi(1 \text{ m})^2 = 3.14 \text{ m}^2$$

$$A_3 = 2\pi r_o H = 2\pi(1 \text{ m})(1 \text{ m}) = 6.28 \text{ m}^2$$

The view factor from the base to the top surface is, from Fig. 13–7,  $F_{12} = 0.38$ . Then the view factor from the base to the side surface is determined by applying the summation rule to be

$$F_{11} + F_{12} + F_{13} = 1 \rightarrow F_{13} = 1 - F_{11} - F_{12} = 1 - 0 - 0.38 = 0.62$$

since the base surface is flat and thus  $F_{11} = 0$ . Noting that the top and bottom surfaces are symmetric about the side surface,  $F_{21} = F_{12} = 0.38$  and  $F_{23} = F_{13} = 0.62$ . The view factor  $F_{31}$  is determined from the reciprocity relation,

$$A_1 F_{13} = A_3 F_{31} \rightarrow F_{31} = F_{13}(A_1/A_3) = (0.62)(0.314/0.628) = 0.31$$

Also,  $F_{32} = F_{31} = 0.31$  because of symmetry. Now that all the view factors are available, we apply Eq. 13–35 to each surface to determine the radiosities:

$$\text{Top surface } (i = 1): \sigma T_1^4 = J_1 + \frac{1 - \varepsilon_1}{\varepsilon_1} [F_{12}(J_1 - J_2) + F_{13}(J_1 - J_3)]$$

$$\text{Bottom surface } (i = 2): \sigma T_2^4 = J_2 + \frac{1 - \varepsilon_2}{\varepsilon_2} [F_{21}(J_2 - J_1) + F_{23}(J_2 - J_3)]$$

$$\text{Side surface } (i = 3): \sigma T_3^4 = J_3 + 0 \text{ (since surface 3 is black and thus } \varepsilon_3 = 1)$$

Substituting the known quantities,

$$(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(700 \text{ K})^4 = J_1 + \frac{1 - 0.8}{0.8} [0.38(J_1 - J_2) + 0.62(J_1 - J_3)]$$

$$(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(500 \text{ K})^4 = J_2 + \frac{1 - 0.4}{0.4} [0.38(J_2 - J_1) + 0.62(J_2 - J_3)]$$

$$(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(400 \text{ K})^4 = J_3$$

Solving these equations for  $J_1$ ,  $J_2$ , and  $J_3$  gives

$$J_1 = 11,418 \text{ W/m}^2, J_2 = 4562 \text{ W/m}^2, \quad \text{and} \quad J_3 = 1452 \text{ W/m}^2$$

Then the net rates of radiation heat transfer at the three surfaces are determined from Eq. 13–34 to be

$$\begin{aligned} \dot{Q}_1 &= A_1 [F_{1 \rightarrow 2}(J_1 - J_2) + F_{1 \rightarrow 3}(J_1 - J_3)] \\ &= (3.14 \text{ m}^2)[0.38(11,418 - 4562) + 0.62(11,418 - 1452)] \text{ W/m}^2 \\ &= \mathbf{27.6 \text{ kW}} \end{aligned}$$

$$\begin{aligned} \dot{Q}_2 &= A_2 [F_{2 \rightarrow 1}(J_2 - J_1) + F_{2 \rightarrow 3}(J_2 - J_3)] \\ &= (3.14 \text{ m}^2)[0.38(4562 - 11,418) + 0.62(4562 - 1452)] \text{ W/m}^2 \\ &= \mathbf{-2.13 \text{ kW}} \end{aligned}$$

$$\begin{aligned}\dot{Q}_3 &= A_3[F_{3 \rightarrow 1}(J_3 - J_1) + F_{3 \rightarrow 2}(J_3 - J_2)] \\ &= (6.28 \text{ m}^2)[0.31(1452 - 11,418) + 0.31(1452 - 4562)] \text{ W/m}^2 \\ &= -25.5 \text{ kW}\end{aligned}$$

Note that the direction of net radiation heat transfer is *from* the top surface to the base and side surfaces, and the algebraic sum of these three quantities must be equal to zero. That is,

$$\dot{Q}_1 + \dot{Q}_2 + \dot{Q}_3 = 27.6 + (-2.13) + (-25.5) \approx 0$$

**Discussion** To maintain the surfaces at the specified temperatures, we must supply heat to the top surface continuously at a rate of 27.6 kW while removing 2.13 kW from the base and 25.5 kW from the side surfaces.

The direct method presented here is straightforward, and it does not require the evaluation of radiation resistances. Also, it can be applied to enclosures with any number of surfaces in the same manner.

### EXAMPLE 13–9 Radiation Heat Transfer in a Triangular Furnace

A furnace is shaped like a long equilateral triangular duct, as shown in Fig. 13–28. The width of each side is 1 m. The base surface has an emissivity of 0.7 and is maintained at a uniform temperature of 600 K. The heated left-side surface closely approximates a blackbody at 1000 K. The right-side surface is well insulated. Determine the rate at which heat must be supplied to the heated side externally per unit length of the duct in order to maintain these operating conditions.

**FIGURE 13–28**  
The triangular furnace considered in Example 13–9.

**SOLUTION** Two of the surfaces of a long equilateral triangular furnace are maintained at uniform temperatures while the third surface is insulated. The external rate of heat transfer to the heated side per unit length of the duct during steady operation is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The surfaces are opaque, diffuse, and gray. 3 Convection heat transfer is not considered.

**Analysis** The furnace can be considered to be a three-surface enclosure with a radiation network as shown in the figure, since the duct is very long and thus the end effects are negligible. We observe that the view factor from any surface to any other surface in the enclosure is 0.5 because of symmetry. Surface 3 is a reradiating surface since the net rate of heat transfer at that surface is zero. Then we must have  $\dot{Q}_1 = -\dot{Q}_2$ , since the entire heat lost by surface 1 must be gained by surface 2. The radiation network in this case is a simple series-parallel connection, and we can determine  $\dot{Q}_1$  directly from

$$\dot{Q}_1 = \frac{E_{b1} - E_{b2}}{R_1 + \left( \frac{1}{R_{12}} + \frac{1}{R_{13}} + \frac{1}{R_{23}} \right)^{-1}} = \frac{E_{b1} - E_{b2}}{\frac{1 - \varepsilon_1}{A_1 \varepsilon_1} + \left( A_1 F_{12} + \frac{1}{1/A_1 F_{13} + 1/A_2 F_{23}} \right)^{-1}}$$

where

$$A_1 = A_2 = A_3 = wL = 1 \text{ m} \times 1 \text{ m} = 1 \text{ m}^2 \quad (\text{per unit length of the duct})$$

$$F_{12} = F_{13} = F_{23} = 0.5 \quad (\text{symmetry})$$

$$E_{b1} = \sigma T_1^4 = (5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(600 \text{ K})^4 = 7348 \text{ W/m}^2$$

$$E_{b2} = \sigma T_2^4 = (5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(1000 \text{ K})^4 = 56,700 \text{ W/m}^2$$

Substituting,

$$\begin{aligned} \dot{Q}_1 &= \frac{(56,700 - 7348) \text{ W/m}^2}{\frac{1 - 0.7}{0.7 \times 1 \text{ m}^2} + \left[ (0.5 \times 1 \text{ m}^2) + \frac{1}{1/(0.5 \times 1 \text{ m}^2) + 1/(0.5 \times 1 \text{ m}^2)} \right]^{-1}} \\ &= 28.0 \text{ kW} \end{aligned}$$

Therefore, heat at a rate of 28 kW must be supplied to the heated surface per unit length of the duct to maintain steady operation in the furnace.

### EXAMPLE 13–10 Heat Transfer through a Tubular Solar Collector

A solar collector consists of a horizontal aluminum tube having an outer diameter of 2 in enclosed in a concentric thin glass tube of 4-in diameter, as shown in Fig. 13–29. Water is heated as it flows through the tube, and the space between the aluminum and the glass tubes is filled with air at 1 atm pressure. The pump circulating the water fails during a clear day, and the water temperature in the tube starts rising. The aluminum tube absorbs solar radiation at a rate of 30 Btu/h per foot length, and the temperature of the ambient air outside is 70°F. The emissivities of the tube and the glass cover are 0.95 and 0.9, respectively. Taking the effective sky temperature to be 50°F, determine the temperature of the aluminum tube when steady operating conditions are established (i.e., when the rate of heat loss from the tube equals the amount of solar energy gained by the tube).

**SOLUTION** The circulating pump of a solar collector that consists of a horizontal tube and its glass cover fails. The equilibrium temperature of the tube is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The tube and its cover are isothermal. 3 Air is an ideal gas. 4 The surfaces are opaque, diffuse, and gray for infrared radiation. 5 The glass cover is transparent to solar radiation.

**Properties** The properties of air should be evaluated at the average temperature. But we do not know the exit temperature of the air in the duct, and thus we cannot determine the bulk fluid and glass cover temperatures at this point, and thus we cannot evaluate the average temperatures. Therefore, we assume

**FIGURE 13–29**  
Schematic for Example 13–10.

the glass temperature to be 110°F, and use properties at an anticipated average temperature of  $(70 + 110)/2 = 90^\circ\text{F}$  (Table A-15E),

$$\begin{aligned} k &= 0.01505 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F} & \text{Pr} &= 0.7275 \\ \nu &= 1.753 \times 10^{-4} \text{ ft}^2/\text{s} & \beta &= \frac{1}{T_{\text{avg}}} = \frac{1}{550 \text{ R}} \end{aligned}$$

**Analysis** This problem was solved in Chap. 9 by disregarding radiation heat transfer. Now we repeat the solution by considering natural convection and radiation occurring simultaneously.

We have a horizontal cylindrical enclosure filled with air at 1 atm pressure. The problem involves heat transfer from the aluminum tube to the glass cover and from the outer surface of the glass cover to the surrounding ambient air. When steady operation is reached, these two heat transfer rates must equal the rate of heat gain. That is,

$$\dot{Q}_{\text{tube-glass}} = \dot{Q}_{\text{glass-ambient}} = \dot{Q}_{\text{solar gain}} = 30 \text{ Btu/h} \quad (\text{per foot of tube})$$

The heat transfer surface area of the glass cover is

$$A_o = A_{\text{glass}} = (\pi D_o L) = \pi(4/12 \text{ ft})(1 \text{ ft}) = 1.047 \text{ ft}^2 \quad (\text{per foot of tube})$$

To determine the Rayleigh number, we need to know the surface temperature of the glass, which is not available. Therefore, it is clear that the solution requires a trial-and-error approach unless we use an equation solver such as EES. Assuming the glass cover temperature to be 110°F, the Rayleigh number, the Nusselt number, the convection heat transfer coefficient, and the rate of natural convection heat transfer from the glass cover to the ambient air are determined to be

$$\begin{aligned} \text{Ra}_{D_o} &= \frac{g\beta(T_o - T_\infty) D_o^3}{\nu^2} \text{Pr} \\ &= \frac{(32.2 \text{ ft/s}^2)[1/(550 \text{ R})](110 - 70 \text{ R})(4/12 \text{ ft})^3}{(1.753 \times 10^{-4} \text{ ft}^2/\text{s})^2} (0.7275) = 2.053 \times 10^6 \end{aligned}$$

$$\begin{aligned} \text{Nu} &= \left\{ 0.6 + \frac{0.387 \text{ Ra}_{D_o}^{1/6}}{[1 + (0.559/\text{Pr})^{9/16}]^{8/27}} \right\}^2 = \left\{ 0.6 + \frac{0.387(2.053 \times 10^6)^{1/6}}{[1 + (0.559/0.7275)^{9/16}]^{8/27}} \right\}^2 \\ &= 17.88 \end{aligned}$$

$$h_o = \frac{k}{D_o} \text{Nu} = \frac{0.01505 \text{ Btu/h}\cdot\text{ft}\cdot^\circ\text{F}}{4/12 \text{ ft}} (17.88) = 0.8073 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F}$$

$$\begin{aligned} \dot{Q}_{o,\text{conv}} &= h_o A_o (T_o - T_\infty) = (0.8073 \text{ Btu/h}\cdot\text{ft}^2\cdot^\circ\text{F})(1.047 \text{ ft}^2)(110 - 70)^\circ\text{F} \\ &= 33.8 \text{ Btu/h} \end{aligned}$$

Also,

$$\begin{aligned} \dot{Q}_{o,\text{rad}} &= \varepsilon_o \sigma A_o (T_o^4 - T_{\text{sky}}^4) \\ &= (0.9)(0.1714 \times 10^{-8} \text{ Btu/h}\cdot\text{ft}^2\cdot\text{R}^4)(1.047 \text{ ft}^2)[(570 \text{ R})^4 - (510 \text{ R})^4] \\ &= 61.2 \text{ Btu/h} \end{aligned}$$

Then the total rate of heat loss from the glass cover becomes

$$\dot{Q}_{o,\text{total}} = \dot{Q}_{o,\text{conv}} + \dot{Q}_{o,\text{rad}} = 33.8 + 61.2 = 95.0 \text{ Btu/h}$$

which is much larger than 30 Btu/h. Therefore, the assumed temperature of 110°F for the glass cover is high. Repeating the calculations with lower temperatures (including the evaluation of properties), the glass cover temperature corresponding to 30 Btu/h is determined to be 78°F (it would be 106°F if radiation were ignored).

The temperature of the aluminum tube is determined in a similar manner using the natural convection and radiation relations for two horizontal concentric cylinders. The characteristic length in this case is the distance between the two cylinders, which is

$$L_c = (D_o - D_i)/2 = (4 - 2)/2 = 1 \text{ in} = 1/12 \text{ ft}$$

Also,

$$A_i = A_{\text{tube}} = (\pi D_i L) = \pi(2/12 \text{ ft})(1 \text{ ft}) = 0.5236 \text{ ft}^2 \quad (\text{per foot of tube})$$

We start the calculations by assuming the tube temperature to be 122°F, and thus an average temperature of  $(78 + 122)/2 = 100^\circ\text{F} = 560 \text{ R}$ . Using properties at 100°F,

$$\begin{aligned} Ra_L &= \frac{g\beta(T_i - T_o)L_c^3}{\nu^2} \text{Pr} \\ &= \frac{(32.2 \text{ ft/s}^2)[1/(560 \text{ R})](122 - 78 \text{ R})(1/12 \text{ ft})^3}{(1.809 \times 10^{-4} \text{ ft}^2/\text{s})^2} (0.726) = 3.246 \times 10^4 \end{aligned}$$

The effective thermal conductivity is

$$\begin{aligned} F_{\text{cyl}} &= \frac{[\ln(D_o/D_i)]^4}{L_c^3 (D_i^{-3/5} + D_o^{-3/5})^5} = \frac{[\ln(4/2)]^4}{(1/12 \text{ ft})^3 [(2/12 \text{ ft})^{-3/5} + (4/12 \text{ ft})^{-3/5}]^5} = 0.1466 \\ k_{\text{eff}} &= 0.386k \left( \frac{\text{Pr}}{0.861 + \text{Pr}} \right)^{1/4} (F_{\text{cyl}} Ra_L)^{1/4} \\ &= 0.386(0.01529 \text{ Btu/h}\cdot\text{ft}\cdot{}^\circ\text{F}) \left( \frac{0.726}{0.861 + 0.726} \right)^{1/4} (0.1466 \times 3.248 \times 10^4)^{1/4} \\ &= 0.04032 \text{ Btu/h}\cdot\text{ft}\cdot{}^\circ\text{F} \end{aligned}$$

Then the rate of heat transfer between the cylinders by convection becomes

$$\begin{aligned} \dot{Q}_{i,\text{conv}} &= \frac{2\pi k_{\text{eff}}}{\ln(D_o/D_i)} (T_i - T_o) \\ &= \frac{2\pi(0.04032 \text{ Btu/h}\cdot\text{ft}\cdot{}^\circ\text{F})}{\ln(4/2)} (122 - 78)^\circ\text{F} = 16.1 \text{ Btu/h} \end{aligned}$$

Also,

$$\begin{aligned} \dot{Q}_{i,\text{rad}} &= \frac{\sigma A_i (T_i^4 - T_o^4)}{\frac{1}{\varepsilon_i} + \frac{1 - \varepsilon_o}{\varepsilon_o} \left( \frac{D_i}{D_o} \right)} \\ &= \frac{(0.1714 \times 10^{-8} \text{ Btu/h}\cdot\text{ft}^2\cdot\text{R}^4)(0.5236 \text{ ft}^2)[(582 \text{ R})^4 - (538 \text{ R})^4]}{\frac{1}{0.95} + \frac{1 - 0.9}{0.9} \left( \frac{2 \text{ in}}{4 \text{ in}} \right)} \\ &= 25.1 \text{ Btu/h} \end{aligned}$$

Then the total rate of heat loss from the glass cover becomes

$$\dot{Q}_{i,\text{total}} = \dot{Q}_{i,\text{conv}} + \dot{Q}_{i,\text{rad}} = 16.1 + 25.1 = 41.2 \text{ Btu/h}$$

which is larger than 30 Btu/h. Therefore, the assumed temperature of 122°F for the tube is high. By trying other values, the tube temperature corresponding to 30 Btu/h is determined to be 112°F (it would be 180°F if radiation were ignored). Therefore, the tube will reach an equilibrium temperature of 112°F when the pump fails.

**Discussion** It is clear from the results obtained that radiation should always be considered in systems that are heated or cooled by natural convection, unless the surfaces involved are polished and thus have very low emissivities.

## 13–5 • RADIATION SHIELDS AND THE RADIATION EFFECTS

Radiation heat transfer between two surfaces can be reduced greatly by inserting a thin, high-reflectivity (low-emissivity) sheet of material between the two surfaces. Such highly reflective thin plates or shells are called **radiation shields**. Multilayer radiation shields constructed of about 20 sheets per cm thickness separated by evacuated space are commonly used in cryogenic and space applications. Radiation shields are also used in temperature measurements of fluids to reduce the error caused by the radiation effect when the temperature sensor is exposed to surfaces that are much hotter or colder than the fluid itself. The role of the radiation shield is to reduce the rate of radiation heat transfer by placing additional resistances in the path of radiation heat flow. The lower the emissivity of the shield, the higher the resistance.

Radiation heat transfer between two large parallel plates of emissivities  $\varepsilon_1$  and  $\varepsilon_2$  maintained at uniform temperatures  $T_1$  and  $T_2$  is given by Eq. 13–38:

$$\dot{Q}_{12, \text{no shield}} = \frac{A\sigma(T_1^4 - T_2^4)}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1}$$

Now consider a radiation shield placed between these two plates, as shown in Fig. 13–30. Let the emissivities of the shield facing plates 1 and 2 be  $\varepsilon_{3,1}$  and  $\varepsilon_{3,2}$ , respectively. Note that the emissivity of different surfaces of the shield may be different. The radiation network of this geometry is constructed, as usual, by drawing a surface resistance associated with each surface and connecting these surface resistances with space resistances, as shown in the figure. The resistances are connected in series, and thus the rate of radiation heat transfer is

$$\dot{Q}_{12, \text{one shield}} = \frac{E_{b1} - E_{b2}}{\frac{1 - \varepsilon_1}{A_1 \varepsilon_1} + \frac{1}{A_1 F_{13}} + \frac{1 - \varepsilon_{3,1}}{A_3 \varepsilon_{3,1}} + \frac{1 - \varepsilon_{3,2}}{A_3 \varepsilon_{3,2}} + \frac{1}{A_3 F_{32}} + \frac{1 - \varepsilon_2}{A_2 \varepsilon_2}}$$
(13–42)

**FIGURE 13-30**

The radiation shield placed between two parallel plates and the radiation network associated with it.

Noting that  $F_{13} = F_{32} = 1$  and  $A_1 = A_2 = A_3 = A$  for infinite parallel plates, Eq. 13-42 simplifies to

$$\dot{Q}_{12, \text{one shield}} = \frac{A\sigma(T_1^4 - T_2^4)}{\left(\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1\right) + \left(\frac{1}{\varepsilon_{3,1}} + \frac{1}{\varepsilon_{3,2}} - 1\right)} \quad (13-43)$$

where the terms in the second set of parentheses in the denominator represent the additional resistance to radiation introduced by the shield. The appearance of the equation above suggests that parallel plates involving multiple radiation shields can be handled by adding a group of terms like those in the second set of parentheses to the denominator for each radiation shield. Then the radiation heat transfer through large parallel plates separated by  $N$  radiation shields becomes

$$\dot{Q}_{12, N \text{ shields}} = \frac{A\sigma(T_1^4 - T_2^4)}{\left(\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1\right) + \left(\frac{1}{\varepsilon_{3,1}} + \frac{1}{\varepsilon_{3,2}} - 1\right) + \dots + \left(\frac{1}{\varepsilon_{N,1}} + \frac{1}{\varepsilon_{N,2}} - 1\right)} \quad (13-44)$$

If the emissivities of all surfaces are equal, Eq. 13-44 reduces to

$$\dot{Q}_{12, N \text{ shields}} = \frac{A\sigma(T_1^4 - T_2^4)}{(N+1)\left(\frac{1}{\varepsilon} + \frac{1}{\varepsilon} - 1\right)} = \frac{1}{N+1} \dot{Q}_{12, \text{no shield}} \quad (13-45)$$

Therefore, when all emissivities are equal, 1 shield reduces the rate of radiation heat transfer to one-half, 9 shields reduce it to one-tenth, and 19 shields reduce it to one-twentieth (or 5 percent) of what it was when there were no shields.

The equilibrium temperature of the radiation shield  $T_3$  in Figure 13-30 can be determined by expressing Eq. 13-43 for  $\dot{Q}_{13}$  or  $\dot{Q}_{23}$  (which involves  $T_3$ ) after evaluating  $\dot{Q}_{12}$  from Eq. 13-43 and noting that  $\dot{Q}_{12} = \dot{Q}_{13} = \dot{Q}_{23}$  when steady conditions are reached.

Radiation shields used to reduce the rate of radiation heat transfer between concentric cylinders and spheres can be handled in a similar manner. In case of one shield, Eq. 13-42 can be used by taking  $F_{13} = F_{32} = 1$  for both cases and by replacing the  $A$ 's by the proper area relations.

## Radiation Effect on Temperature Measurements

A temperature measuring device indicates the temperature of its *sensor*, which is supposed to be, but is not necessarily, the temperature of the medium that the sensor is in contact with. When a thermometer (or any other temperature measuring device such as a thermocouple) is placed in a medium, heat transfer takes place between the sensor of the thermometer and the medium by convection until the sensor reaches the temperature of the medium. But when the sensor is surrounded by surfaces that are at a different temperature than the fluid, radiation exchange also takes place between the sensor and the surrounding surfaces. When the heat transfers by convection and radiation balance each other, the sensor indicates a temperature that falls between the fluid and surface temperatures. Below we develop a procedure to account for the radiation effect and to determine the actual fluid temperature.

Consider a thermometer that is used to measure the temperature of a fluid flowing through a large channel whose walls are at a lower temperature than the fluid (Fig. 13–31). Equilibrium will be established and the reading of the thermometer will stabilize when heat gain by convection, as measured by the sensor, equals heat loss by radiation (or vice versa). That is, on a unit-area basis,

**FIGURE 13–31**

A thermometer used to measure the temperature of a fluid in a channel.

$$\dot{q}_{\text{conv, to sensor}} = \dot{q}_{\text{rad, from sensor}}$$

$$h(T_f - T_{\text{th}}) = \varepsilon\sigma(T_{\text{th}}^4 - T_w^4)$$

or

$$T_f = T_{\text{th}} + \frac{\varepsilon\sigma(T_{\text{th}}^4 - T_w^4)}{h} \quad (13-46)$$

where

$T_f$  = actual temperature of the fluid, K

$T_{\text{th}}$  = temperature value measured by the thermometer, K

$T_w$  = temperature of the surrounding surfaces, K

$h$  = convection heat transfer coefficient, W/m<sup>2</sup>·K

$\varepsilon$  = emissivity of the sensor of the thermometer

The last term in Eq. 13–46 is due to the *radiation effect* and represents the *radiation correction*. Note that the radiation correction term is most significant when the convection heat transfer coefficient is small and the emissivity of the surface of the sensor is large. Therefore, the sensor should be coated with a material of high reflectivity (low emissivity) to reduce the radiation effect.

Placing the sensor in a radiation shield without interfering with the fluid flow also reduces the radiation effect. The sensors of temperature measurement devices used outdoors must be protected from direct sunlight since the radiation effect in that case is sure to reach unacceptable levels.

The radiation effect is also a significant factor in *human comfort* in heating and air-conditioning applications. A person who feels fine in a room at a specified temperature may feel chilly in another room at the same temperature as a result of the radiation effect if the walls of the second room are at a considerably lower temperature. For example, most people feel comfortable in a room at 22°C if the walls of the room are also roughly at that temperature. When the wall temperature drops to 5°C for some reason, the interior temperature of the room must be raised to at least 27°C to maintain the same level

of comfort. Therefore, well-insulated buildings conserve energy not only by reducing the heat loss or heat gain, but also by allowing the thermostats to be set at a lower temperature in winter and at a higher temperature in summer without compromising the comfort level.

### EXAMPLE 13–11 Radiation Shields

A thin aluminum sheet with an emissivity of 0.1 on both sides is placed between two very large parallel plates that are maintained at uniform temperatures  $T_1 = 800\text{ K}$  and  $T_2 = 500\text{ K}$  and have emissivities  $\varepsilon_1 = 0.2$  and  $\varepsilon_2 = 0.7$ , respectively, as shown in Fig. 13–32. Determine the net rate of radiation heat transfer between the two plates per unit surface area of the plates and compare the result to that without the shield.

**SOLUTION** A thin aluminum sheet is placed between two large parallel plates maintained at uniform temperatures. The net rates of radiation heat transfer between the two plates with and without the radiation shield are to be determined.

**Assumptions** The surfaces are opaque, diffuse, and gray.

**Analysis** The net rate of radiation heat transfer between these two plates without the shield was determined in Example 13–7 to be  $3625\text{ W/m}^2$ . Heat transfer in the presence of one shield is determined from Eq. 13–43 to be

$$\begin{aligned}\dot{q}_{12, \text{one shield}} &= \frac{\dot{Q}_{12, \text{one shield}}}{A} = \frac{\sigma(T_1^4 - T_2^4)}{\left(\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1\right) + \left(\frac{1}{\varepsilon_{3,1}} + \frac{1}{\varepsilon_{3,2}} - 1\right)} \\ &= \frac{(5.67 \times 10^{-8} \text{ W/m}^2\text{-K}^4)[(800\text{ K})^4 - (500\text{ K})^4]}{\left(\frac{1}{0.2} + \frac{1}{0.7} - 1\right) + \left(\frac{1}{0.1} + \frac{1}{0.1} - 1\right)} \\ &= 806 \text{ W/m}^2\end{aligned}$$

**Discussion** Note that the rate of radiation heat transfer reduces to about one-fourth of what it was as a result of placing a radiation shield between the two parallel plates.

### PtD EXAMPLE 13–12 Prevention of Thermal Burn Hazards by using Radiation Shields

Heat treatment of metals is commonly done using electrically heated draw batch furnaces. Consider a furnace that is situated in a room with surrounding air temperature of  $30^\circ\text{C}$  and an average convection heat transfer coefficient of  $10\text{ W/m}^2\cdot\text{K}$ , as shown in Fig. 13–33. Convection and radiation heat transfer occur between the furnace outer surface and the surroundings. The furnace front is made of two parallel plates, where the inner plate has a temperature of  $600^\circ\text{C}$ . To ensure safety and prevent thermal burn on people working around the furnace, the outer surface of the furnace should be kept below  $45^\circ\text{C}$ . Based on the given information, determine the number of radiation shields that should be placed parallel in the furnace front. Assume all the surfaces have the same emissivity of 0.1.

**FIGURE 13–32**  
Schematic for Example 13–11.

**FIGURE 13–33**  
Schematic for Example 13–12.

**SOLUTION** In this example, the concepts of Prevention through Design (PtD) are applied in conjunction with the concepts of radiation shield and radiation heat transfer between surfaces.

**Assumptions** 1 Steady operating conditions exist. 2 The surfaces are opaque, diffuse, and gray. 3 Convection heat transfer in between the furnace front plates is not considered. 4 The ambient temperature is equal to the temperature of the surrounding surfaces,  $T_\infty = T_{\text{surr}}$ .

**Properties** The emissivity of all the surfaces is given as  $\varepsilon = 0.1$ .

**Analysis** The net radiation heat transfer between the parallel plates of the furnace front is

$$\dot{q}_{12} = \frac{\sigma(T_1^4 - T_2^4)}{(N + 1)\left(\frac{1}{\varepsilon} + \frac{1}{\varepsilon} - 1\right)}$$

The convection and radiation heat transfer between the outer furnace front surface and the surroundings are

$$\dot{q}_{\text{conv}} = h(T_2 - T_{\text{surr}}) \quad \text{and} \quad \dot{q}_{\text{rad}} = \varepsilon\sigma(T_2^4 - T_{\text{surr}}^4)$$

Performing the energy balance on the outer surface, we have

$$\begin{aligned} \dot{q}_{12} &= \dot{q}_{\text{rad}} + \dot{q}_{\text{conv}} \\ \frac{\sigma(T_1^4 - T_2^4)}{(N + 1)\left(\frac{1}{\varepsilon} + \frac{1}{\varepsilon} - 1\right)} &= h(T_2 - T_\infty) + \varepsilon\sigma(T_2^4 - T_{\text{surr}}^4) \end{aligned}$$

Hence,

$$\begin{aligned} N &= \left( \frac{1}{1/\varepsilon + 1/\varepsilon - 1} \right) \left[ \frac{\sigma(T_1^4 - T_2^4)}{h(T_2 - T_\infty) + \varepsilon\sigma(T_2^4 - T_{\text{surr}}^4)} \right] - 1 \\ &= \left( \frac{1}{2/0.1 - 1} \right) \\ &\quad \left[ \frac{(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(873^4 - 318^4) \text{ K}^4}{(10 \text{ W/m}^2 \cdot \text{K})(318 - 303) \text{ K} + (0.1)(5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)(318^4 - 303^4) \text{ K}^4} \right] - 1 \\ &= 9.63 \approx 10 \end{aligned}$$

Thus, placing 10 radiation shields inside the furnace front will keep the outer surface temperature below 45°C to prevent thermal burn hazards.

**Discussion** Without the radiation shield, the temperature of the furnace front outer surface will be 174°C. By placing radiation shields in the furnace front, heat transfer through the furnace front is reduced to 45°C as specified in the problem statement.

**FIGURE 13–34**  
Schematic for Example 13–13.

### EXAMPLE 13–13 Radiation Effect on Temperature Measurements

A thermocouple used to measure the temperature of hot air flowing in a duct whose walls are maintained at  $T_w = 400$  K shows a temperature reading of  $T_{\text{th}} = 650$  K (Fig. 13–34). Assuming the emissivity of the thermocouple junction to be  $\varepsilon = 0.6$  and the convection heat transfer coefficient to be  $h = 80 \text{ W/m}^2 \cdot \text{K}$ , determine the actual temperature of the air.

**SOLUTION** The temperature of air in a duct is measured. Accounting for the radiation effect, and the actual air temperature is to be determined.

**Assumptions** The surfaces are opaque, diffuse, and gray.

**Analysis** The walls of the duct are at a considerably lower temperature than the air in it, and thus we expect the thermocouple to show a reading lower than the actual air temperature as a result of the radiation effect. The actual air temperature is determined from Eq. 13–46 to be

$$\begin{aligned} T_f &= T_{\text{th}} + \frac{\varepsilon\sigma(T_{\text{th}}^4 - T_w^4)}{h} \\ &= (650 \text{ K}) + \frac{0.6 \times (5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4)[(650 \text{ K})^4 - (400 \text{ K})^4]}{80 \text{ W/m}^2 \cdot \text{K}} \\ &= 715 \text{ K} \end{aligned}$$

Note that the radiation effect causes a difference of 65°C (or 65 K since °C ≡ K for temperature differences) in temperature reading in this case.

## 13–6 • RADIATION EXCHANGE WITH EMITTING AND ABSORBING GASES

So far we considered radiation heat transfer between surfaces separated by a medium that does not emit, absorb, or scatter radiation—a nonparticipating medium that is completely transparent to thermal radiation. A vacuum satisfies this condition perfectly, and air at ordinary temperatures and pressures comes very close. Gases that consist of monatomic molecules such as Ar and He and symmetric diatomic molecules such as N<sub>2</sub> and O<sub>2</sub> are essentially transparent to radiation, except at extremely high temperatures at which ionization occurs. Therefore, atmospheric air can be considered to be a nonparticipating medium in radiation calculations.

Gases with asymmetric molecules such as H<sub>2</sub>O, CO<sub>2</sub>, CO, SO<sub>2</sub>, and hydrocarbons H<sub>m</sub>C<sub>n</sub> may participate in the radiation process by absorption at moderate temperatures, and by absorption and emission at high temperatures such as those encountered in combustion chambers. Therefore, air or any other medium that contains such gases with asymmetric molecules at sufficient concentrations must be treated as a participating medium in radiation calculations. Combustion gases in a furnace or a combustion chamber, for example, contain sufficient amounts of H<sub>2</sub>O and CO<sub>2</sub>, and thus the emission and absorption of gases in furnaces must be taken into consideration.

The presence of a participating medium complicates the radiation analysis considerably for several reasons:

- A participating medium emits and absorbs radiation throughout its entire volume. That is, gaseous radiation is a *volumetric phenomena*, and thus it depends on the size and shape of the body. This is the case even if the temperature is uniform throughout the medium.
- Gases emit and absorb radiation at a number of narrow wavelength bands. This is in contrast to solids, which emit and absorb radiation over the entire spectrum. Therefore, the gray assumption may not always be appropriate for a gas even when the surrounding surfaces are gray.

- The emission and absorption characteristics of the constituents of a gas mixture also depends on the temperature, pressure, and composition of the gas mixture. Therefore, the presence of other participating gases affects the radiation characteristics of a particular gas.

The propagation of radiation through a medium can be complicated further by the presence of *aerosols* such as dust, ice particles, liquid droplets, and soot (unburned carbon) particles that *scatter* radiation. Scattering refers to the change of direction of radiation due to reflection, refraction, and diffraction. Scattering caused by gas molecules themselves is known as the *Rayleigh scattering*, and it has negligible effect on heat transfer. Radiation transfer in scattering media is considered in advanced books such as the ones by Modest (1993) and Siegel and Howell (1992).

The participating medium can also be semitransparent liquids or solids such as water, glass, and plastics. To keep complexities to a manageable level, we limit our consideration to gases that emit and absorb radiation. In particular, we consider the emission and absorption of radiation by H<sub>2</sub>O and CO<sub>2</sub> only since they are the participating gases most commonly encountered in practice (combustion products in furnaces and combustion chambers burning hydrocarbon fuels contain both gases at high concentrations), and they are sufficient to demonstrate the basic principles involved.

**FIGURE 13-35**

The attenuation of a radiation beam while passing through an absorbing medium of thickness  $L$ .

## Radiation Properties of a Participating Medium

Consider a participating medium of thickness  $L$ . A spectral radiation beam of intensity  $I_{\lambda,0}$  is incident on the medium, which is attenuated as it propagates due to absorption. The decrease in the intensity of radiation as it passes through a layer of thickness  $dx$  is proportional to the intensity itself and the thickness  $dx$ . This is known as **Beer's law**, and is expressed as (Fig. 13-35)

$$dI_{\lambda}(x) = -\kappa_{\lambda} I_{\lambda}(x) dx \quad (13-47)$$

where the constant of proportionality  $\kappa_{\lambda}$  is the **spectral absorption coefficient** of the medium whose unit is m<sup>-1</sup> (from the requirement of dimensional homogeneity). This is just like the amount of interest earned by a bank account during a time interval being proportional to the amount of money in the account and the time interval, with the interest rate being the constant of proportionality.

Separating the variables and integrating from  $x = 0$  to  $x = L$  gives

$$\frac{I_{\lambda,L}}{I_{\lambda,0}} = e^{-\kappa_{\lambda} L} \quad (13-48)$$

where we have assumed the absorptivity of the medium to be independent of  $x$ . Note that radiation intensity decays exponentially in accordance with Beer's law.

The **spectral transmissivity** of a medium can be defined as the ratio of the intensity of radiation leaving the medium to that entering the medium. That is,

$$\tau_{\lambda} = \frac{I_{\lambda,L}}{I_{\lambda,0}} = e^{-\kappa_{\lambda} L} \quad (13-49)$$

Note that  $\tau_{\lambda} = 1$  when no radiation is absorbed and thus radiation intensity remains constant. Also, the spectral transmissivity of a medium represents the fraction of radiation transmitted by the medium at a given wavelength.

Radiation passing through a nonscattering (and thus nonreflecting) medium is either absorbed or transmitted. Therefore  $\alpha_\lambda + \tau_\lambda = 1$ , and the **spectral absorptivity** of a medium of thickness  $L$  is

$$\alpha_\lambda = 1 - \tau_\lambda = 1 - e^{-\kappa_\lambda L} \quad (13-50)$$

From Kirchoff's law, the **spectral emissivity** of the medium is

$$\varepsilon_\lambda = \alpha_\lambda = 1 - e^{-\kappa_\lambda L} \quad (13-51)$$

Note that the spectral absorptivity, transmissivity, and emissivity of a medium are dimensionless quantities, with values less than or equal to 1. The spectral absorption coefficient of a medium (and thus  $\varepsilon_\lambda$ ,  $\alpha_\lambda$ , and  $\tau_\lambda$ ), in general, vary with wavelength, temperature, pressure, and composition.

For an *optically thick* medium (a medium with a large value of  $\kappa_\lambda L$ ), Eq. 13-51 gives  $\varepsilon_\lambda \approx \alpha_\lambda \approx 1$ . For  $\kappa_\lambda L = 5$ , for example,  $\varepsilon_\lambda = \alpha_\lambda = 0.993$ . Therefore, an optically thick medium emits like a blackbody at the given wavelength. As a result, an optically thick absorbing-emitting medium with no significant scattering at a given temperature  $T_g$  can be viewed as a "black surface" at  $T_g$  since it will absorb essentially all the radiation passing through it, and it will emit the maximum possible radiation that can be emitted by a surface at  $T_g$ , which is  $E_{b\lambda}(T_g)$ .

## Emissivity and Absorptivity of Gases and Gas Mixtures

The spectral absorptivity of CO<sub>2</sub> is given in Figure 13-36 as a function of wavelength. The various peaks and dips in the figure together with discontinuities show clearly the band nature of absorption and the strong nongray characteristics. The shape and the width of these absorption bands vary with temperature and pressure, but the magnitude of absorptivity also varies with the thickness of the gas layer. Therefore, absorptivity values without specified thickness and pressure are meaningless.

The nongray nature of properties should be considered in radiation calculations for high accuracy. This can be done using a band model, and thus performing calculations for each absorption band. However, satisfactory results can be obtained by assuming the gas to be gray, and using an effective total absorptivity and emissivity determined by some averaging process. Charts for

**FIGURE 13-36**  
Spectral absorptivity of CO<sub>2</sub> at 830 K and 10 atm for a path length of 38.8 cm.  
*From Siegel and Howell, 1992.*

the total emissivities of gases are first presented by Hottel (1954), and they have been widely used in radiation calculations with reasonable accuracy. Alternative emissivity charts and calculation procedures have been developed more recently by Edwards and Matavosian (1984). Here we present the Hottel approach because of its simplicity.

Even with gray assumption, the total emissivity and absorptivity of a gas depends on the geometry of the gas body as well as the temperature, pressure, and composition. Gases that participate in radiation exchange such as CO<sub>2</sub> and H<sub>2</sub>O typically coexist with nonparticipating gases such as N<sub>2</sub> and O<sub>2</sub>, and thus radiation properties of an absorbing and emitting gas are usually reported for a mixture of the gas with nonparticipating gases rather than the pure gas. The emissivity and absorptivity of a gas component in a mixture depends primarily on its density, which is a function of temperature and partial pressure of the gas.

The emissivity of H<sub>2</sub>O vapor in a mixture of nonparticipating gases is plotted in Figure 13–37a for a total pressure of  $P = 1$  atm as a function of gas temperature  $T_g$  for a range of values for  $P_w L$ , where  $P_w$  is the partial pressure of water vapor and  $L$  is the mean distance traveled by the radiation beam. Emissivity at a total pressure  $P$  other than  $P = 1$  atm is determined by multiplying the emissivity value at 1 atm by a **pressure correction factor**  $C_w$  obtained from Figure 13–38a for water vapor. That is,

$$\varepsilon_w = C_w \varepsilon_{w, 1 \text{ atm}} \quad (13-52)$$

Note that  $C_w = 1$  for  $P = 1$  atm and thus  $(P_w + P)/2 \cong 0.5$  (a very low concentration of water vapor is used in the preparation of the emissivity chart in Fig. 13–37a and thus  $P_w$  is very low). Emissivity values are presented in a similar manner for a mixture of CO<sub>2</sub> and nonparticipating gases in Figs. 13–37b and 13–38b.

Now the question that comes to mind is what will happen if the CO<sub>2</sub> and H<sub>2</sub>O gases exist *together* in a mixture with nonparticipating gases. The emissivity of each participating gas can still be determined as explained above using its partial pressure, but the effective emissivity of the mixture cannot be determined by simply adding the emissivities of individual gases (although this would be the case if different gases emitted at different wavelengths). Instead, it should be determined from

$$\begin{aligned} \varepsilon_g &= \varepsilon_c + \varepsilon_w - \Delta\varepsilon \\ &= C_c \varepsilon_{c, 1 \text{ atm}} + C_w \varepsilon_{w, 1 \text{ atm}} - \Delta\varepsilon \end{aligned} \quad (13-53)$$

where  $\Delta\varepsilon$  is the **emissivity correction factor**, which accounts for the overlap of emission bands. For a gas mixture that contains both CO<sub>2</sub> and H<sub>2</sub>O gases,  $\Delta\varepsilon$  is plotted in Figure 13–39.

The emissivity of a gas also depends on the *mean length* an emitted radiation beam travels in the gas before reaching a bounding surface, and thus the shape and the size of the gas body involved. During their experiments in the 1930s, Hottel and his coworkers considered the emission of radiation from a hemispherical gas body to a small surface element located at the center of the base of the hemisphere. Therefore, the given charts represent emissivity data for the emission of radiation from a hemispherical gas body of radius  $L$  toward the center of the base of the hemisphere. It is certainly desirable to extend the reported emissivity data to gas bodies of other geometries, and this is done by introducing the concept of **mean beam length**  $L$ , which represents the radius of an equivalent hemisphere. The mean beam lengths for various gas geometries are listed in Table 13–4. More extensive lists are available

Emissivities of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  gases in a mixture of nonparticipating gases at a total pressure of 1 atm for a mean beam length of  $L$  ( $1 \text{ m-atm} = 3.28 \text{ ft-atm}$ ).

From Hottel, 1954.

Correction factors for the emissivities of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  gases at pressures other than 1 atm for use in the relations  $\varepsilon_w = C_w \varepsilon_{w, 1 \text{ atm}}$  and  $\varepsilon_c = C_c \varepsilon_{c, 1 \text{ atm}}$  ( $1 \text{ m-atm} = 3.28 \text{ ft-atm}$ ).

TABLE 13-4

Mean beam length  $L$  for various gas volume shapes

| Gas Volume Geometry   | $L$        |
|---|------------|
| Hemisphere of radius $R$ radiating to the center of its base                      | $R$        |
| Sphere of diameter $D$ radiating to its surface                                   | $0.65D$    |
| Infinite circular cylinder of diameter $D$ radiating to curved surface            | $0.95D$    |
| Semi-infinite circular cylinder of diameter $D$ radiating to its base             | $0.65D$    |
| Semi-infinite circular cylinder of diameter $D$ radiating to center of its base   | $0.90D$    |
| Infinite semicircular cylinder of radius $R$ radiating to center of its base      | $1.26R$    |
| Circular cylinder of height equal to diameter $D$ radiating to entire surface     | $0.60D$    |
| Circular cylinder of height equal to diameter $D$ radiating to center of its base | $0.71D$    |
| Infinite slab of thickness $D$ radiating to either bounding plane                 | $1.80D$    |
| Cube of side length $L$ radiating to any face                                     | $0.66L$    |
| Arbitrary shape of volume $V$ and surface area $A_s$ radiating to surface         | $3.6V/A_s$ |

in the literature [such as Hottel (1954), and Siegel and Howell, (1992)]. The emissivities associated with these geometries can be determined from Figures 13-37 through 13-39 by using the appropriate mean beam length.

Following a procedure recommended by Hottel, the absorptivity of a gas that contains  $\text{CO}_2$  and  $\text{H}_2\text{O}$  gases for radiation emitted by a source at temperature  $T_s$  can be determined similarly from

$$\alpha_g = \alpha_c + \alpha_w - \Delta\alpha \quad (13-54)$$

where  $\Delta\alpha = \Delta\varepsilon$  and is determined from Figure 13–39 at the source temperature  $T_s$ . The absorptivities of CO<sub>2</sub> and H<sub>2</sub>O can be determined from the emissivity charts (Figs. 13–37 and 13–38) as

$$\text{CO}_2: \quad \alpha_c = C_c \times (T_g/T_s)^{0.65} \times \varepsilon_c(T_s, P_c L T_s/T_g) \quad (13-55)$$

and

$$\text{H}_2\text{O}: \quad \alpha_w = C_w \times (T_g/T_s)^{0.45} \times \varepsilon_w(T_s, P_w L T_s/T_g) \quad (13-56)$$

The notation indicates that the emissivities should be evaluated using  $T_s$  instead of  $T_g$  (both in K or R),  $P_c L T_s/T_g$  instead of  $P_c L$ , and  $P_w L T_s/T_g$  instead of  $P_w L$ . Note that the absorptivity of the gas depends on the source temperature  $T_s$  as well as the gas temperature  $T_g$ . Also,  $\alpha = \varepsilon$  when  $T_s = T_g$ , as expected. The pressure correction factors  $C_c$  and  $C_w$  are evaluated using  $P_c L$  and  $P_w L$ , as in emissivity calculations.

When the total emissivity of a gas  $\varepsilon_g$  at temperature  $T_g$  is known, the emissive power of the gas (radiation emitted by the gas per unit surface area) can be expressed as  $E_g = \varepsilon_g \sigma T_g^4$ . Then the rate of radiation energy emitted by a gas to a bounding surface of area  $A_s$  becomes

$$\dot{Q}_{g,e} = \varepsilon_g A_s \sigma T_g^4 \quad (13-57)$$

If the bounding surface is black at temperature  $T_s$ , the surface will emit radiation to the gas at a rate of  $A_s \sigma T_s^4$  without reflecting any, and the gas will absorb this radiation at a rate of  $\alpha_g A_s \sigma T_s^4$ , where  $\alpha_g$  is the absorptivity of the gas. Then the net rate of radiation heat transfer between the gas and a black surface surrounding it becomes

$$\text{Black enclosure:} \quad \dot{Q}_{\text{net}} = A_s \sigma (\varepsilon_g T_g^4 - \alpha_g T_s^4) \quad (13-58)$$

If the surface is not black, the analysis becomes more complicated because of the radiation reflected by the surface. But for surfaces that are nearly black with an emissivity  $\varepsilon_s > 0.7$ , Hottel (1954), recommends this modification,

$$\dot{Q}_{\text{net, gray}} = \frac{\varepsilon_s + 1}{2} \dot{Q}_{\text{net, black}} = \frac{\varepsilon_s + 1}{2} A_s \sigma (\varepsilon_g T_g^4 - \alpha_g T_s^4) \quad (13-59)$$

The emissivity of wall surfaces of furnaces and combustion chambers are typically greater than 0.7, and thus the relation above provides great convenience for preliminary radiation heat transfer calculations.

### EXAMPLE 13–14 Effective Emissivity of Combustion Gases

A cylindrical furnace whose height and diameter are 5 m contains combustion gases at 1200 K and a total pressure of 2 atm. The composition of the combustion gases is determined by volumetric analysis to be 80 percent N<sub>2</sub>, 8 percent H<sub>2</sub>O, 7 percent O<sub>2</sub>, and 5 percent CO<sub>2</sub>. Determine the effective emissivity of the combustion gases (Fig. 13–40).

**SOLUTION** The temperature, pressure, and composition of a gas mixture is given. The emissivity of the mixture is to be determined.

**Assumptions** 1 All the gases in the mixture are ideal gases. 2 The emissivity determined is the mean emissivity for radiation emitted to all surfaces of the cylindrical enclosure.

**FIGURE 13–40**  
Schematic for Example 13–14.

**Analysis** The volumetric analysis of a gas mixture gives the mole fractions  $y_i$  of the components, which are equivalent to pressure fractions for an ideal gas mixture. Therefore, the partial pressures of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  are

$$\begin{aligned}P_c &= y_{\text{CO}_2} P = 0.05(2 \text{ atm}) = 0.10 \text{ atm} \\P_w &= y_{\text{H}_2\text{O}} P = 0.08(2 \text{ atm}) = 0.16 \text{ atm}\end{aligned}$$

The mean beam length for a cylinder of equal diameter and height for radiation emitted to all surfaces is, from Table 13–4,

$$L = 0.60D = 0.60(5 \text{ m}) = 3 \text{ m}$$

Then,

$$P_c L = (0.10 \text{ atm})(3 \text{ m}) = 0.30 \text{ m} \cdot \text{atm} = 0.98 \text{ ft} \cdot \text{atm}$$

$$P_w L = (0.16 \text{ atm})(3 \text{ m}) = 0.48 \text{ m} \cdot \text{atm} = 1.57 \text{ ft} \cdot \text{atm}$$

The emissivities of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  corresponding to these values at the gas temperature of  $T_g = 1200 \text{ K}$  and 1 atm are, from Figure 13–37,

$$\varepsilon_{c, 1 \text{ atm}} = 0.16 \quad \text{and} \quad \varepsilon_{w, 1 \text{ atm}} = 0.23$$

These are the base emissivity values at 1 atm, and they need to be corrected for the 2 atm total pressure. Noting that  $(P_w + P)/2 = (0.16 + 2)/2 = 1.08 \text{ atm}$ , the pressure correction factors are, from Figure 13–38,

$$C_c = 1.1 \quad \text{and} \quad C_w = 1.4$$

Both  $\text{CO}_2$  and  $\text{H}_2\text{O}$  are present in the same mixture, and we need to correct for the overlap of emission bands. The emissivity correction factor at  $T = T_g = 1200 \text{ K}$  is, from Figure 13–39,

$$\left. \begin{aligned}P_c L + P_w L &= 0.98 + 1.57 = 2.55 \\ \frac{P_w}{P_w + P_c} &= \frac{0.16}{0.16 + 0.10} = 0.615\end{aligned} \right\} \Delta\varepsilon = 0.048$$

Then the effective emissivity of the combustion gases becomes

$$\varepsilon_g = C_c \varepsilon_{c, 1 \text{ atm}} + C_w \varepsilon_{w, 1 \text{ atm}} - \Delta\varepsilon = 1.1 \times 0.16 + 1.4 \times 0.23 - 0.048 = 0.45$$

**Discussion** This is the average emissivity for radiation emitted to all surfaces of the cylindrical enclosure. For radiation emitted towards the center of the base, the mean beam length is  $0.71D$  instead of  $0.60D$ , and the emissivity value would be different.

**FIGURE 13–41**  
Schematic for Example 13–15.

### EXAMPLE 13–15 Radiation Heat Transfer in a Cylindrical Furnace

Reconsider the cylindrical furnace discussed in Example 13–14. For a wall temperature of 600 K, determine the absorptivity of the combustion gases and the rate of radiation heat transfer from the combustion gases to the furnace walls (Fig. 13–41).

**SOLUTION** The temperatures for the wall surfaces and the combustion gases are given for a cylindrical furnace. The absorptivity of the gas mixture and the rate of radiation heat transfer are to be determined.

**Assumptions** 1 All the gases in the mixture are ideal gases. 2 All interior surfaces of furnace walls are black. 3 Scattering by soot and other particles is negligible.

**Analysis** The average emissivity of the combustion gases at the gas temperature of  $T_g = 1200$  K was determined in the preceding example to be  $\varepsilon_g = 0.45$ . For a source temperature of  $T_s = 600$  K, the absorptivity of the gas is again determined using the emissivity charts as

$$P_c L \frac{T_s}{T_g} = (0.10 \text{ atm})(3 \text{ m}) \frac{600 \text{ K}}{1200 \text{ K}} = 0.15 \text{ m}\cdot\text{atm} = 0.49 \text{ ft}\cdot\text{atm}$$

$$P_w L \frac{T_s}{T_g} = (0.16 \text{ atm})(3 \text{ m}) \frac{600 \text{ K}}{1200 \text{ K}} = 0.24 \text{ m}\cdot\text{atm} = 0.79 \text{ ft}\cdot\text{atm}$$

The emissivities of CO<sub>2</sub> and H<sub>2</sub>O corresponding to these values at a temperature of  $T_s = 600$  K and 1 atm are, from Figure 13–37,

$$\varepsilon_{c, 1 \text{ atm}} = 0.11 \quad \text{and} \quad \varepsilon_{w, 1 \text{ atm}} = 0.25$$

The pressure correction factors were determined in the preceding example to be  $C_c = 1.1$  and  $C_w = 1.4$ , and they do not change with surface temperature. Then the absorptivities of CO<sub>2</sub> and H<sub>2</sub>O become

$$\alpha_c = C_c \left( \frac{T_g}{T_s} \right)^{0.65} \varepsilon_{c, 1 \text{ atm}} = (1.1) \left( \frac{1200 \text{ K}}{600 \text{ K}} \right)^{0.65} (0.11) = 0.19$$

$$\alpha_w = C_w \left( \frac{T_g}{T_s} \right)^{0.45} \varepsilon_{w, 1 \text{ atm}} = (1.4) \left( \frac{1200 \text{ K}}{600 \text{ K}} \right)^{0.45} (0.25) = 0.48$$

Also  $\Delta\alpha = \Delta\varepsilon$ , but the emissivity correction factor is to be evaluated from Figure 13–39 at  $T = T_s = 600$  K instead of  $T_g = 1200$  K. There is no chart for 600 K in the figure, but we can read  $\Delta\varepsilon$  values at 400 K and 800 K, and take their average. At  $P_w/(P_w + P_c) = 0.615$  and  $P_c L + P_w L = 2.55$  we read  $\Delta\varepsilon = 0.027$ . Then the absorptivity of the combustion gases becomes

$$\alpha_g = \alpha_c + \alpha_w - \Delta\alpha = 0.19 + 0.48 - 0.027 = \mathbf{0.64}$$

The surface area of the cylindrical surface is

$$A_s = \pi D H + 2 \frac{\pi D^2}{4} = \pi(5 \text{ m})(5 \text{ m}) + 2 \frac{\pi(5 \text{ m})^2}{4} = 118 \text{ m}^2$$

Then the net rate of radiation heat transfer from the combustion gases to the walls of the furnace becomes

$$\begin{aligned} \dot{Q}_{\text{net}} &= A_s \sigma (\varepsilon_g T_g^4 - \alpha_g T_s^4) \\ &= (118 \text{ m}^2)(5.67 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4)[0.45(1200 \text{ K})^4 - 0.64(600 \text{ K})^4] \\ &= \mathbf{5.69 \times 10^6 \text{ W}} \end{aligned}$$

**Discussion** The heat transfer rate determined above is for the case of black wall surfaces. If the surfaces are not black but the surface emissivity  $\varepsilon_s$  is greater than 0.7, the heat transfer rate can be determined by multiplying the rate of heat transfer already determined by  $(\varepsilon_s + 1)/2$ .

## TOPIC OF SPECIAL INTEREST\*

**FIGURE 13-42**

Mechanisms of heat loss from the human body and relative magnitudes for a resting person.

*Heat Transfer from the Human Body*

The metabolic heat generated in the body is dissipated to the environment through the skin and the lungs by convection and radiation as *sensible heat* and by evaporation as *latent heat* (Fig. 13-42). Latent heat represents the heat of vaporization of water as it evaporates in the lungs and on the skin by absorbing body heat, and latent heat is released as the moisture condenses on cold surfaces. The warming of the inhaled air represents sensible heat transfer in the lungs and is proportional to the temperature rise of inhaled air. The total rate of heat loss from the body can be expressed as

$$\begin{aligned}\dot{Q}_{\text{body, total}} &= \dot{Q}_{\text{skin}} + \dot{Q}_{\text{lungs}} \\ &= (\dot{Q}_{\text{sensible}} + \dot{Q}_{\text{latent}})_{\text{skin}} + (\dot{Q}_{\text{sensible}} + \dot{Q}_{\text{latent}})_{\text{lungs}} \\ &= (\dot{Q}_{\text{convection}} + \dot{Q}_{\text{radiation}} + \dot{Q}_{\text{latent}})_{\text{skin}} + (\dot{Q}_{\text{convection}} + \dot{Q}_{\text{latent}})_{\text{lungs}}\end{aligned}\quad (13-60)$$

Therefore, the determination of heat transfer from the body by analysis alone is difficult. Clothing further complicates the heat transfer from the body, and thus we must rely on experimental data. Under steady conditions, the total rate of heat transfer from the body is equal to the rate of metabolic heat generation in the body, which varies from about 100 W for light office work to roughly 1000 W during heavy physical work.

*Sensible heat loss* from the skin depends on the temperatures of the skin, the environment, and the surrounding surfaces as well as the air motion. The *latent heat loss*, on the other hand, depends on the skin wettedness and the relative humidity of the environment as well. *Clothing* serves as insulation and reduces both the sensible and latent forms of heat loss. The heat transfer from the lungs through respiration obviously depends on the frequency of breathing and the volume of the lungs as well as the environmental factors that affect heat transfer from the skin.

Sensible heat from the clothed skin is first transferred to the clothing and then from the clothing to the environment. The convection and radiation heat losses from the outer surface of a clothed body can be expressed as

$$\dot{Q}_{\text{conv}} = h_{\text{conv}} A_{\text{clothing}} (T_{\text{clothing}} - T_{\text{ambient}}) \quad (13-61)$$

$$\dot{Q}_{\text{rad}} = h_{\text{rad}} A_{\text{clothing}} (T_{\text{clothing}} - T_{\text{surr}}) \quad (W) \quad (13-62)$$

where

$h_{\text{conv}}$  = convection heat transfer coefficient, as given in Table 13-5

$h_{\text{rad}}$  = radiation heat transfer coefficient,  $4.7 \text{ W/m}^2 \cdot \text{K}$  for typical indoor conditions; the emissivity is assumed to be 0.95, which is typical

$A_{\text{clothing}}$  = outer surface area of a clothed person

$T_{\text{clothing}}$  = average temperature of exposed skin and clothing

$T_{\text{ambient}}$  = ambient air temperature

$T_{\text{surr}}$  = average temperature of the surrounding surfaces

\*This section can be skipped without a loss of continuity.

The convection heat transfer coefficients at 1 atm pressure are given in Table 13–5. Convection coefficients at pressures  $P$  other than 1 atm are obtained by multiplying the values at atmospheric pressure by  $P^{0.55}$  where  $P$  is in atm. Also, it is recognized that the temperatures of different surfaces surrounding a person are probably different, and  $T_{\text{surr}}$  represents the **mean radiation temperature**, which is the temperature of an imaginary isothermal enclosure in which radiation heat exchange with the human body equals the radiation heat exchange with the actual enclosure. Noting that most clothing and building materials are very nearly black, the *mean radiation temperature* of an enclosure that consists of  $N$  surfaces at different temperatures can be determined from

$$T_{\text{surr}} \cong F_{\text{person-1}} T_1 + F_{\text{person-2}} T_2 + \dots + F_{\text{person-}N} T_N \quad (13-63)$$

where  $T_i$  is the *temperature of the surface  $i$*  and  $F_{\text{person-}i}$  is the *view factor* between the person and surface  $i$ .

*Total sensible heat loss* can also be expressed conveniently by combining the convection and radiation heat losses as

$$\dot{Q}_{\text{conv+rad}} = h_{\text{combined}} A_{\text{clothing}} (T_{\text{clothing}} - T_{\text{operative}}) \quad (13-64)$$

$$= (h_{\text{conv}} + h_{\text{rad}}) A_{\text{clothing}} (T_{\text{clothing}} - T_{\text{operative}}) \quad (13-65)$$

where the **operative temperature**  $T_{\text{operative}}$  is the average of the mean radiant and ambient temperatures weighed by their respective convection and radiation heat transfer coefficients and is expressed as (Fig. 13–43)

$$T_{\text{operative}} = \frac{h_{\text{conv}} T_{\text{ambient}} + h_{\text{rad}} T_{\text{surr}}}{h_{\text{conv}} + h_{\text{rad}}} \cong \frac{T_{\text{ambient}} + T_{\text{surr}}}{2} \quad (13-66)$$

Note that the operative temperature will be the arithmetic average of the ambient and surrounding surface temperatures when the convection and radiation heat transfer coefficients are equal to each other. Another environmental index used in thermal comfort analysis is the **effective temperature**, which combines the effects of temperature and humidity. Two environments with the same effective temperature evokes the same thermal response in people even though they are at different temperatures and humidities.

Heat transfer through the *clothing* can be expressed as

$$\dot{Q}_{\text{conv+rad}} = \frac{A_{\text{clothing}} (T_{\text{skin}} - T_{\text{clothing}})}{R_{\text{clothing}}} \quad (13-67)$$

where  $R_{\text{clothing}}$  is the **unit thermal resistance of clothing** in  $\text{m}^2 \cdot \text{K}/\text{W}$ , which involves the combined effects of conduction, convection, and radiation between the skin and the outer surface of clothing. The thermal resistance of clothing is usually expressed in the unit **clo** where  $1 \text{ clo} = 0.155 \text{ m}^2 \cdot \text{K}/\text{W} = 0.880 \text{ ft}^2 \cdot ^\circ\text{F} \cdot \text{h}/\text{Btu}$ . The thermal resistance of trousers, long-sleeve shirt, long-sleeve sweater, and T-shirt is 1.0 clo, or  $0.155 \text{ m}^2 \cdot \text{K}/\text{W}$ . Summer clothing such as light slacks and short-sleeved shirt has an insulation value of 0.5 clo, whereas winter clothing such as heavy slacks, long-sleeve shirt, and a sweater or jacket has an insulation value of 0.9 clo.

TABLE 13–5

Convection heat transfer coefficients for a clothed body at 1 atm ( $V$  is in m/s) (compiled from various sources)

| Activity   | $h_{\text{conv}},^*$<br>$\text{W}/\text{m}^2 \cdot \text{K}$ |
|--|--|
| Seated in air moving at<br>$0 < V < 0.2 \text{ m/s}$                 | 3.1  |
| $0.2 < V < 4 \text{ m/s}$  | $8.3V^{0.6}$   |
| Walking in still air at<br>$0.5 < V < 2 \text{ m/s}$                 | $8.6V^{0.53}$  |
| Walking on treadmill<br>in still air at<br>$0.5 < V < 2 \text{ m/s}$ | $6.5V^{0.39}$  |
| Standing in moving air at<br>$0 < V < 0.15 \text{ m/s}$              | 4.0  |
| $0.15 < V < 1.5 \text{ m/s}$   | $14.8V^{0.69}$   |

\*At pressures other than 1 atm, multiply by  $P^{0.55}$ , where  $P$  is in atm.

(a) Convection and radiation, separate

(b) Convection and radiation, combined

FIGURE 13–43

Heat loss by convection and radiation from the body can be combined into a single term by defining an equivalent operative temperature.

**FIGURE 13-44**

Simplified thermal resistance network for heat transfer from a clothed person.

**FIGURE 13-45**

An average person can lose heat at a rate of up to 730 W by evaporation.

Then the total sensible heat loss can be expressed in terms of the skin temperature instead of the inconvenient clothing temperature as (Fig. 13-44)

$$\dot{Q}_{\text{conv} + \text{rad}} = \frac{A_{\text{clothing}} (T_{\text{skin}} - T_{\text{operative}})}{R_{\text{clothing}} + \frac{1}{h_{\text{combined}}}} \quad (13-68)$$

At a state of thermal comfort, the average skin temperature of the body is observed to be 33°C (91.5°F). No discomfort is experienced as the skin temperature fluctuates by  $\pm 1.5^\circ\text{C}$  (2.5°F). This is the case whether the body is clothed or unclothed.

**Evaporative or latent heat loss** from the skin is proportional to the difference between the water vapor pressure at the skin and the ambient air, and the skin wettedness, which is a measure of the amount of moisture on the skin. It is due to the combined effects of the *evaporation of sweat* and the *diffusion of water through the skin*, and can be expressed as

$$\dot{Q}_{\text{latent}} = \dot{m}_{\text{vapor}} h_{fg} \quad (13-69)$$

where

$\dot{m}_{\text{vapor}}$  = the rate of evaporation from the body, kg/s

$h_{fg}$  = the enthalpy of vaporization of water = 2430 kJ/kg at 30°C

Heat loss by evaporation is maximum when the skin is completely wetted. Also, clothing offers resistance to evaporation, and the rate of evaporation in clothed bodies depends on the moisture permeability of the clothes. The maximum evaporation rate for an average man is about 1 L/h (0.3 g/s), which represents an upper limit of 730 W for the evaporative cooling rate. A person can lose as much as 2 kg of water per hour during a workout on a hot day, but any excess sweat slides off the skin surface without evaporating (Fig. 13-45).

During *respiration*, the inhaled air enters at ambient conditions and exhaled air leaves nearly saturated at a temperature close to the deep body temperature (Fig. 13-46). Therefore, the body loses both sensible heat by convection and latent heat by evaporation from the lungs, and these can be expressed as

$$\dot{Q}_{\text{conv, lungs}} = \dot{m}_{\text{air, lungs}} c_{p, \text{air}} (T_{\text{exhale}} - T_{\text{ambient}}) \quad (13-70)$$

$$\dot{Q}_{\text{latent, lungs}} = \dot{m}_{\text{vapor, lungs}} h_{fg} = \dot{m}_{\text{air, lungs}} (\omega_{\text{exhale}} - \omega_{\text{ambient}}) h_{fg} \quad (13-71)$$

where

$\dot{m}_{\text{air, lungs}}$  = rate of air intake to the lungs, kg/s

$c_{p, \text{air}}$  = specific heat of air = 1.0 kJ/kg·K

$T_{\text{exhale}}$  = temperature of exhaled air

$\omega$  = humidity ratio (the mass of moisture per unit mass of dry air)

The rate of air intake to the lungs is directly proportional to the metabolic rate  $\dot{Q}_{\text{met}}$ . The rate of total heat loss from the lungs through respiration can be expressed approximately as

$$\dot{Q}_{\text{conv} + \text{latent, lungs}} = 0.0014 \dot{Q}_{\text{met}} (34 - T_{\text{ambient}}) + 0.0173 \dot{Q}_{\text{met}} (5.87 - P_{v, \text{ambient}}) \quad (13-72)$$

where  $P_{v, \text{ambient}}$  is the vapor pressure of ambient air in kPa.

The fraction of sensible heat varies from about 40 percent in the case of heavy work to about 70 percent during light work. The rest of the energy is rejected from the body by perspiration in the form of latent heat.

### EXAMPLE 13–16 Effect of Clothing on Thermal Comfort

It is well established that a clothed or unclothed person feels comfortable when the skin temperature is about 33°C. Consider an average man wearing summer clothes whose thermal resistance is 0.6 clo. The man feels very comfortable while standing in a room maintained at 22°C. The air motion in the room is negligible, and the interior surface temperature of the room is about the same as the air temperature. If this man were to stand in that room unclothed, determine the temperature at which the room must be maintained for him to feel thermally comfortable.

**SOLUTION** A man wearing summer clothes feels comfortable in a room at 22°C. The room temperature at which this man would feel thermally comfortable when unclothed is to be determined.

**Assumptions** 1 Steady conditions exist. 2 The latent heat loss from the person remains the same. 3 The heat transfer coefficients remain the same.

**Analysis** The body loses heat in sensible and latent forms, and the sensible heat consists of convection and radiation heat transfer. At low air velocities, the convection heat transfer coefficient for a standing man is given in Table 13–5 to be 4.0 W/m<sup>2</sup>·K. The radiation heat transfer coefficient at typical indoor conditions is 4.7 W/m<sup>2</sup>·K. Therefore, the surface heat transfer coefficient for a standing person for combined convection and radiation is

$$h_{\text{combined}} = h_{\text{conv}} + h_{\text{rad}} = 4.0 + 4.7 = 8.7 \text{ W/m}^2 \cdot \text{K}$$

The thermal resistance of the clothing is given to be

$$R_{\text{clothing}} = 0.6 \text{ clo} = 0.6 \times 0.155 \text{ m}^2 \cdot \text{K/W} = 0.093 \text{ m}^2 \cdot \text{K/W}$$

Noting that the surface area of an average man is 1.8 m<sup>2</sup>, the sensible heat loss from this person when clothed is determined to be (Fig. 13–47)

$$\begin{aligned} \dot{Q}_{\text{sensible, clothed}} &= \frac{A_s(T_{\text{skin}} - T_{\text{ambient}})}{R_{\text{clothing}} + \frac{1}{h_{\text{combined}}}} = \frac{(1.8 \text{ m}^2)(33 - 22)^\circ\text{C}}{0.093 \text{ m}^2 \cdot \text{K/W} + \frac{1}{8.7 \text{ W/m}^2 \cdot \text{K}}} \\ &= 95.2 \text{ W} \end{aligned}$$

From a heat transfer point of view, taking the clothes off is equivalent to removing the clothing insulation or setting  $R_{\text{clothing}} = 0$ . The heat transfer in this case can be expressed as

$$\dot{Q}_{\text{sensible, unclothed}} = \frac{A_s(T_{\text{skin}} - T_{\text{ambient}})}{\frac{1}{h_{\text{combined}}}} = \frac{(1.8 \text{ m}^2)(33 - T_{\text{ambient}})^\circ\text{C}}{8.7 \text{ W/m}^2 \cdot \text{K}}$$

FIGURE 13–46

Part of the metabolic heat generated in the body is rejected to the air from the lungs during respiration.

FIGURE 13–47

Schematic for Example 13–16.

FIGURE 13-48

Clothing serves as insulation, and the room temperature needs to be raised when a person is unclothed to maintain the same comfort level.

To maintain thermal comfort after taking the clothes off, the skin temperature of the person and the rate of heat transfer from him must remain the same. Then setting the equation above equal to 95.2 W gives

$$T_{\text{ambient}} = 26.9^{\circ}\text{C}$$

Therefore, the air temperature needs to be raised from 22 to 26.9°C to ensure that the person feels comfortable in the room after he takes his clothes off (Fig. 13-48).

**Discussion** Note that the effect of clothing on latent heat is assumed to be negligible in the solution above. We also assumed the surface area of the clothed and unclothed person to be the same for simplicity, and these two effects should counteract each other.

## SUMMARY

Radiation heat transfer between surfaces depends on the orientation of the surfaces relative to each other. In a radiation analysis, this effect is accounted for by the geometric parameter *view factor*. The *view factor* from a surface *i* to a surface *j* is denoted by  $F_{i \rightarrow j}$  or  $F_{ij}$ , and is defined as the fraction of the radiation leaving surface *i* that strikes surface *j* directly. The view factors between differential and finite surfaces are expressed as

$$\begin{aligned} dF_{dA_1 \rightarrow dA_2} &= \frac{\dot{Q}_{dA_1 \rightarrow dA_2}}{\dot{Q}_{dA_1}} = \frac{\cos \theta_1 \cos \theta_2}{\pi r^2} dA_2 \\ F_{dA_1 \rightarrow A_2} &= \int_{A_2} \frac{\cos \theta_1 \cos \theta_2}{\pi r^2} dA_2 \\ F_{12} = F_{A_1 \rightarrow A_2} &= \frac{\dot{Q}_{A_1 \rightarrow A_2}}{\dot{Q}_{A_1}} = \frac{1}{A_1} \int_{A_2} \int_{A_1} \frac{\cos \theta_1 \cos \theta_2}{\pi r^2} dA_1 dA_2 \end{aligned}$$

where  $r$  is the distance between  $dA_1$  and  $dA_2$ , and  $\theta_1$  and  $\theta_2$  are the angles between the normals of the surfaces and the line that connects  $dA_1$  and  $dA_2$ .

The view factor  $F_{i \rightarrow i}$  represents the fraction of the radiation leaving surface *i* that strikes itself directly;  $F_{i \rightarrow i} = 0$  for *plane* or *convex* surfaces and  $F_{i \rightarrow i} \neq 0$  for *concave* surfaces. For view factors, the *reciprocity rule* is expressed as

$$A_i F_{i \rightarrow j} = A_j F_{j \rightarrow i}$$

The sum of the view factors from surface *i* of an enclosure to all surfaces of the enclosure, including to itself, must equal unity. This is known as the *summation rule* for an enclosure. The *superposition rule* is expressed as the view factor from a surface *i* to a surface *j* is equal to the sum of the view factors from surface *i* to the parts of surface *j*. The *symmetry rule* is expressed as if the surfaces *j* and *k* are symmetric about the surface *i* then  $F_{i \rightarrow j} = F_{i \rightarrow k}$ .

The rate of net radiation heat transfer between two *black* surfaces is determined from

$$\dot{Q}_{1 \rightarrow 2} = A_1 F_{1 \rightarrow 2} \sigma (T_1^4 - T_2^4)$$

The *net* radiation heat transfer from any surface *i* of a *black* enclosure is determined by adding up the net radiation heat transfers from surface *i* to each of the surfaces of the enclosure:

$$\dot{Q}_i = \sum_{j=1}^N \dot{Q}_{i \rightarrow j} = \sum_{j=1}^N A_i F_{i \rightarrow j} \sigma (T_i^4 - T_j^4)$$

The total radiation energy leaving a surface per unit time and per unit area is called the *radiosity* and is denoted by  $J$ . The *net* rate of radiation heat transfer from a surface *i* of surface area  $A_i$  is expressed as

$$\dot{Q}_i = \frac{E_{bi} - J_i}{R_i}$$

where

$$R_i = \frac{1 - \varepsilon_i}{A_i \varepsilon_i}$$

is the *surface resistance* to radiation. The *net* rate of radiation heat transfer from surface *i* to surface *j* can be expressed as

$$\dot{Q}_{i \rightarrow j} = \frac{J_i - J_j}{R_{i \rightarrow j}}$$

where

$$R_{i \rightarrow j} = \frac{1}{A_i F_{i \rightarrow j}}$$

is the *space resistance* to radiation. The *network method* is applied to radiation enclosure problems by drawing a surface resistance associated with each surface of an enclosure and

connecting them with space resistances. Then the problem is solved by treating it as an electrical network problem where the radiation heat transfer replaces the current and the radiosity replaces the potential. The *direct method* is based on the following two equations:

$$\text{Surfaces with specified net heat transfer rate } \dot{Q}_i \quad \dot{Q}_i = A_i \sum_{j=1}^N F_{i \rightarrow j} (J_i - J_j)$$

$$\text{Surfaces with specified temperature } T_i \quad \sigma T_i^4 = J_i + \frac{1 - \varepsilon_i}{\varepsilon_i} \sum_{j=1}^N F_{i \rightarrow j} (J_i - J_j)$$

The first and the second groups of equations give  $N$  linear algebraic equations for the determination of the  $N$  unknown radiosities for an  $N$ -surface enclosure. Once the radiosities  $J_1, J_2, \dots, J_N$  are available, the unknown surface temperatures and heat transfer rates can be determined from the equations just shown.

The net rate of radiation transfer between any two gray, diffuse, opaque surfaces that form an enclosure is given by

$$\dot{Q}_{12} = \frac{\sigma(T_1^4 - T_2^4)}{\frac{1 - \varepsilon_1}{A_1 \varepsilon_1} + \frac{1}{A_1 F_{12}} + \frac{1 - \varepsilon_2}{A_2 \varepsilon_2}}$$

Radiation heat transfer between two surfaces can be reduced greatly by inserting between the two surfaces thin, high-reflectivity (low-emissivity) sheets of material called *radiation shields*. Radiation heat transfer between two large parallel plates separated by  $N$  radiation shields is

$$\dot{Q}_{12, N \text{ shields}} = \frac{A \sigma (T_1^4 - T_2^4)}{\left( \frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1 \right) + \dots + \left( \frac{1}{\varepsilon_{N,1}} + \frac{1}{\varepsilon_{N,2}} - 1 \right)}$$

The radiation effect in temperature measurements can be properly accounted for by

$$T_f = T_{\text{th}} + \frac{\varepsilon \sigma (T_{\text{th}}^4 - T_w^4)}{h}$$

where  $T_f$  is the actual fluid temperature,  $T_{\text{th}}$  is the temperature value measured by the thermometer, and  $T_w$  is the temperature of the surrounding walls, all in K.

Gases with asymmetric molecules such as  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{CO}$ ,  $\text{SO}_2$ , and hydrocarbons  $\text{H}_n\text{C}_m$  participate in the radiation process by absorption and emission. The *spectral transmissivity*, *absorptivity*, and *emissivity* of a medium are expressed as

$$\tau_\lambda = e^{-\kappa_\lambda L}, \quad \alpha_\lambda = 1 - \tau_\lambda = 1 - e^{-\kappa_\lambda L}, \quad \text{and} \\ \varepsilon_\lambda = \alpha_\lambda = 1 - e^{-\kappa_\lambda L}$$

where  $\kappa_\lambda$  is the *spectral absorption coefficient* of the medium.

The emissivities of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  gases are given in Figure 13–36 for a total pressure of  $P = 1 \text{ atm}$ . Emissivities at other pressures are determined from

$$\varepsilon_w = C_w \varepsilon_{w, 1 \text{ atm}} \quad \text{and} \quad \varepsilon_c = C_c \varepsilon_{c, 1 \text{ atm}}$$

where  $C_w$  and  $C_c$  are the *pressure correction factors*. For gas mixtures that contain both of  $\text{H}_2\text{O}$  and  $\text{CO}_2$ , the emissivity is determined from

$$\varepsilon_g = \varepsilon_c + \varepsilon_w - \Delta\varepsilon = C_c \varepsilon_{c, 1 \text{ atm}} + C_w \varepsilon_{w, 1 \text{ atm}} - \Delta\varepsilon$$

where  $\Delta\varepsilon$  is the *emissivity correction factor*, which accounts for the overlap of emission bands. The gas absorptivities for radiation emitted by a source at temperature  $T_s$  are determined similarly from

$$\alpha_g = \alpha_c + \alpha_w - \Delta\alpha$$

where  $\Delta\alpha = \Delta\varepsilon$  at the source temperature  $T_s$  and

$$\begin{aligned} \text{CO}_2: \quad \alpha_c &= C_c \times (T_g/T_s)^{0.65} \times \varepsilon_c(T_s, P_c L T_s/T_g) \\ \text{H}_2\text{O}: \quad \alpha_w &= C_w \times (T_g/T_s)^{0.45} \times \varepsilon_w(T_s, P_w L T_s/T_g) \end{aligned}$$

The rate of radiation heat transfer between a gas and a surrounding surface is

$$\text{Black enclosure:} \quad \dot{Q}_{\text{net}} = A_s \sigma (\varepsilon_g T_g^4 - \alpha_g T_s^4)$$

$$\text{Gray enclosure,} \quad \dot{Q}_{\text{net, gray}} = \frac{\varepsilon_s + 1}{2} A_s \sigma (\varepsilon_g T_g^4 - \alpha_g T_s^4)$$

**Radiation Heat Transfer between Surfaces**

**13-28C** Why is the radiation analysis of enclosures that consist of black surfaces relatively easy? How is the rate of radiation heat transfer between two surfaces expressed in this case?

**13-29C** How does radiosity for a surface differ from the emitted energy? For what kind of surfaces are these two quantities identical?

**13-30C** What are the radiation surface and space resistances? How are they expressed? For what kind of surfaces is the radiation surface resistance zero?

**13-31C** What is a reradiating surface? What simplifications does a reradiating surface offer in the radiation analysis?

**13-32C** What are the two methods used in radiation analysis? How do these two methods differ?

**13-33** Consider a person whose exposed surface area is  $1.9 \text{ m}^2$ , emissivity is 0.85, and surface temperature is  $30^\circ\text{C}$ . Determine the rate of heat loss from that person by radiation in a large room whose walls are at a temperature of (a)  $300 \text{ K}$  and (b)  $280 \text{ K}$ .

**13-34** Consider two black coaxial parallel circular disks of equal diameter  $D$  that are spaced apart by a distance  $L$ . The top and bottom disks have uniform temperatures of  $500^\circ\text{C}$  and  $520^\circ\text{C}$ , respectively. Determine the radiation heat transfer coefficient  $h_{\text{rad}}$  between the disks if they are spaced apart by  $L = D$ .

FIGURE P13-34

**13-35** Reconsider Prob. 13-34. Using the EES (or other) software, evaluate the effect of the distance  $L$  between the black coaxial parallel disks ( $D = 1 \text{ m}$ ) on the radiation heat transfer coefficient. By varying the distance  $L$  between the disks from 0.05 to 3 m, plot the radiation heat transfer coefficient  $h_{\text{rad}}$  as a function of the distance  $L$  between the disks.

**13-36** Two coaxial parallel disks of equal diameter 1 m are originally placed at a distance of 1 m apart. If both disks behave as black surfaces, determine the new distance between the disks such that there is a 75% reduction in radiation heat transfer rate from the original distance of 1 m.

FIGURE P13-36

**13-37** A row of tubes, equally spaced at a distance that is twice the diameter of the tubes, is positioned between two large parallel plates. The surface temperature of the tubes is constant at  $10^\circ\text{C}$  and the top and bottom plates are at constant temperatures of  $100^\circ\text{C}$  and  $350^\circ\text{C}$ , respectively. If the surfaces behave as blackbody, determine the net radiation heat flux leaving the bottom plate.

FIGURE P13-37

**13-38E** Two black parallel rectangles with dimensions  $3 \text{ ft} \times 5 \text{ ft}$  are spaced apart by a distance of 1 ft. The two parallel rectangles are experiencing radiation heat transfer as black surfaces, where the top rectangle receives a total of 180,000 Btu/h radiation heat transfer rate from the bottom rectangle. If the top rectangle has a uniform temperature of 60°F, determine the temperature of the bottom rectangle.

FIGURE P13-38E

**13-39E** The room shown in Fig. P13-39E is 20 ft by 20 ft wide and 9 ft high. The floor is at 100°F, the walls are at 60°F, and the ceiling is at 40°F. All surfaces are assumed black. Calculate the net radiation heat transfer (a) from floor to walls and (b) from floor to ceiling.

FIGURE P13-39E

**13-40** Two aligned parallel rectangles with dimensions  $6 \text{ m} \times 8 \text{ m}$  are spaced apart by a distance of 2 m. If the two parallel rectangles are experiencing radiation heat transfer as black surfaces, determine the percentage of change in radiation heat transfer rate when the rectangles are moved 8 m apart.

FIGURE P13-40

**13-41** A dryer is shaped like a long semi-cylindrical duct of diameter 1.5 m. The base of the dryer is occupied with water soaked materials to be dried. The base is maintained at a temperature of 370 K, while the dome of the dryer is maintained at 1000 K. If both surfaces behave as blackbody, determine the drying rate per unit length experienced by the wet materials.

FIGURE P13-41

**13-42** A furnace is of cylindrical shape with  $R = H = 2 \text{ m}$ . The base, top, and side surfaces of the furnace are all black and are maintained at uniform temperatures of 500, 700, and 1400 K, respectively. Determine the net rate of radiation heat transfer to or from the top surface during steady operation.

FIGURE P13-42

**13-43** Two parallel disks of diameter  $D = 0.6 \text{ m}$  separated by  $L = 0.4 \text{ m}$  are located directly on top of each other. Both disks are black and are maintained at a temperature of 450 K. The back sides of the disks are insulated, and the environment that the disks are in can be considered to be a blackbody at 300 K. Determine the net rate of radiation heat transfer from the disks to the environment. *Answer: 781 W*

**13-44** Consider a hemispherical furnace of diameter  $D = 5 \text{ m}$  with a flat base, as shown in Fig. P13-44. The dome of the furnace is black, and the base has an emissivity of 0.7. The base and the dome of the furnace are maintained at uniform temperatures of 400 and 1000 K, respectively. Determine the net rate of radiation heat transfer from the dome to the base surface during steady operation. *Answer: 759 kW*

FIGURE P13-44

**13-45** A dryer is shaped like a long semi-cylindrical duct of diameter 2 m. The base of the dryer is occupied with water-soaked materials that are to be dried. The dome of the dryer has a constant temperature of  $500^{\circ}\text{C}$ , while the materials at the base are at  $40^{\circ}\text{C}$ . Both surfaces can be approximated as blackbody. Determine the length of the dryer so that the materials are dried at a rate of  $0.1 \text{ kg/s}$ .

FIGURE P13-45

**13-46** Two parallel black disks are positioned coaxially with a distance of 0.25 m apart in a surrounding with a constant temperature of  $300 \text{ K}$ . The lower disk is  $0.2 \text{ m}$  in diameter and the upper disk is  $0.4 \text{ m}$  in diameter. If the lower disk is heated electrically at  $100 \text{ W}$  to maintain a uniform temperature of  $500 \text{ K}$ , determine the temperature of the upper disk.

FIGURE P13-46

**13-47E** Two parallel disks of diameter  $D = 3 \text{ ft}$  separated by  $L = 2 \text{ ft}$  are located directly on top of each other. The disks are separated by a radiation shield whose emissivity is 0.15. Both disks are black and are maintained at temperatures of  $1200 \text{ R}$  and  $700 \text{ R}$ , respectively. The environment that the disks are in can be considered to be a blackbody at  $540 \text{ R}$ . Determine the net rate of radiation heat transfer through the shield under steady conditions.

FIGURE P13-47E

**13-48** Consider a hot cylindrical surface and a disk oriented as shown in the figure. Both the cylindrical surface and the disk behave as blackbody. The cylinder has a diameter  $D$  and a length  $L$  of  $0.2 \text{ m}$ . The disk of diameter  $D = 0.2 \text{ m}$  is placed coaxially with the cylinder at a distance of  $L = 0.2 \text{ m}$  apart. The cylindrical surface and the disk are maintained at uniform temperatures of  $1000 \text{ K}$  and  $300 \text{ K}$ , respectively. Determine the rate of heat transfer by radiation from cylindrical surface to the disk.

FIGURE P13-48

**13-49** Two infinitely long parallel plates of width  $w$  are located at  $w$  distance apart, as shown in the figure. The two plates behave as black surfaces, where surface  $A_1$  has a temperature of  $700 \text{ K}$  and surface  $A_2$  has a temperature of  $300 \text{ K}$ . Determine the radiation heat flux between the two surfaces.

FIGURE P13-49

- 13–50** Two long parallel 20-cm-diameter cylinders are located 30 cm apart from each other. Both cylinders are black, and are maintained at temperatures 425 K and 275 K. The surroundings can be treated as a blackbody at 300 K. For a 1-m-long section of the cylinders, determine the rates of radiation heat transfer between the cylinders and between the hot cylinder and the surroundings.

FIGURE P13–50

and are maintained at temperatures 425 K and 275 K. The surroundings can be treated as a blackbody at 300 K. For a 1-m-long section of the cylinders, determine the rates of radiation heat transfer between the cylinders and between the hot cylinder and the surroundings.

- 13–51** Two infinitely long parallel plates of width  $w$  are located at  $w$  distance apart, as shown in Fig. P13–51. The two plates behave as black surfaces, where surface 1 has a temperature of 500°C and surface 2 has a temperature of 50°C. Determine the radiation heat flux between the two surfaces.

FIGURE P13–51

- 13–52** Consider two rectangular surfaces perpendicular to each other with a common edge which is 1.6 m long. The horizontal surface is 0.8 m wide and the vertical surface is 1.2 m high. The horizontal surface has an emissivity of 0.75 and is maintained at 400 K. The vertical surface is black and is maintained at 550 K. The back sides of the surfaces are insulated. The surrounding surfaces are at 290 K, and can be considered to have an emissivity of 0.85. Determine the net rate of radiation heat transfers between the two surfaces, and between the horizontal surface and the surroundings.

FIGURE P13–52

- 13–53** A furnace is shaped like a long equilateral-triangular duct where the width of each side is 2 m. Heat is supplied from the base surface, whose emissivity is  $\epsilon_1 = 0.8$ , at a rate of  $800 \text{ W/m}^2$  while the side surfaces, whose emissivities are 0.5, are maintained at 500 K. Neglecting the end effects, determine the temperature of the base surface. Can you treat this geometry as a two-surface enclosure?

- 13–54** Reconsider Prob. 13–53. Using EES (or other) software, investigate the effects of the rate of the heat transfer at the base surface and the temperature of the side surfaces on the temperature of the base surface. Let the rate of heat transfer vary from  $500 \text{ W/m}^2$  to  $1000 \text{ W/m}^2$  and the temperature from 300 K to 700 K. Plot the temperature of the base surface as functions of the rate of heat transfer and the temperature of the side surfaces, and discuss the results.

- 13–55** A solid sphere of 1 m diameter at 600 K is kept in an evacuated equilateral triangular enclosure (a tetrahedron) whose side length is  $L$ . Note that for the sphere to touch the tetrahedron's surfaces, the tetrahedron's side length should be  $L = D\sqrt{6}$ . The emissivity of the sphere is 0.45 and the temperature of the enclosure is 420 K. If heat is generated uniformly within the sphere at a rate of 3100 W, determine (a) the view factor from the enclosure to the sphere and (b) the emissivity of the enclosure.

FIGURE P13–55

**13–56** Consider a long semicylindrical duct of diameter 1.0 m. Heat is supplied from the base surface, which is black, at a rate of  $1200 \text{ W/m}^2$ , while the side surface with an emissivity of 0.4 is maintained at 650 K. Neglecting the end effects, determine the temperature of the base surface.

**13–57** Consider a 20-cm-diameter hemispherical enclosure. The dome is maintained at 600 K and heat is supplied from the dome at a rate of 50 W while the base surface with an emissivity of 0.55 is maintained at 400 K. Determine the emissivity of the dome.

**13–58E** A furnace is shaped like a long semicylindrical duct of diameter  $D = 15 \text{ ft}$ . The base and the dome of the furnace have emissivities of 0.5 and 0.9 and are maintained at uniform temperatures of 550 and 1800 R, respectively. Determine the net rate of radiation heat transfer from the dome to the base surface per unit length during steady operation.

FIGURE P13–58E

**13–59** This question deals with steady-state radiation heat transfer between a sphere ( $r_1 = 30 \text{ cm}$ ) and a circular disk ( $r_2 = 120 \text{ cm}$ ), which are separated by a center-to-center distance  $h = 60 \text{ cm}$ . When the normal to the center of disk passes through the center of the sphere, the radiation view factor is given by

$$F_{12} = 0.5 \left\{ 1 - \left[ 1 + \left( \frac{r_2}{h} \right)^2 \right]^{-0.5} \right\}$$

Surface temperatures of the sphere and the disk are  $600^\circ\text{C}$  and  $200^\circ\text{C}$ , respectively; and their emissivities are 0.9 and 0.5, respectively.

- (a) Calculate the view factors  $F_{12}$  and  $F_{21}$ .
- (b) Calculate the net rate of radiation heat exchange between the sphere and the disk.
- (c) For the given radii and temperatures of the sphere and the disk, the following four possible modifications could increase the net rate of radiation heat exchange: paint each of the two surfaces to alter their emissivities, adjust the distance between them, and provide an (refractory) enclosure. Calculate the net rate of radiation heat exchange between the two bodies if the *best values* are selected for each of the above modifications.

FIGURE P13–59

**13–60** Two very large parallel plates are maintained at uniform temperatures of  $T_1 = 600 \text{ K}$  and  $T_2 = 400 \text{ K}$  and have emissivities  $\varepsilon_1 = 0.5$  and  $\varepsilon_2 = 0.9$ , respectively. Determine the net rate of radiation heat transfer between the two surfaces per unit area of the plates.

**13–61** Reconsider Prob. 13–60. Using EES (or other) software, investigate the effects of the temperature and the emissivity of the hot plate on the net rate of radiation heat transfer between the plates. Let the temperature vary from 500 K to 1000 K and the emissivity from 0.1 to 0.9. Plot the net rate of radiation heat transfer as functions of temperature and emissivity, and discuss the results.

**13–62** Air is flowing between two infinitely large parallel plates. The upper plate is at  $500 \text{ K}$  and has an emissivity of 0.7, while the lower plate is a black surface with temperature at  $330 \text{ K}$ . If the air temperature is  $290 \text{ K}$ , determine the convection heat transfer coefficient associated with the air.

FIGURE P13–62

**13–63** Liquid nitrogen is stored in a spherical tank of 1-m diameter, where tank surface is maintained uniformly at 80 K. The spherical tank is enclosed by a 1.6-m diameter concentric sphere with uniform surface temperature of 273 K. Both spherical surfaces have an emissivity of 0.01, and the gap between the inner sphere and outer sphere is vacuumed. Determine the rate of vaporization for the liquid nitrogen.

FIGURE P13–63

**13–64** Two very long concentric cylinders of diameters  $D_1 = 0.35\text{ m}$  and  $D_2 = 0.5\text{ m}$  are maintained at uniform temperatures of  $T_1 = 950\text{ K}$  and  $T_2 = 500\text{ K}$  and have emissivities  $\varepsilon_1 = 1$  and  $\varepsilon_2 = 0.55$ , respectively. Determine the net rate of radiation heat transfer between the two cylinders per unit length of the cylinders.

**13–65** A long cylindrical black surface fuel rod of diameter 25 mm is shielded by a surface concentric to the rod. The shield has diameter of 50 mm, and its outer surface is exposed to surrounding air at 300 K with a convection heat transfer coefficient of 15 W/m<sup>2</sup>·K. Inner and outer surfaces of the shield have an emissivity of 0.05, and the gap between the fuel rod and the shield is a vacuum. If the shield maintains a uniform temperature of 320 K, determine the surface temperature of the fuel rod.

FIGURE P13–65

**13–66** This experiment is conducted to determine the emissivity of a certain material. A long cylindrical rod of diameter  $D_1 = 0.01\text{ m}$  is coated with this new material and is placed in an evacuated long cylindrical enclosure of diameter  $D_2 = 0.1\text{ m}$  and emissivity  $\varepsilon_2 = 0.95$ , which is cooled externally and maintained at a temperature of 200 K at all times. The rod is heated by passing electric current through it. When steady operating conditions are reached, it is observed that the rod is dissipating electric power at a rate of 8 W per unit of its length and its surface temperature is 500 K. Based on these measurements, determine the emissivity of the coating on the rod.

**13–67** Liquid ammonia is being transported in an insulated tube with an outer diameter of  $D_1 = 4\text{ cm}$  and the outer tube surface temperature is uniform at  $T_1 = 0^\circ\text{C}$ . Exposure to high concentration of gaseous ammonia can cause lung damage. To prevent gaseous ammonia from forming and leaking out, ammonia is transported in its liquid state inside the tube. In addition, the tube is enclosed by an outer concentric cylindrical shield with a diameter of  $D_2 = 8\text{ cm}$ , which gives a vacuumed gap in between the tube and the shield surfaces. Keeping the surface temperature of the shield uniform at  $10^\circ\text{C}$  or lower would prevent the liquid ammonia to vaporize. Both the outer tube and the shield surfaces have the same emissivity of 0.33. The tube is situated in a surrounding at where the natural convection heat transfer coefficient is

3 W/m<sup>2</sup>·K, and both natural convection and radiation heat transfer occur at the outer shield surface. To keep the ammonia inside the tube in its liquid state, determine the surrounding temperature that would maintain temperatures of the outer tube and the shield at the specified values.

**13–68** A hot liquid is being transported inside a long tube with a diameter of 25 mm. The hot liquid causes the tube surface temperature to be  $150^\circ\text{C}$ . To prevent thermal burn hazards, the tube is enclosed with a concentric outer cylindrical cover of 5 cm in diameter allowing a vacuumed gap in between the two surfaces. The concentric outer cover has an emissivity of 0.6 and the outer surface is exposed to natural convection with a heat transfer coefficient of 8 W/m<sup>2</sup>·K and radiation heat transfer with the surrounding at a temperature of  $20^\circ\text{C}$ . Determine the necessary emissivity of the inside tube so that the outer cover temperature is below  $45^\circ\text{C}$  to prevent thermal burns.

**13–69** Two-phase gas-liquid oxygen is stored in a spherical tank of 1-m diameter, where it is maintained at its normal boiling point. The spherical tank is enclosed by a 1.6-m diameter concentric spherical surface at 273 K. Both spherical surfaces have an emissivity of 0.01, and the gap between the inner sphere and outer sphere is vacuumed. Assuming that the spherical tank surface has the same temperature as the oxygen, determine the heat transfer rate at the spherical tank surface.

FIGURE P13–69

**13–70** Two concentric spheres of diameters  $D_1 = 0.3\text{ m}$  and  $D_2 = 0.4\text{ m}$  are maintained at uniform temperatures  $T_1 = 700\text{ K}$  and  $T_2 = 500\text{ K}$  and have emissivities  $\varepsilon_1 = 0.5$  and  $\varepsilon_2 = 0.7$ , respectively. Determine the net rate of radiation heat transfer between the two spheres. Also, determine the convection heat transfer coefficient at the outer surface if both the surrounding medium and the surrounding surfaces are at  $30^\circ\text{C}$ . Assume the emissivity of the outer surface is 0.35.

**13–71** A spherical tank of diameter  $D = 2\text{ m}$  that is filled with liquid nitrogen at  $100\text{ K}$  is kept in an evacuated cubic enclosure whose sides are 3 m long. The emissivities of the spherical tank and the enclosure are  $\varepsilon_1 = 0.1$  and  $\varepsilon_2 = 0.8$ , respectively. If the temperature of the cubic enclosure is measured to be  $240\text{ K}$ , determine the net rate of radiation heat transfer to the liquid nitrogen. *Answer: 228 W*

FIGURE P13-71

**13-72** Repeat Prob. 13-71 by replacing the cubic enclosure by a spherical enclosure whose diameter is 3 m.

**13-73** Reconsider Prob. 13-71. Using EES (or other) software, investigate the effects of the side length and the emissivity of the cubic enclosure, and the emissivity of the spherical tank on the net rate of radiation heat transfer. Let the side length vary from 2.5 m to 5 m and both emissivities from 0.1 to 0.9. Plot the net rate of radiation heat transfer as functions of side length and emissivities, and discuss the results.

**13-74** A 3-m spherical tank storing cold fluid has a uniform surface temperature of  $T_1 = 5^\circ\text{C}$ . The lower temperature of the tank surface is causing condensation of moisture in the air at  $13^\circ\text{C}$  and a dew point at  $10^\circ\text{C}$ . If the outer surface temperature of the tank drops below the dew point, condensation can occur on the surface. The tank is situated in the vicinity of high voltage devices, and water from the condensation on the tank surface can cause electrical hazards. In an attempt to remedy the situation, the tank is enclosed with a concentric outer cover that provides an evacuated gap in the enclosure. On the outer surface, the natural convection heat transfer coefficient is  $3 \text{ W/m}^2\cdot\text{K}$  and radiation exchange with the surrounding is negligible. If the emissivity of the tank and the concentric outer cover is the same at 0.6, determine the necessary gap of the vacuumed enclosure so that the outer cover surface temperature is not below the dew point of  $10^\circ\text{C}$ .

**13-75** A spherical tank, with an inner diameter of  $D_1 = 3 \text{ m}$ , is filled with a solution undergoing an exothermic reaction that heats the surface to a uniform temperature of  $120^\circ\text{C}$ . To prevent thermal burn hazards, the tank is enclosed with a concentric outer cover that provides an evacuated gap of 5 cm in the enclosure. Both spherical surfaces have the same emissivity of 0.5, and the outer surface is exposed to natural convection with a heat transfer coefficient of  $5 \text{ W/m}^2\cdot\text{K}$  and radiation heat transfer with the surrounding at a temperature of  $30^\circ\text{C}$ . Determine whether or not the vacuumed gap is sufficient to keep the outer surface temperature below  $45^\circ\text{C}$  to prevent thermal burns. If not, propose a solution to keep the outer surface temperature below  $45^\circ\text{C}$ .

FIGURE P13-75

**13-76E** A 9-ft-high room with a base area of  $12 \text{ ft} \times 12 \text{ ft}$  is to be heated by electric resistance heaters placed on the ceiling, which is maintained at a uniform temperature of  $90^\circ\text{F}$  at all times. The floor of the room is at  $65^\circ\text{F}$  and has an emissivity of 0.8. The side surfaces are well insulated. Treating the ceiling as a blackbody, determine the rate of heat loss from the room through the floor.

**13-77** Consider a  $4\text{-m} \times 4\text{-m} \times 4\text{-m}$  cubical furnace whose floor and ceiling are black and whose side surfaces are reradiating. The floor and the ceiling of the furnace are maintained at temperatures of  $550 \text{ K}$  and  $1100 \text{ K}$ , respectively. Determine the net rate of radiation heat transfer between the floor and the ceiling of the furnace.

**13-78** Consider a circular grill whose diameter is 0.3 m. The bottom of the grill is covered with hot coal bricks at  $950 \text{ K}$ , while the wire mesh on top of the grill is covered with steaks initially at  $5^\circ\text{C}$ . The distance between the coal bricks and the steaks is 0.20 m. Treating both the steaks and the coal bricks as blackbodies, determine the initial rate of radiation heat transfer from the coal bricks to the steaks. Also, determine the initial rate of radiation heat transfer to the steaks if the side opening of the grill is covered by aluminum foil, which can be approximated as a reradiating surface. *Answers: 928 W, 2085 W*

FIGURE P13-78

**13-79E** Consider a  $10\text{-ft} \times 10\text{-ft} \times 10\text{-ft}$  cubical furnace whose top and side surfaces closely approximate black surfaces and whose base surface has an emissivity  $\varepsilon = 0.7$ . The

base, top, and side surfaces of the furnace are maintained at uniform temperatures of 800 R, 1600 R, and 2400 R, respectively. Determine the net rate of radiation heat transfer between (a) the base and the side surfaces and (b) the base and the top surfaces. Also, determine the net rate of radiation heat transfer to the base surface.

**13–80E**  Reconsider Prob. 13–79E. Using EES (or other) software, investigate the effect of base surface emissivity on the net rates of radiation heat transfer between the base and the side surfaces, between the base and top surfaces, and to the base surface. Let the emissivity vary from 0.1 to 0.9. Plot the rates of heat transfer as a function of emissivity, and discuss the results.

### Radiation Shields and the Radiation Effect

**13–81C** What is a radiation shield? Why is it used?

**13–82C** What is the radiation effect? How does it influence the temperature measurements?

**13–83C** Give examples of radiation effects that affect human comfort.

**13–84** A thin aluminum sheet with an emissivity of 0.15 on both sides is placed between two very large parallel plates, which are maintained at uniform temperatures  $T_1 = 900\text{ K}$  and  $T_2 = 650\text{ K}$  and have emissivities  $\varepsilon_1 = 0.5$  and  $\varepsilon_2 = 0.8$ , respectively. Determine the net rate of radiation heat transfer between the two plates per unit surface area of the plates and compare the result with that without the shield.

FIGURE P13–84

**13–85**  Reconsider Prob. 13–84. Using EES (or other) software, plot the net rate of radiation heat transfer between the two plates as a function of the emissivity of the aluminum sheet as the emissivity varies from 0.05 to 0.25, and discuss the results.

**13–86** A radiation shield that has the same emissivity  $\varepsilon_3$  on both sides is placed between two large parallel plates, which are maintained at uniform temperatures of  $T_1 = 650\text{ K}$  and  $T_2 = 400\text{ K}$  and have emissivities of  $\varepsilon_1 = 0.6$  and  $\varepsilon_2 = 0.9$ , respectively. Determine the emissivity of the radiation shield if the radiation heat transfer between the plates is to be reduced to 15 percent of that without the radiation shield.

**13–87**  Reconsider Prob. 13–86. Using EES (or other) software, investigate the effect of the percent reduction in the net rate of radiation heat transfer between the plates on the emissivity of the radiation shields. Let the percent reduction vary from 40 to 95 percent. Plot the emissivity versus the percent reduction in heat transfer, and discuss the results.

**13–88** Two coaxial cylinders of diameters  $D_1 = 0.10\text{ m}$  and  $D_2 = 0.50\text{ m}$  and emissivities  $\varepsilon_1 = 0.7$  and  $\varepsilon_2 = 0.4$  are maintained at uniform temperatures of  $T_1 = 750\text{ K}$  and  $T_2 = 500\text{ K}$ , respectively. Now a coaxial radiation shield of diameter  $D_3 = 0.20\text{ m}$  and emissivity  $\varepsilon_3 = 0.2$  is placed between the two cylinders. Determine the net rate of radiation heat transfer between the two cylinders per unit length of the cylinders and compare the result with that without the shield.

**13–89**  Reconsider Prob. 13–88. Using EES (or other) software, investigate the effects of the diameter of the outer cylinder and the emissivity of the radiation shield on the net rate of radiation heat transfer between the two cylinders. Let the diameter vary from  $0.25\text{ m}$  to  $0.50\text{ m}$  and the emissivity from 0.05 to 0.35. Plot the rate of radiation heat transfer as functions of the diameter and the emissivity, and discuss the results.

**13–90** Two very large parallel plates are maintained at uniform temperatures of  $T_1 = 1000\text{ K}$  and  $T_2 = 800\text{ K}$  and have emissivities of  $\varepsilon_1 = \varepsilon_2 = 0.5$ , respectively. It is desired to reduce the net rate of radiation heat transfer between the two plates to one-fifth by placing thin aluminum sheets with an emissivity of 0.1 on both sides between the plates. Determine the number of sheets that need to be inserted.

**13–91** Five identical thin aluminum sheets with emissivities of 0.1 on both sides are placed between two very large parallel plates, which are maintained at uniform temperatures of  $T_1 = 800\text{ K}$  and  $T_2 = 450\text{ K}$  and have emissivities of  $\varepsilon_1 = \varepsilon_2 = 0.1$ , respectively. Determine the net rate of radiation heat transfer between the two plates per unit surface area of the plates and compare the result to that without the shield.

**13–92**  Reconsider Prob. 13–91. Using EES (or other) software, investigate the effects of the number of the aluminum sheets and the emissivities of the plates on the net rate of radiation heat transfer between the two plates. Let the number of sheets vary from 1 to 10 and the emissivities of the plates from 0.1 to 0.9. Plot the rate of radiation heat transfer as functions of the number of sheets and the emissivities of the plates, and discuss the results.

**13–93** Two thin radiation shields with emissivities of  $\varepsilon_3 = 0.10$  and  $\varepsilon_4 = 0.15$  on both sides are placed between two very large parallel plates, which are maintained at uniform temperatures  $T_1 = 600\text{ K}$  and  $T_2 = 300\text{ K}$  and have emissivities  $\varepsilon_1 = 0.6$  and  $\varepsilon_2 = 0.7$ , respectively (Fig. P13–93). Determine the net rates of radiation heat transfer between the two plates with and without the shields per unit surface area of the plates, and the temperatures of the radiation shields in steady operation.

FIGURE P13-93

**13-94 PTD** Heat dissipated from an engine in operation can cause hot spots on its surface. If the outer surface of an engine is situated in a place where oil leakage is possible, then when leaked oil comes in contact with the hot spots above the oil's autoignition temperature, it can ignite spontaneously. Consider an engine cover that is made of two large parallel plates. The heat flux from the engine is  $125 \text{ W/m}^2$  and heating the bottom plate to  $300^\circ\text{C}$ . To prevent fire hazard in the event of oil leak on the engine cover, the top plate of the engine cover should be kept below  $150^\circ\text{C}$ . Determine whether the top plate of the engine cover is below  $150^\circ\text{C}$ , if not determine the number of radiation shields that should be positioned in parallel between the plates. Assume all the surfaces have the same emissivity of 0.3.

FIGURE P13-94

**13-95** A thermocouple shielded by aluminum foil of emissivity 0.15 is used to measure the temperature of hot gases flowing in a duct whose walls are maintained at  $T_w = 380 \text{ K}$ . The thermometer shows a temperature reading of  $T_{th} = 530 \text{ K}$ . Assuming the emissivity of the thermocouple junction to be  $\epsilon = 0.7$  and the convection heat transfer coefficient to be  $h = 120 \text{ W/m}^2 \cdot \text{K}$ , determine the actual temperature of the gas. What would the thermometer reading be if no radiation shield was used?

FIGURE P13-95

## Radiation Exchange with Absorbing and Emitting Gases

**13-96C** How does radiation transfer through a participating medium differ from that through a nonparticipating medium?

**13-97C** Define spectral transmissivity of a medium of thickness  $L$  in terms of (a) spectral intensities and (b) the spectral absorption coefficient.

**13-98C** How does the wavelength distribution of radiation emitted by a gas differ from that of a surface at the same temperature?

**13-99C** Define spectral emissivity of a medium of thickness  $L$  in terms of the spectral absorption coefficient.

**13-100** Consider an equimolar mixture of  $\text{CO}_2$  and  $\text{O}_2$  gases at  $800 \text{ K}$  and a total pressure of  $0.5 \text{ atm}$ . For a path length of  $1.2 \text{ m}$ , determine the emissivity of the gas.

**13-101** A cylindrical container whose height and diameter are  $8 \text{ m}$  is filled with a mixture of  $\text{CO}_2$  and  $\text{N}_2$  gases at  $600 \text{ K}$  and  $1 \text{ atm}$ . The partial pressure of  $\text{CO}_2$  in the mixture is  $0.15 \text{ atm}$ . If the walls are black at a temperature of  $450 \text{ K}$ , determine the rate of radiation heat transfer between the gas and the container walls.

**13-102** Repeat Prob. 13-101 by replacing  $\text{CO}_2$  by the  $\text{H}_2\text{O}$  gas.

**13-103** A 3-m-diameter spherical furnace contains a mixture of  $\text{CO}_2$  and  $\text{N}_2$  gases at  $1200 \text{ K}$  and  $1 \text{ atm}$ . The mole fraction of  $\text{CO}_2$  in the mixture is 0.15. If the furnace wall is black and its temperature is to be maintained at  $600 \text{ K}$ , determine the net rate of radiation heat transfer between the gas mixture and the furnace walls.

**13-104** A cubic furnace whose side length is  $6 \text{ m}$  contains combustion gases at  $1000 \text{ K}$  and a total pressure of  $1 \text{ atm}$ . The composition of the combustion gases is 75 percent  $\text{N}_2$ , 9 percent  $\text{H}_2\text{O}$ , 6 percent  $\text{O}_2$ , and 10 percent  $\text{CO}_2$ . Determine the effective emissivity of the combustion gases.

**13-105** In a cogeneration plant, combustion gases at  $1 \text{ atm}$  and  $800 \text{ K}$  are used to preheat water by passing them through 6-m-long, 10-cm-diameter tubes. The inner surface of the tube is black, and the partial pressures of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  in combustion gases are  $0.12 \text{ atm}$  and  $0.18 \text{ atm}$ , respectively. If the tube temperature is  $500 \text{ K}$ , determine the rate of radiation heat transfer from the gases to the tube.

**13-106** A flow-through combustion chamber consists of 15-cm diameter long tubes immersed in water. Compressed air is routed to the tube, and fuel is sprayed into the compressed air. The combustion gases consist of 70 percent  $\text{N}_2$ , 9 percent  $\text{H}_2\text{O}$ , 15 percent  $\text{O}_2$ , and 6 percent  $\text{CO}_2$ , and are maintained at  $1 \text{ atm}$  and  $1500 \text{ K}$ . The tube surfaces are near black, with an emissivity of 0.9. If the tubes are to be maintained at a temperature of  $600 \text{ K}$ , determine the rate of heat transfer from combustion gases to tube wall by radiation per m length of tube.

**13-107** Repeat Prob. 13-106 for a total pressure of 3 atm.

**13-108** A gas at 1200 K and 1 atm consists of 10 percent CO<sub>2</sub>, 10 percent H<sub>2</sub>O, 10 percent O<sub>2</sub>, and 70 percent N<sub>2</sub> by volume. The gas flows between two large parallel black plates maintained at 600 K. If the plates are 20 cm apart, determine the rate of heat transfer from the gas to each plate per unit surface area.

### Special Topic: Heat Transfer from the Human Body

**13-109C** Explain all the different mechanisms of heat transfer from the human body (*a*) through the skin and (*b*) through the lungs.

**13-110C** What is sensible heat? How is the sensible heat loss from a human body affected by (*a*) skin temperature, (*b*) environment temperature, and (*c*) air motion?

**13-111C** What is latent heat? How is the latent heat loss from the human body affected by (*a*) skin wettedness and (*b*) relative humidity of the environment? How is the rate of evaporation from the body related to the rate of latent heat loss?

**13-112C** How is the insulating effect of clothing expressed? How does clothing affect heat loss from the body by convection, radiation, and evaporation? How does clothing affect heat gain from the sun?

**13-113C** Consider a person who is resting or doing light work. Is it fair to say that roughly one-third of the metabolic heat generated in the body is dissipated to the environment by convection, one-third by evaporation, and the remaining one-third by radiation?

**13-114C** What is operative temperature? How is it related to the mean ambient and radiant temperatures? How does it differ from effective temperature?

**13-115** The convection heat transfer coefficient for a clothed person while walking in still air at a velocity of 0.5 to 2 m/s is given by  $h = 8.6V^{0.53}$ , where  $V$  is in m/s and  $h$  is in W/m<sup>2</sup>·K. Plot the convection coefficient against the walking velocity, and compare the convection coefficients in that range to the average radiation coefficient of about 5 W/m<sup>2</sup>·K.

**13-116** An average (1.82 kg or 4.0 lbm) chicken has a basal metabolic rate of 5.47 W and an average metabolic rate of 10.2 W (3.78 W sensible and 6.42 W latent) during normal activity. If there are 100 chickens in a breeding room, determine the rate of total heat generation and the rate of moisture production in the room. Take the heat of vaporization of water to be 2430 kJ/kg.

**13-117** A person feels very comfortable in his house in light clothing when the thermostat is set at 22°C and the mean radiation temperature (the average temperature of the surrounding surfaces) is also 22°C. During a cold day, the average mean radiation temperature drops to 18°C. To what level must the indoor air temperature be raised to maintain the same level of comfort in the same clothing?

FIGURE P13-117

**13-118** Repeat Prob. 13-117 for a mean radiation temperature of 10°C.

**13-119** Consider a large classroom with 90 students on a hot summer day. All the lights with 2.0 kW of rated power are kept on. The room has no external walls, and thus heat gain through the walls and the roof is negligible. Chilled air is available at 15°C, and the temperature of the return air is not to exceed 25°C. The average rate of metabolic heat generation by a person sitting or doing light work is 115 W (70 W sensible and 45 W latent). Determine the required flow rate of air that needs to be supplied to the room.

**13-120** A car mechanic is working in a shop whose interior space is not heated. Comfort for the mechanic is provided by two radiant heaters that radiate heat at a total rate of 4 kJ/s. About 5 percent of this heat strikes the mechanic directly. The shop and its surfaces can be assumed to be at the ambient temperature, and the emissivity and absorptivity of the mechanic can be taken to be 0.95 and the surface area to be 1.8 m<sup>2</sup>. The mechanic is generating heat at a rate of 350 W, half of which is latent, and is wearing medium clothing with a thermal resistance of 0.7 clo. Determine the lowest ambient temperature in which the mechanic can work comfortably.

FIGURE P13-120

**13–121E** An average person produces 0.50 lbm of moisture while taking a shower and 0.12 lbm while bathing in a tub. Consider a family of four who shower once a day in a bathroom that is not ventilated. Taking the heat of vaporization of water to be 1050 Btu/lbm, determine the contribution of showers to the latent heat load of the air conditioner in summer per day.

**13–122** A clothed or unclothed person feels comfortable when the skin temperature is about 33°C. Consider an average man wearing summer clothes whose thermal resistance is 1.1 clo. The man feels very comfortable while standing in a room maintained at 20°C. If this man were to stand in that room unclothed, determine the temperature at which the room must be maintained for him to feel thermally comfortable. Assume the latent heat loss from the person to remain the same.

*Answer:* 27.8°C

### Review Problems

**13–123** Consider two diffuse surfaces  $A_1$  and  $A_2$  oriented on a spherical surface as shown in the figure. Determine (a) the expression for the view factor  $F_{12}$  in terms of  $A_2$  and  $L$ , and (b) the value of the view factor  $F_{12}$  when  $A_2 = 0.02 \text{ m}^2$  and  $L = 1 \text{ m}$ .

FIGURE P13–123

**13–124** Consider an enclosure consisting of eight surfaces. How many view factors does this geometry involve? How many of these view factors can be determined by the application of the reciprocity and the summation rules?

**13–125** Consider a cylindrical enclosure with  $A_1$ ,  $A_2$ , and  $A_3$  representing the internal base, top, and side surfaces, respectively. Using the length to diameter ratio,  $K = L/D$ , determine (a) the expression for the view factor from the side surface to itself  $F_{33}$  in terms of  $K$  and (b) the value of the view factor  $F_{33}$  for  $L = D$ .

FIGURE P13–125

**13–126** Two parallel back disks are positioned coaxially with a distance of 0.25 m apart. The lower disk is 0.2 m in diameter and the upper disk is 0.4 m in diameter. If the lower disk is heated electrically at 20 W to maintain a uniform temperature of 500 K, determine the temperature of the upper disk.

FIGURE P13–126

**13–127** A simple solar collector is built by placing a 6-cm-diameter clear plastic tube around a garden hose whose outer diameter is 2 cm (Fig. P13–127 on the next page). The hose is painted black to maximize solar absorption, and some plastic rings are used to keep the spacing between the hose and the clear plastic cover constant. The emissivities of the hose surface and the glass cover are 0.9, and the effective sky temperature is estimated to be 15°C. The temperature of the plastic tube is measured to be 40°C, while the ambient air temperature is 25°C. Determine the rate of heat loss from the water in the hose by natural convection and radiation per meter of its length under steady conditions.

*Answers:* 12.7 W, 26.1 W

FIGURE P13-127

**13-128** Two parallel concentric disks, 20 cm and 40 cm in diameter, are separated by a distance of 10 cm. The smaller disk ( $\varepsilon = 0.80$ ) is at a temperature of 300°C. The larger disk ( $\varepsilon = 0.60$ ) is at a temperature of 800°C.

- Calculate the radiation view factors.
- Determine the rate of radiation heat exchange between the two disks.
- Suppose that the space between the two disks is completely surrounded by a reflective surface. Estimate the rate of radiation heat exchange between the two disks.

**13-129** A dryer is shaped like a long semicylindrical duct of diameter 1.5 m. The base of the dryer is occupied with water soaked materials to be dried, and maintained at a temperature of 370 K and emissivity of 0.5. The dome of the dryer is maintained at 1000 K with emissivity of 0.8. Determine the drying rate per unit length experienced by the wet materials.

FIGURE P13-129

**13-130** A large number of long tubes, each of diameter  $D$ , are placed parallel to each other and at a center-to-center distance of  $s$ . Since all of the tubes are geometrically similar and at the same temperature, these could be treated collectively as one surface ( $A_j$ ) for radiation heat transfer calculations. As shown in Fig. P13-130, the tube-bank ( $A_j$ ) is placed opposite a large flat wall ( $A_i$ ) such that the tube-bank is parallel to the wall.

- Calculate the view factors  $F_{ij}$  and  $F_{ji}$  for  $s = 3.0$  cm and  $D = 1.5$  cm.

- Calculate the net rate of radiation heat transfer between the wall and the tube-bank per unit area of the wall when  $T_i = 900^\circ\text{C}$ ,  $T_j = 60^\circ\text{C}$ ,  $\varepsilon_i = 0.8$ , and  $\varepsilon_j = 0.9$ .
- A fluid flows through the tubes at an average temperature of 40°C, resulting in a heat transfer coefficient of 2.0 kW/m<sup>2</sup>·K. Assuming  $T_i = 900^\circ\text{C}$ ,  $\varepsilon_i = 0.8$  and  $\varepsilon_j = 0.9$  (as above) and neglecting the tube wall thickness and convection from the outer surface, calculate the temperature of the tube surface in steady operation.

FIGURE P13-130

**13-131** Consider the two parallel coaxial disks of diameters  $a$  and  $b$ , shown in Fig. P13-131. For this geometry, the view factor from the smaller disk to the larger disk can be calculated from

$$F_{ij} = 0.5 \left( \frac{B}{A} \right)^2 \left\{ C - \left[ C^2 - 4 \left( \frac{A}{B} \right)^2 \right]^{0.5} \right\}$$

where,  $A = a/2L$ ,  $B = b/2L$ , and  $C = 1 + [(1 + A^2)/B^2]$ . The diameter, emissivity and temperature are 20 cm, 0.60, and 600°C, respectively, for disk  $a$ , and 40 cm, 0.80 and 200°C for disk  $b$ . The distance between the two disks is  $L = 10$  cm.

- Calculate  $F_{ab}$  and  $F_{ba}$ .
- Calculate the net rate of radiation heat exchange between disks  $a$  and  $b$  in steady operation.
- Suppose another (infinitely) large disk  $c$ , of negligible thickness and  $\varepsilon = 0.7$ , is inserted between disks  $a$  and  $b$  such that it is parallel and equidistant to both disks. Calculate the net rate of radiation heat exchange between disks  $a$  and  $c$  and disks  $c$  and  $b$  in steady operation.

FIGURE P13-131

**13-132** Two square plates, with the sides  $a$  and  $b$  (and  $b > a$ ), are coaxial and parallel to each other, as shown in Fig. P13-132, and they are separated by a center-to-center distance of  $L$ . The radiation view factor from the smaller to the larger plate,  $F_{ab}$ , is given by

$$F_{ab} = \frac{1}{2A} \left\{ [(B + A)^2 + 4]^{0.5} - [(B - A)^2 + 4]^{0.5} \right\}$$

where,  $A = a/L$  and  $B = b/L$ .

- Calculate the view factors  $F_{ab}$  and  $F_{ba}$  for  $a = 20$  cm,  $b = 60$  cm, and  $L = 40$  cm.

- (b) Calculate the net rate of radiation heat exchange between the two plates described above if  $T_a = 800^\circ\text{C}$ ,  $T_b = 200^\circ\text{C}$ ,  $\varepsilon_a = 0.8$ , and  $\varepsilon_b = 0.4$ .
- (c) A large square plate (with the side  $c = 2.0 \text{ m}$ ,  $\varepsilon_c = 0.1$ , and negligible thickness) is inserted symmetrically between the two plates such that it is parallel to and equidistant from them. For the data given above, calculate the temperature of this third plate when steady operating conditions are established.

FIGURE P13–132

**13–133** A vertical 2-m-high and 5-m-wide double-pane window consists of two sheets of glass separated by a 3-cm-thick air gap. In order to reduce heat transfer through the window, the air space between the two glasses is partially evacuated to 0.3 atm pressure. The emissivities of the glass surfaces are 0.9. Taking the glass surface temperatures across the air gap to be  $15^\circ\text{C}$  and  $5^\circ\text{C}$ , determine the rate of heat transfer through the window by natural convection and radiation.

FIGURE P13–133

**13–134** Consider a 1.5-m-high and 3-m-wide solar collector that is tilted at an angle  $20^\circ$  from the horizontal. The distance between the glass cover and the absorber plate is 3 cm, and the back side of the absorber is heavily insulated. The absorber plate and the glass cover are maintained at temperatures of

$80^\circ\text{C}$  and  $32^\circ\text{C}$ , respectively. The emissivity of the glass surface is 0.9 and that of the absorber plate is 0.8. Determine the rate of heat loss from the absorber plate by natural convection and radiation. *Answers: 750 W, 1289 W*

FIGURE P13–134

**13–135** A 2-m-internal-diameter double-walled spherical tank is used to store iced water at  $0^\circ\text{C}$ . Each wall is 0.5 cm thick, and the 1.5-cm-thick air space between the two walls of the tank is evacuated in order to minimize heat transfer. The surfaces surrounding the evacuated space are polished so that each surface has an emissivity of 0.15. The temperature of the outer wall of the tank is measured to be  $20^\circ\text{C}$ . Assuming the inner wall of the steel tank to be at  $0^\circ\text{C}$ , determine (a) the rate of heat transfer to the iced water in the tank and (b) the amount of ice at  $0^\circ\text{C}$  that melts during a 24-h period.

FIGURE P13–135

**13–136** A solar collector consists of a horizontal copper tube of outer diameter 5 cm enclosed in a concentric thin glass tube of diameter 12 cm. Water is heated as it flows through the tube, and the annular space between the copper and the glass tubes is filled with air at 1 atm pressure. The emissivities of the tube surface and the glass cover are 0.85 and 0.9, respectively. During a clear day, the temperatures of the tube surface and the glass cover are measured to be  $60^\circ\text{C}$  and  $40^\circ\text{C}$ , respectively. Determine the rate of heat loss from

the collector by natural convection and radiation per meter length of the tube.

**13-137** Two concentric spheres of diameters  $D_1 = 15$  cm and  $D_2 = 25$  cm are separated by air at 1 atm pressure. The surface temperatures of the two spheres enclosing the air are  $T_1 = 350$  K and  $T_2 = 275$  K, respectively, and their emissivities are 0.75. Determine the rate of heat transfer from the inner sphere to the outer sphere by (a) natural convection and (b) radiation.

**13-138E**  A solar collector consists of a horizontal aluminum tube having an outer diameter of 2.5 in enclosed in a concentric thin glass tube of diameter 5 in. Water is heated as it flows through the tube, and the annular space between the aluminum and the glass tube is filled with air at 0.5 atm pressure. The pump circulating the water fails during a clear day, and the water temperature in the tube starts rising. The aluminum tube absorbs solar radiation at a rate of 30 Btu/h per foot length, and the temperature of the ambient air outside is 75°F. The emissivities of the tube and the glass cover are 0.9. Taking the effective sky temperature to be 60°F, determine the temperature of the aluminum tube when thermal equilibrium is established (i.e., when the rate of heat loss from the tube equals the amount of solar energy gained by the tube).

**13-139** A long cylindrical black surface fuel rod of diameter 25 mm is shielded by a surface concentric to the rod. The shield has diameter of 50 mm and a constant surface temperature of 320 K. Both inner and outer surfaces of the shield have an emissivity of 0.05, and the gap between the fuel rod and the shield is a vacuum. If the fuel rod is generating 0.5 MW/m<sup>3</sup> of heat per unit length, determine the surface temperature of the fuel rod.

FIGURE P13-139

**13-140** Consider a cubical furnace with a side length of 3 m. The top surface is maintained at 700 K. The base surface has an emissivity of 0.90 and is maintained at 950 K. The side surface is black and is maintained at 450 K. Heat is supplied from the base surface at a rate of 340 kW. Determine the emissivity of the top surface and the net rates of heat transfer between the top and the bottom surfaces, and between the bottom and side surfaces.

**13-141** A furnace is of cylindrical shape with a diameter of 1.2 m and a length of 1.2 m. The top surface has an emissivity of 0.70 and is maintained at 500 K. The bottom surface has an emissivity of 0.50 and is maintained at 650 K. The side surface has an emissivity of 0.40. Heat is supplied from the base surface at a net rate of 1400 W. Determine the temperature of the side surface and the net rates of heat transfer between the top and the bottom surfaces, and between the bottom and side surfaces.

FIGURE P13-141

**13-142** A thin aluminum sheet with an emissivity of 0.12 on both sides is placed between two very large parallel plates maintained at uniform temperatures of  $T_1 = 750$  K and  $T_2 = 400$  K. The emissivities of the plates are  $\varepsilon_1 = 0.8$  and  $\varepsilon_2 = 0.7$ . Determine the net rate of radiation heat transfer between the two plates per unit surface area of the plates, and the temperature of the radiation shield in steady operation.

**13-143** A thermocouple used to measure the temperature of hot air flowing in a duct whose walls are maintained at  $T_w = 500$  K shows a temperature reading of  $T_{th} = 850$  K. Assuming the emissivity of the thermocouple junction to be  $\varepsilon = 0.6$  and the convection heat transfer coefficient to be  $h = 60 \text{ W/m}^2 \cdot \text{K}$ , determine the actual temperature of air.

FIGURE P13-143

**13–144** In a natural-gas fired boiler, combustion gases pass through 6-m-long 15-cm-diameter tubes immersed in water at 1 atm pressure. The tube temperature is measured to be 105°C, and the emissivity of the inner surfaces of the tubes is estimated to be 0.9. Combustion gases enter the tube at 1 atm and 1200 K at a mean velocity of 3 m/s. The mole fractions of CO<sub>2</sub> and H<sub>2</sub>O in combustion gases are 8 percent and 16 percent, respectively. Assuming fully developed flow and using properties of air for combustion gases, determine (a) the rates of heat transfer by convection and by radiation from the combustion gases to the tube wall and (b) the rate of evaporation of water.

**13–145** Repeat Prob. 13–144 for a total pressure of 3 atm for the combustion gases.

### Fundamentals of Engineering (FE) Exam Problems

**13–146** Consider an infinitely long three-sided triangular enclosure with side lengths 2 cm, 3 cm, and 4 cm. The view factor from the 2 cm side to the 4 cm side is

- (a) 0.25    (b) 0.50    (c) 0.64    (d) 0.75    (e) 0.87

**13–147** Consider a 15-cm-diameter sphere placed within a cubical enclosure with a side length of 15 cm. The view factor from any of the square-cube surfaces to the sphere is

- (a) 0.09    (b) 0.26    (c) 0.52    (d) 0.78    (e) 1

**13–148** A 70-cm-diameter flat black disk is placed in the center of the top surface of a 1-m × 1-m × 1-m black box. The view factor from the entire interior surface of the box to the interior surface of the disk is

- (a) 0.077    (b) 0.144    (c) 0.356  
(d) 0.220    (e) 1.0

**13–149** Consider two concentric spheres with diameters 12 cm and 18 cm forming an enclosure. The view factor from the inner surface of the outer sphere to the inner sphere is

- (a) 0    (b) 0.18    (c) 0.44    (d) 0.56    (e) 0.67

**13–150** The number of view factors that need to be evaluated directly for a 10-surface enclosure is

- (a) 1    (b) 10    (c) 22    (d) 34    (e) 45

**13–151** Consider two concentric spheres forming an enclosure with diameters of 12 cm and 18 cm and surface temperatures 300 K and 500 K, respectively. Assuming that the surfaces are black, the net radiation exchange between the two spheres is

- (a) 21 W    (b) 140 W    (c) 160 W  
(d) 1275 W    (e) 3084 W

**13–152** Consider a vertical 2-m-diameter cylindrical furnace whose surfaces closely approximate black surfaces. The base, top, and side surfaces of the furnace are maintained at 400 K, 600 K, and 900 K, respectively. If the view factor from the base surface to the top surface is 0.2, the net radiation heat transfer between the base and the side surfaces is

- (a) 22.5 kW    (b) 38.6 kW    (c) 60.7 kW  
(d) 89.8 kW    (e) 151 kW

**13–153** Consider a vertical 2-m-diameter cylindrical furnace whose surfaces closely approximate black surfaces. The base, top, and side surfaces of the furnace are maintained at 400 K, 600 K, and 900 K, respectively. If the view factor from the base surface to the top surface is 0.2, the net radiation heat transfer from the bottom surface is

- (a) -93.6 kW    (b) -86.1 kW    (c) 0 kW  
(d) 86.1 kW    (e) 93.6 kW

**13–154** A solar flux of 1400 W/m<sup>2</sup> directly strikes a space-vehicle surface which has a solar absorptivity of 0.4 and thermal emissivity of 0.6. The equilibrium temperature of this surface in space at 0 K is

- (a) 300 K    (b) 360 K    (c) 410 K  
(d) 467 K    (e) 510 K

**13–155** A 70-cm-diameter flat black disk is placed at the center of the ceiling of a 1-m × 1-m × 1-m black box. If the temperature of the box is 620°C and the temperature of the disk is 27°C, the rate of heat transfer by radiation between the interior of the box and the disk is

- (a) 2 kW    (b) 5 kW    (c) 8 kW    (d) 11 kW    (e) 14 kW

**13–156** Consider two infinitely long concentric cylinders with diameters 20 and 25 cm. The inner surface is maintained at 700 K and has an emissivity of 0.40, while the outer surface is black. If the rate of radiation heat transfer from the inner surface to the outer surface is 2400 W per unit area of the inner surface, the temperature of the outer surface is

- (a) 605 K    (b) 538 K    (c) 517 K    (d) 451 K    (e) 415 K

**13–157** Consider a surface at 0°C that may be assumed to be a blackbody in an environment at 25°C. If 300 W/m<sup>2</sup> of radiation is incident on the surface, the radiosity of this black surface is

- (a) 0 W/m<sup>2</sup>    (b) 15 W/m<sup>2</sup>    (c) 132 W/m<sup>2</sup>  
(d) 300 W/m<sup>2</sup>    (e) 315 W/m<sup>2</sup>

**13–158** Consider a gray and opaque surface at 0°C in an environment at 25°C. The surface has an emissivity of 0.8. If the radiation incident on the surface is 240 W/m<sup>2</sup>, the radiosity of the surface is

- (a) 38 W/m<sup>2</sup>    (b) 132 W/m<sup>2</sup>    (c) 240 W/m<sup>2</sup>  
(d) 300 W/m<sup>2</sup>    (e) 315 W/m<sup>2</sup>

**13–159** Consider a 3-m × 3-m × 3-m cubical furnace. The base surface is black and has a temperature of 400 K. The radiosities for the top and side surfaces are calculated to be 7500 W/m<sup>2</sup> and 3200 W/m<sup>2</sup>, respectively. If the temperature of the side surfaces is 485 K, the emissivity of the side surfaces is

- (a) 0.37    (b) 0.55    (c) 0.63    (d) 0.80    (e) 0.89

**13–160** The base surface of a cubical furnace with a side length of 3 m has an emissivity of 0.80 and is maintained at 500 K. If the top and side surfaces also have an emissivity of 0.80 and are maintained at 900 K, the net rate of radiation heat transfer from the top and side surfaces to the bottom surface is

- (a) 194 kW    (b) 233 kW    (c) 288 kW  
(d) 312 kW    (e) 242 kW

**13–161** Two gray surfaces that form an enclosure exchange heat with one another by thermal radiation. Surface 1 has a temperature of 400 K, an area of  $0.2 \text{ m}^2$ , and a total emissivity of 0.4. Surface 2 has a temperature of 600 K, an area of  $0.3 \text{ m}^2$ , and a total emissivity of 0.6. If the view factor  $F_{12}$  is 0.3, the rate of radiation heat transfer between the two surfaces is

- (a) 135 W      (b) 223 W      (c) 296 W  
 (d) 342 W      (e) 422 W

**13–162** The surfaces of a two-surface enclosure exchange heat with one another by thermal radiation. Surface 1 has a temperature of 400 K, an area of  $0.2 \text{ m}^2$ , and a total emissivity of 0.4. Surface 2 is black, has a temperature of 600 K, and an area of  $0.3 \text{ m}^2$ . If the view factor  $F_{12}$  is 0.3, the rate of radiation heat transfer between the two surfaces is

- (a) 87 W      (b) 135 W      (c) 244 W  
 (d) 342 W      (e) 386 W

**13–163** Two concentric spheres are maintained at uniform temperatures  $T_1 = 45^\circ\text{C}$  and  $T_2 = 280^\circ\text{C}$  and have emissivities  $\varepsilon_1 = 0.25$  and  $\varepsilon_2 = 0.7$ , respectively. If the ratio of the diameters is  $D_1/D_2 = 0.30$ , the net rate of radiation heat transfer between the two spheres per unit surface area of the inner sphere is

- (a)  $86 \text{ W/m}^2$       (b)  $1169 \text{ W/m}^2$       (c)  $1181 \text{ W/m}^2$   
 (d)  $2510 \text{ W/m}^2$       (e)  $3306 \text{ W/m}^2$

**13–164** Consider a  $3\text{-m} \times 3\text{-m} \times 3\text{-m}$  cubical furnace. The base surface of the furnace is black and has a temperature of 400 K. The radiosities for the top and side surfaces are calculated to be  $7500 \text{ W/m}^2$  and  $3200 \text{ W/m}^2$ , respectively. The net rate of radiation heat transfer to the bottom surface is

- (a) 2.61 kW      (b) 8.27 kW      (c) 14.7 kW  
 (d) 23.5 kW      (e) 141 kW

**13–165** Two very large parallel plates are maintained at uniform temperatures  $T_1 = 750 \text{ K}$  and  $T_2 = 500 \text{ K}$  and have emissivities  $\varepsilon_1 = 0.85$  and  $\varepsilon_2 = 0.7$ , respectively. If a thin aluminum sheet with the same emissivity on both sides is to be placed between the plates in order to reduce the net rate of radiation heat transfer between the plates by 90 percent, the emissivity of the aluminum sheet must be

- (a) 0.07      (b) 0.10      (c) 0.13      (d) 0.16      (e) 0.19

### Design and Essay Problems

**13–166** Consider an enclosure consisting of  $N$  diffuse and gray surfaces. The emissivity and temperature of each surface as well as the view factors between the surfaces are specified. Write a program to determine the net rate of radiation heat transfer for each surface.

**13–167** Radiation shields are commonly used in the design of superinsulations for use in space and cryogenics applications. Write an essay on superinsulations and how they are used in different applications.

**13–168** Thermal comfort in a house is strongly affected by the so-called radiation effect, which is due to radiation heat transfer between the person and surrounding surface. A person feels much colder in the morning, for example, because of the lower surface temperature of the walls at that time, although the thermostat setting of the house is fixed. Write an essay on the radiation effect, how it affects human comfort, and how it is accounted for in heating and air-conditioning applications.

## MASS TRANSFER

To this point we have restricted our attention to heat transfer problems that did not involve any mass transfer. However, many significant heat transfer problems encountered in practice involve mass transfer. For example, about one-third of the heat loss from a resting person is due to evaporation. It turns out that mass transfer is analogous to heat transfer in many respects, and there is close resemblance between heat and mass transfer relations. In this chapter we discuss the mass transfer mechanisms and develop relations for mass transfer rate for situations commonly encountered in practice.

Distinction should be made between *mass transfer* and the *bulk fluid motion* (or *fluid flow*) that occurs on a macroscopic level as a fluid is transported from one location to another. Mass transfer requires the presence of two regions at different chemical compositions, and mass transfer refers to the movement of a chemical species from a high concentration region toward a lower concentration one. The primary driving force for fluid flow is the *pressure difference*, whereas for mass transfer it is the *concentration difference*.

We begin this chapter by pointing out numerous analogies between heat and mass transfer and draw several parallels between them. We then discuss boundary conditions associated with mass transfer and one-dimensional steady and transient mass diffusion, followed by a discussion of mass transfer in a moving medium. Finally, we consider convection mass transfer and simultaneous heat and mass transfer.

### OBJECTIVES

When you finish studying this chapter, you should be able to:

- Understand the concentration gradient and the physical mechanism of mass transfer,
- Recognize the analogy between heat and mass transfer,
- Describe the concentration at a location on mass or mole basis, and relate the rate of diffusion to the concentration gradient by Fick's law,
- Calculate the rate of mass diffusion through a plane layer under steady conditions,
- Predict the migration of water vapor in buildings,
- Perform a transient mass diffusion analysis in large mediums,
- Calculate mass transfer by convection, and
- Analyze simultaneous heat and mass transfer.

## 14–1 • INTRODUCTION

It is a common observation that whenever there is an imbalance of a commodity in a medium, nature tends to redistribute it until a “balance” or “equality” is established. This tendency is often referred to as the *driving force*, which is the mechanism behind many naturally occurring transport phenomena.

If we define the amount of a commodity per unit volume as the **concentration** of that commodity, we can say that the flow of a commodity is always in the direction of decreasing concentration; that is, from the region of high concentration to the region of low concentration (Fig. 14–1). The commodity simply creeps away during redistribution, and thus the flow is a *diffusion process*. The rate of flow of the commodity is proportional to the *concentration gradient*  $dC/dx$ , which is the change in the concentration  $C$  per unit length in the flow direction  $x$ , and the area  $A$  normal to flow direction, and is expressed as

$$\text{Flow rate} \propto (\text{Normal area})(\text{Concentration gradient})$$

or

$$\dot{Q} = -k_{\text{diff}} A \frac{dC}{dx} \quad (14-1)$$

Here the proportionality constant  $k_{\text{diff}}$  is the *diffusion coefficient* of the medium, which is a measure of how fast a commodity diffuses in the medium, and the negative sign is to make the flow in the positive direction a positive quantity (note that  $dC/dx$  is a negative quantity since concentration decreases in the flow direction). *Fourier's law of heat conduction*, *Ohm's law of electrical conduction*, and *Newton's law of viscosity* are all in the form of Eq. 14–1.

To understand the diffusion process better, consider a tank that is divided into two equal parts by a partition. Initially, the left half of the tank contains nitrogen  $N_2$  gas while the right half contains air (about 21 percent  $O_2$  and 79 percent  $N_2$ ) at the same temperature and pressure. The  $O_2$  and  $N_2$  molecules are indicated by dark and light circles, respectively. When the partition is removed, we know that the  $N_2$  molecules will start diffusing into the air while the  $O_2$  molecules diffuse into the  $N_2$ , as shown in Fig. 14–2. If we wait long enough, we will have a homogeneous mixture of  $N_2$  and  $O_2$  in the tank. This mass diffusion process can be explained by considering an imaginary plane indicated by the dashed line in the figure as: Gas molecules move randomly, and thus the probability of a molecule moving to the right or to the left is the same. Consequently, half of the molecules on one side of the dashed line at any given moment will move to the other side. Since the concentration of  $N_2$  is greater on the left side than it is on the right side, more  $N_2$  molecules will move toward the right than toward the left, resulting in a net flow of  $N_2$  toward the right. As a result,  $N_2$  is said to be *transferred* to the right. A similar argument can be given for  $O_2$  being transferred to the left. The process continues until uniform concentrations of  $N_2$  and  $O_2$  are established throughout the tank so that the number of  $N_2$  (or  $O_2$ ) molecules moving to the right equals the number moving to the left, resulting in zero net transfer of  $N_2$  or  $O_2$  across an imaginary plane.

The molecules in a gas mixture continually collide with each other, and the diffusion process is strongly influenced by this collision process. The collision of like molecules is of little consequence since both molecules

**FIGURE 14–1**

Whenever there is concentration difference of a physical quantity in a medium, nature tends to equalize things by forcing a flow from the high to the low concentration region.

**FIGURE 14–2**

A tank that contains  $N_2$  and air in its two compartments, and the diffusion of  $N_2$  into the air (and the diffusion of  $O_2$  into  $N_2$ ) when the partition is removed.

are identical and it makes no difference which molecule crosses a certain plane. The collisions of unlike molecules, however, influence the rate of diffusion since unlike molecules may have different masses and thus different momentums, and thus the diffusion process is dominated by the heavier molecules. The diffusion coefficients and thus diffusion rates of gases depend strongly on *temperature* since the temperature is a measure of the average velocity of gas molecules. Therefore, the diffusion rates are higher at higher temperatures.

Mass transfer can also occur in liquids and solids as well as in gases. For example, a cup of water left in a room eventually evaporates as a result of water molecules diffusing into the air (*liquid-to-gas mass transfer*). A piece of solid CO<sub>2</sub> (dry ice) also gets smaller and smaller in time as the CO<sub>2</sub> molecules diffuse into the air (*solid-to-gas mass transfer*). A spoon of sugar in a cup of coffee eventually moves up and sweetens the coffee although the sugar molecules are much heavier than the water molecules, and the molecules of a colored pencil inserted into a glass of water diffuses into the water as evidenced by the gradual spread of color in the water (*solid-to-liquid mass transfer*). Of course, mass transfer can also occur from a gas to a liquid or solid if the concentration of the species is higher in the gas phase. For example, a small fraction of O<sub>2</sub> in the air diffuses into the water and meets the oxygen needs of marine animals. The diffusion of carbon into iron during case-hardening, doping of semiconductors for transistors, and the migration of doped molecules in semiconductors at high temperature are examples of solid-to-solid diffusion processes (Fig. 14–3).

Another factor that influences the diffusion process is the *molecular spacing*. The larger the spacing, in general, the higher the diffusion rate. Therefore, the diffusion rates are typically much higher in gases than they are in liquids and much higher in liquids than in solids. Diffusion coefficients in gas mixtures are a few orders of magnitude larger than these of liquid or solid solutions.

## 14–2 • ANALOGY BETWEEN HEAT AND MASS TRANSFER

We have spent a considerable amount of time studying heat transfer, and we could spend just as much time studying mass transfer. However, the mechanisms of heat and mass transfer are analogous to each other, and thus we can develop an understanding of mass transfer in a short time with little effort by simply drawing *parallels* between heat and mass transfer. Establishing those “bridges” between the two seemingly unrelated areas will make it possible to use our heat transfer knowledge to solve mass transfer problems. Alternately, gaining a working knowledge of mass transfer will help us to better understand the heat transfer processes by thinking of heat as a massless substance as they did in the nineteenth century. The short-lived caloric theory of heat is the origin of most heat transfer terminology used today and served its purpose well until it was replaced by the kinetic theory. Mass is, in essence, energy since mass and energy can be converted to each other according to Einstein’s formula  $E = mc^2$ , where  $c$  is the speed of light. Therefore, we can look at mass and heat as two different forms of energy and exploit this to advantage without going overboard.

**FIGURE 14–3**  
Some examples of mass transfer that involve a liquid and/or a solid.

**FIGURE 14-4**

Analogy between heat and mass transfer.

**FIGURE 14-5**

Unlike heat radiation, there is no such thing as mass radiation.

**FIGURE 14-6**

Analogy between heat conduction and mass diffusion.

## Temperature

The driving force for heat transfer is the *temperature difference*. In contrast, the driving force for mass transfer is the *concentration difference*. We can view temperature as a measure of “heat concentration,” and thus a high temperature region as one that has a high heat concentration (Fig. 14-4). Therefore, both heat and mass are transferred from the more concentrated regions to the less concentrated ones. If there is no temperature difference between two regions, then there is no heat transfer. Likewise, if there is no difference between the concentrations of a species at different parts of a medium, there will be no mass transfer.

## Conduction

You will recall that heat is transferred by conduction, convection, and radiation. Mass, however, is transferred by *conduction* (called diffusion) and *convection* only, and there is no such thing as “mass radiation” (unless there is something Scotty knows that we don’t when he “beams” people to anywhere in space at the speed of light) (Fig. 14-5). The rate of heat conduction in a direction  $x$  is proportional to the temperature gradient  $dT/dx$  in that direction and is expressed by **Fourier’s law of heat conduction** as

$$\dot{Q}_{\text{cond}} = -kA \frac{dT}{dx} \quad (14-2)$$

where  $k$  is the thermal conductivity of the medium and  $A$  is the area normal to the direction of heat transfer. Likewise, the rate of mass diffusion  $\dot{m}_{\text{diff}}$  of a chemical species  $A$  in a stationary medium in the direction  $x$  is proportional to the concentration gradient  $dC/dx$  in that direction and is expressed by **Fick’s law of diffusion** by (Fig. 14-6)

$$\dot{m}_{\text{diff}} = -D_{AB}A \frac{dC_A}{dx} \quad (14-3)$$

where  $D_{AB}$  is the **diffusion coefficient** (or *mass diffusivity*) of the species in the mixture and  $C_A$  is the concentration of the species in the mixture at that location.

It can be shown that the differential equations for both heat conduction and mass diffusion are of the same form. Therefore, the solutions of mass diffusion equations can be obtained from the solutions of corresponding heat conduction equations for the same type of boundary conditions by simply switching the corresponding coefficients and variables.

## Heat Generation

Heat generation refers to the conversion of some form of energy such as electrical, chemical, or nuclear energy into *sensible thermal* energy in the medium. Heat generation occurs throughout the medium and exhibits itself as a rise in temperature. Similarly, some mass transfer problems involve chemical reactions that occur within the medium and result in the *generation of a species* throughout. Therefore, species generation is a *volumetric phenomenon*, and the rate of generation may vary from point to point in the medium. Such reactions that occur within the medium are called **homogeneous reactions** and are analogous to internal heat generation.

In contrast, some chemical reactions result in the generation of a species *at the surface* as a result of chemical reactions occurring at the surface due to contact between the medium and the surroundings. This is a *surface phenomenon*, and as such it needs to be treated as a boundary condition. In mass transfer studies, such reactions are called **heterogeneous reactions** and are analogous to *specified surface heat flux*.

## Convection

You may recall that *heat convection* is the heat transfer mechanism that involves both *heat conduction* (molecular diffusion) and *bulk fluid motion*. Fluid motion enhances heat transfer considerably by removing the heated fluid near the surface and replacing it by the cooler fluid farther away. In the limiting case of no bulk fluid motion, convection reduces to conduction. Likewise, **mass convection** (or *convective mass transfer*) is the mass transfer mechanism between a surface and a moving fluid that involves both *mass diffusion* and *bulk fluid motion*. Fluid motion also enhances mass transfer considerably by removing the high concentration fluid near the surface and replacing it by the lower concentration fluid farther away. In mass convection, we define a *concentration boundary layer* in an analogous manner to the thermal boundary layer and define new dimensionless numbers that are counterparts of the Nusselt and Prandtl numbers.

The rate of heat convection for external flow was expressed conveniently by *Newton's law of cooling* as

$$\dot{Q}_{\text{conv}} = h_{\text{conv}} A_s (T_s - T_\infty) \quad (14-4)$$

where  $h_{\text{conv}}$  is the heat transfer coefficient,  $A_s$  is the surface area, and  $T_s - T_\infty$  is the temperature difference across the thermal boundary layer. Likewise, the rate of mass convection can be expressed as (Fig. 14-7)

$$\dot{m}_{\text{conv}} = h_{\text{mass}} A_s (C_s - C_\infty) \quad (14-5)$$

where  $h_{\text{mass}}$  is the *mass transfer coefficient*,  $A_s$  is the surface area, and  $C_s - C_\infty$  is a suitable concentration difference across the concentration boundary layer.

Various aspects of the analogy between heat and mass convection are explored in Section 14-9. The analogy is valid for *low mass transfer rate* cases in which the flow rate of species undergoing mass flow is low (under 10 percent) relative to the total flow rate of the liquid or gas mixture.

## 14-3 • MASS DIFFUSION

Fick's law of diffusion, proposed in 1855, states that the rate of diffusion of a chemical species at a location in a gas mixture (or liquid or solid solution) is proportional to the *concentration gradient* of that species at that location. Although a higher concentration for a species means more molecules of that species per unit volume, the concentration of a species can be expressed in several ways. Next we describe two common ways.

### 1 Mass Basis

On a *mass basis*, concentration is expressed in terms of **density** (or *mass concentration*), which is mass per unit volume. Considering a small volume  $V$  at

**FIGURE 14-7**

Analogy between convection heat transfer and convection mass transfer.

Mass basis:

$$\rho_A = \frac{m_A}{V}, \quad \rho = \frac{m}{V}, \quad w_A = \frac{\rho_A}{\rho}$$

Mole basis:

$$C_A = \frac{N_A}{V}, \quad C = \frac{N}{V}, \quad y_A = \frac{C_A}{C}$$

Relation between them:

$$C_A = \frac{\rho_A}{M_A}, \quad w_A = y_A \frac{M_A}{M}$$

**FIGURE 14–8**

Different ways of expressing the concentration of species A of a binary mixture A and B.

a location within the mixture, the densities of a species (subscript  $i$ ) and of the mixture (no subscript) at that location are given by (Fig. 14–8)

$$\text{Partial density of species } i: \quad \rho_i = m_i/V \quad (\text{kg/m}^3)$$

$$\text{Total density of mixture:} \quad \rho = m/V = \sum m_i/V = \sum \rho_i$$

Therefore, the *density of a mixture* at a location is equal to the sum of the *densities of its constituents* at that location. Mass concentration can also be expressed in dimensionless form in terms of **mass fraction**  $w$  as

$$\text{Mass fraction of species } i: \quad w_i = \frac{m_i}{m} = \frac{m_i/V}{m/V} = \frac{\rho_i}{\rho} \quad (14-6)$$

Note that the mass fraction of a species ranges between 0 and 1, and the conservation of mass requires that the sum of the mass fractions of the constituents of a mixture be equal to 1. That is,  $\sum w_i = 1$ . Also note that the density and mass fraction of a constituent in a mixture, in general, vary with location unless the concentration gradients are zero.

## 2 Mole Basis

On a *mole basis*, concentration is expressed in terms of **molar concentration** (or *molar density*), which is the amount of matter in kmol per unit volume. Again considering a small volume  $V$  at a location within the mixture, the molar concentrations of a species (subscript  $i$ ) and of the mixture (no subscript) at that location are given by

$$\text{Partial molar concentration of species } i: \quad C_i = N_i/V \quad (\text{kmol/m}^3)$$

$$\text{Total molar concentration of mixture:} \quad C = N/V = \sum N_i/V = \sum C_i$$

Therefore, the molar concentration of a mixture at a location is equal to the sum of the molar concentrations of its constituents at that location. Molar concentration can also be expressed in dimensionless form in terms of **mole fraction**  $y$  as

$$\text{Mole fraction of species } i: \quad y_i = \frac{N_i}{N} = \frac{N_i/V}{N/V} = \frac{C_i}{C} \quad (14-7)$$

Again the mole fraction of a species ranges between 0 and 1, and the sum of the mole fractions of the constituents of a mixture is unity,  $\sum y_i = 1$ .

The mass  $m$  and mole number  $N$  of a substance are related to each other by  $m = NM$  (or, for a unit volume,  $\rho = CM$ ) where  $M$  is the *molar mass* (also called the *molecular weight*) of the substance. This is expected since the mass of 1 kmol of the substance is  $M$  kg, and thus the mass of  $N$  kmol is  $NM$  kg. Therefore, the mass and molar concentrations are related to each other by

$$C_i = \frac{\rho_i}{M_i} \quad (\text{for species } i) \quad \text{and} \quad C = \frac{\rho}{M} \quad (\text{for the mixture}) \quad (14-8)$$

where  $M$  is the molar mass of the mixture which can be determined from

$$M = \frac{m}{N} = \frac{\sum N_i M_i}{N} = \sum \frac{N_i}{N} M_i = \sum y_i M_i \quad (14-9)$$

The mass and mole fractions of species  $i$  of a mixture are related to each other by

$$w_i = \frac{\rho_i}{\rho} = \frac{C_i M_i}{CM} = y_i \frac{M_i}{M} \quad (14-10)$$

Two different approaches are presented above for the description of concentration at a location, and you may be wondering which approach is better to use. Well, the answer depends on the situation on hand. Both approaches are equivalent, and the better approach for a given problem is the one that yields the desired solution more easily.

## Special Case: Ideal Gas Mixtures

At low pressures, a gas or gas mixture can conveniently be approximated as an ideal gas with negligible error. For example, a mixture of dry air and water vapor at atmospheric conditions can be treated as an ideal gas with an error much less than 1 percent. The total pressure of a gas mixture  $P$  is equal to the sum of the partial pressures  $P_i$  of the individual gases in the mixture and is expressed as  $P = \sum P_i$ . Here  $P_i$  is called the **partial pressure** of species  $i$ , which is the pressure species  $i$  would exert if it existed alone at the mixture temperature and volume. This is known as **Dalton's law of additive pressures**. Then using the ideal gas relation  $PV = NR_u T$  where  $R_u$  is the universal gas constant for both the species  $i$  and the mixture, the **pressure fraction** of species  $i$  can be expressed as (Fig. 14-9)

$$\frac{P_i}{P} = \frac{N_i R_u T / V}{N R_u T / V} = \frac{N_i}{N} = y_i \quad (14-11)$$

Therefore, the *pressure fraction* of species  $i$  of an ideal gas mixture is equivalent to the *mole fraction* of that species and can be used in place of it in mass transfer analysis.

## Fick's Law of Diffusion: Stationary Medium

### Consisting of Two Species

We mentioned earlier that the rate of mass diffusion of a chemical species in a stagnant medium in a specified direction is proportional to the local concentration gradient in that direction. This linear relationship between the rate of diffusion and the concentration gradient proposed by Fick in 1855 is known as **Fick's law of diffusion** and can be expressed as

$$\text{Mass flux} = \text{Constant of proportionality} \times \text{Concentration gradient}$$

But the concentration of a species in a gas mixture or liquid or solid solution can be defined in several ways such as density, mass fraction, molar concentration, and mole fraction, as already discussed, and thus Fick's law can be expressed mathematically in many ways. It turns out that it is best to express the concentration gradient in terms of the mass or mole fraction, and the most appropriate formulation of *Fick's law* for the diffusion of a species  $A$  in a stationary binary mixture of species  $A$  and  $B$  in a specified direction  $x$  is given by (Fig. 14-10)

$$\text{Mass basis: } j_{\text{diff}, A} = \frac{\dot{m}_{\text{diff}, A}}{A} = -\rho D_{AB} \frac{d(\rho_A/\rho)}{dx} = -\rho D_{AB} \frac{dw_A}{dx} \text{ (kg/s·m}^2\text{)} \quad (14-12)$$

$$\text{Mole basis: } \bar{j}_{\text{diff}, A} = \frac{\dot{N}_{\text{diff}, A}}{A} = -CD_{AB} \frac{d(C_A/C)}{dx} = -CD_{AB} \frac{dy_A}{dx} \text{ (kmol/s·m}^2\text{)}$$

A mixture of two ideal gases  $A$  and  $B$

$$y_A = \frac{N_A}{N} = \frac{2}{2+6} = 0.25$$

$$P_A = y_A P = 0.25 \times 120 = 30 \text{ kPa}$$

**FIGURE 14-9**

For ideal gas mixtures, pressure fraction of a gas is equal to its mole fraction.

Mass basis:

$$\begin{aligned} \dot{m}_{\text{diff}} &= -\rho A D_{AB} \frac{dw_A}{dx} \\ &= -\rho A D_{AB} \frac{d(\rho_A/\rho)}{dx} \\ &= -AD_{AB} \frac{d\rho_A}{dx} \text{ (if } \rho = \text{constant)} \end{aligned}$$

Mole basis:

$$\begin{aligned} \dot{N}_{\text{diff}, A} &= -CAD_{AB} \frac{dy_A}{dx} \\ &= -CAD_{AB} \frac{d(C_A/C)}{dx} \\ &= -AD_{AB} \frac{dC_A}{dx} \text{ (if } C = \text{constant)} \end{aligned}$$

\*Multiply by 10.76 to convert to ft<sup>2</sup>/s.

Here  $j_{\text{diff}, A}$  is the (**diffusive**) **mass flux** of species A (mass transfer by diffusion per unit time and per unit area normal to the direction of mass transfer, in kg/s·m<sup>2</sup>) and  $\bar{j}_{\text{diff}, A}$  is the (**diffusive**) **molar flux** (in kmol/s·m<sup>2</sup>). The mass flux of a species at a location is proportional to the density of the mixture at that location. Note that  $\rho = \rho_A + \rho_B$  is the density and  $C = C_A + C_B$  is the molar concentration of the binary mixture, and in general, they may vary throughout the mixture. Therefore,  $\rho d(\rho_A/\rho) \neq d\rho_A$  or  $Cd(C_A/C) \neq dC_A$ . But in the special case of constant mixture density  $\rho$  or constant molar concentration  $C$ , the relations above simplify to

$$\begin{aligned} \text{Mass basis } (\rho = \text{constant}): \quad j_{\text{diff}, A} &= -D_{AB} \frac{dp_A}{dx} \quad (\text{kg/s} \cdot \text{m}^2) \\ \text{Mole basis } (C = \text{constant}): \quad \bar{j}_{\text{diff}, A} &= -D_{AB} \frac{dC_A}{dx} \quad (\text{kmol/s} \cdot \text{m}^2) \end{aligned} \quad (14-13)$$

The constant density or constant molar concentration assumption is usually appropriate for *solid* and *dilute liquid* solutions, but often this is not the case for gas mixtures or concentrated liquid solutions. Therefore, Eq. 14-12 should be used in the latter case. In this introductory treatment we limit our consideration to one-dimensional mass diffusion. For two- or three-dimensional cases, Fick's law can conveniently be expressed in vector form by simply replacing the derivatives in the above relations by the corresponding gradients (such as  $\mathbf{j}_A = -\rho D_{AB} \nabla w_A$ ).

Remember that the constant of proportionality in Fourier's law was defined as the transport property *thermal conductivity*. Similarly, the constant of proportionality in Fick's law is defined as another transport property called the **binary diffusion coefficient** or **mass diffusivity**,  $D_{AB}$ . The unit of mass diffusivity is m<sup>2</sup>/s, which is the same as the units of *thermal diffusivity* or *momentum diffusivity* (also called *kinematic viscosity*) (Fig. 14-11).

Because of the complex nature of mass diffusion, the diffusion coefficients are usually determined experimentally. The kinetic theory of gases indicates that the diffusion coefficient for dilute gases at ordinary pressures is essentially independent of mixture composition and tends to increase with temperature while decreasing with pressure as

$$D_{AB} \propto \frac{T^{3/2}}{P} \quad \text{or} \quad \frac{D_{AB, 1}}{D_{AB, 2}} = \frac{P_2}{P_1} \left( \frac{T_1}{T_2} \right)^{3/2} \quad (14-14)$$

This relation is useful in determining the diffusion coefficient for gases at different temperatures and pressures from a knowledge of the diffusion coefficient at a specified temperature and pressure. More general but complicated relations that account for the effects of molecular collisions are also available. The diffusion coefficients of some gases in air at 1 atm pressure are given in Table 14-1 at various temperatures.

The diffusion coefficients of solids and liquids also tend to increase with temperature while exhibiting a strong dependence on the composition. The diffusion process in solids and liquids is a great deal more complicated than that in gases, and the diffusion coefficients in this case are almost exclusively determined experimentally.

The binary diffusion coefficients for several binary gas mixtures and solid and liquid solutions are given in Tables 14–2 and 14–3. We make two observations from these tables:

1. The diffusion coefficients, in general, are *highest in gases* and *lowest in solids*. The diffusion coefficients of gases are several orders of magnitude greater than those of liquids.
2. Diffusion coefficients *increase with temperature*. The diffusion coefficient (and thus the mass diffusion rate) of carbon through iron during a hardening process, for example, increases by 6000 times as the temperature is raised from 500°C to 1000°C.

Due to its practical importance, the diffusion of *water vapor* in *air* has been the topic of several studies, and some empirical formulas have been developed for the diffusion coefficient  $D_{\text{H}_2\text{O-air}}$ . Marrero and Mason (1972) proposed this popular formula (Table 14–4):

$$D_{\text{H}_2\text{O-air}} = 1.87 \times 10^{-10} \frac{T^{2.072}}{P} \quad (\text{m}^2/\text{s}), \quad 280 \text{ K} < T < 450 \text{ K} \quad (14-15)$$

where  $P$  is total pressure in atm and  $T$  is the temperature in K.

The primary driving mechanism of mass diffusion is the concentration gradient, and mass diffusion due to a concentration gradient is known as the **ordinary diffusion**. However, diffusion may also be caused by other effects. Temperature gradients in a medium can cause **thermal diffusion** (also called the **soret effect**), and pressure gradients may result in **pressure diffusion**. Both of these effects are usually negligible, however, unless the gradients are very large. In centrifuges, the pressure gradient generated by

**TABLE 14–2**

| 150   | 5.18 × 10 <sup>-5</sup>  |

the centrifugal effect is used to separate liquid solutions and gaseous isotopes. An external force field such as an electric or magnetic field applied on a mixture or solution can be used successfully to separate electrically charged or magnetized molecules (as in an electrolyte or ionized gas) from the mixture. This is called **forced diffusion**. Also, when the pores of a porous solid such as silica-gel are smaller than the mean free path of the gas molecules, the molecular collisions may be negligible and a free molecule flow may be initiated. This is known as **Knudsen diffusion**. When the size of the gas molecules is comparable to the pore size, adsorbed molecules move along the pore walls. This is known as **surface diffusion**. Finally, particles whose diameter is under 0.1 μm such as mist and soot particles act like large molecules, and the diffusion process of such particles due to the concentration gradient is called **Brownian motion**. Large particles (those whose diameter is greater than 1 μm) are not affected by diffusion as the motion of such particles is governed by Newton's laws. In our elementary treatment of mass diffusion, we assume these additional effects to be nonexistent or negligible, as is usually the case, and refer the interested reader to advanced books on these topics.

**EXAMPLE 14–1 Determining Mass Fractions from Mole Fractions**

The composition of dry standard atmosphere is given on a molar basis to be 78.1 percent N<sub>2</sub>, 20.9 percent O<sub>2</sub>, and 1.0 percent Ar and small amounts of other constituents (Fig. 14–12). Treating other constituents as Ar, determine the mass fractions of the constituents of air.

**SOLUTION** The molar fractions of the constituents of air are given. The mass fractions are to be determined.

**Assumptions** The small amounts of other gases in air are treated as argon.

**Properties** The molar masses of N<sub>2</sub>, O<sub>2</sub>, and Ar are 28.0, 32.0, and 39.9 kg/kmol, respectively (Table A–1).

**Analysis** The molar mass of air is determined to be

$$M = \sum y_i M_i = 0.781 \times 28.0 + 0.209 \times 32.0 + 0.01 \times 39.9 = 29.0 \text{ kg/kmol}$$

Then the mass fractions of constituent gases are determined from Eq. 14–10 to be

$$\text{N}_2: w_{\text{N}_2} = y_{\text{N}_2} \frac{M_{\text{N}_2}}{M} = (0.781) \frac{28.0}{29.0} = \mathbf{0.754}$$

$$\text{O}_2: w_{\text{O}_2} = y_{\text{O}_2} \frac{M_{\text{O}_2}}{M} = (0.209) \frac{32.0}{29.0} = \mathbf{0.231}$$

$$\text{Ar: } w_{\text{Ar}} = y_{\text{Ar}} \frac{M_{\text{Ar}}}{M} = (0.01) \frac{39.9}{29.0} = \mathbf{0.014}$$

Therefore, the mass fractions of N<sub>2</sub>, O<sub>2</sub>, and Ar in dry standard atmosphere are 75.4 percent, 23.1 percent, and 1.4 percent, respectively.

**FIGURE 14–12**

Schematic for Example 14–1.

**FIGURE 14–13**

Unlike temperature, the concentration of species on the two sides of a liquid–gas (or solid–gas or solid–liquid) interface are usually not the same.

## 14–4 • BOUNDARY CONDITIONS

We mentioned earlier that the mass diffusion equation is analogous to the heat diffusion (conduction) equation, and thus we need comparable boundary conditions to determine the species concentration distribution in a medium. Two common types of boundary conditions are the (1) *specified species concentration*, which corresponds to specified temperature, and (2) *specified species flux*, which corresponds to specified heat flux.

Despite their apparent similarity, an important difference exists between temperature and concentration: temperature is necessarily a *continuous* function, but concentration, in general, is not. The wall and air temperatures at a wall surface, for example, are always the same. The concentrations of air on the two sides of a water–air interface, however, are obviously very different (in fact, the concentration of air in water is close to zero). Likewise, the concentrations of water on the two sides of a water–air interface are also different even when air is saturated (Fig. 14–13). Therefore, when specifying a boundary condition, specifying the location is not enough. We also need to specify the side of the boundary. To do this, we consider two imaginary surfaces on the two sides of the interface that are infinitesimally close to the interface. Whenever there is a doubt, we indicate the desired side of the interface by specifying its phase as a subscript. For example, the water (liquid or vapor)

**FIGURE 14-14**

An impermeable surface in mass transfer is analogous to an insulated surface in heat transfer.

**TABLE 14-5**

Solubility of two inorganic compounds in water at various temperatures, in kg, in 100 kg of water [from *Handbook of Chemistry* (New York: McGraw-Hill, 1961)]

| 373.15              | 39.8          | 18.40   |

concentration at the liquid and gas sides of a water–air interface at  $x = 0$  can be expressed on a molar basis as

$$y_{\text{H}_2\text{O, liquid side}}(0) = y_1 \quad \text{and} \quad y_{\text{H}_2\text{O, gas side}}(0) = y_2 \quad (14-16)$$

Using Fick's law, the constant species flux boundary condition for a diffusing species  $A$  at a boundary at  $x = 0$  is expressed, in the absence of any blowing or suction, as

$$-CD_{AB} \frac{dy_A}{dx} \Big|_{x=0} = \bar{j}_{A,0} \quad \text{or} \quad -\rho D_{AB} \frac{dw_A}{dx} \Big|_{x=0} = j_{A,0} \quad (14-17)$$

where  $\bar{j}_{A,0}$  and  $j_{A,0}$  are the specified mole and mass fluxes of species  $A$  at the boundary, respectively. The special case of zero mass flux ( $\bar{j}_{A,0} = j_{A,0} = 0$ ) corresponds to an **impermeable surface** for which  $dy_A(0)/dx = dw_A(0)/dx = 0$  (Fig. 14-14).

To apply the *specified concentration* boundary condition, we must know the concentration of a species at the boundary. This information is usually obtained from the requirement that *thermodynamic equilibrium* must exist at the interface of two phases of a species. In the case of air–water interface, the concentration values of water vapor in the air are easily determined from saturation data.

The situation is similar at *solid–liquid* interfaces. Again, at a given temperature, only a certain amount of solid can be dissolved in a liquid, and the solubility of the solid in the liquid is determined from the requirement that thermodynamic equilibrium exists between the solid and the solution at the interface. The **solubility** represents *the maximum amount of solid that can be dissolved in a liquid at a specified temperature* and is widely available in chemistry handbooks. In Table 14-5 we present sample solubility data for sodium chloride (NaCl) and calcium bicarbonate [Ca(HCO<sub>3</sub>)<sub>2</sub>] at various temperatures. For example, the solubility of salt (NaCl) in water at 310 K is 36.5 kg per 100 kg of water. Therefore, the mass fraction of salt in the brine at the interface is simply

$$w_{\text{salt, liquid side}} = \frac{m_{\text{salt}}}{m} = \frac{36.5 \text{ kg}}{(100 + 36.5) \text{ kg}} = 0.267 \quad (\text{or } 26.7 \text{ percent})$$

whereas the mass fraction of salt in the pure solid salt is  $w = 1.0$ . Note that water becomes *saturated* with salt when 36.5 kg of salt are dissolved in 100 kg of water at 310 K.

Many processes involve the absorption of a gas into a liquid. Most gases are weakly soluble in liquids (such as air in water), and for such dilute solutions the mole fractions of a species  $i$  in the gas and liquid phases at the interface are observed to be proportional to each other. That is,  $y_{i, \text{gas side}} \propto y_{i, \text{liquid side}}$  or  $P_{i, \text{gas side}} \propto P y_{i, \text{liquid side}}$  since  $y_{i, \text{gas side}} = P_{i, \text{gas side}}/P$  for ideal gas mixtures. This is known as **Henry's law** and is expressed as

$$y_{i, \text{liquid side}} = \frac{P_{i, \text{gas side}}}{H} \quad (\text{at interface}) \quad (14-18)$$

where  $H$  is **Henry's constant**, which is the ratio of the partial pressure in the gas phase over the mole fraction of the liquid phase. For a given species, it is a function of temperature only and is practically independent of pressure for pressures under about 5 atm. Values of Henry's constant for a number of

**TABLE 14–6**

Henry's constant  $H$  (in bars) for selected gases in water at low to moderate pressures (for gas  $i$ ,  $H = P_{i,\text{gas side}}/y_{i,\text{water side}}$ )  
(from Mills, 1995; Table A.21)

| Solute               | 290 K  | 300 K  | 310 K   | 320 K   | 330 K   | 340 K   |
|----------------------|--------|--------|---------|---------|---------|---------|

| $\text{CO}_2$        | 1280   | 1710   | 2170    | 2720    | 3220    | —       |
| $\text{O}_2$         | 38,000 | 45,000 | 52,000  | 57,000  | 61,000  | 65,000  |
| $\text{H}_2$         | 67,000 | 72,000 | 75,000  | 76,000  | 77,000  | 76,000  |
| $\text{CO}$          | 51,000 | 60,000 | 67,000  | 74,000  | 80,000  | 84,000  |
| Air                  | 62,000 | 74,000 | 84,000  | 92,000  | 99,000  | 104,000 |
| $\text{N}_2$         | 76,000 | 89,000 | 101,000 | 110,000 | 118,000 | 124,000 |

aqueous solutions are given in Table 14–6 for various temperatures. From this table and the equation above we make the following observations:

1. The concentration of a gas dissolved in a liquid is inversely proportional to Henry's constant. Therefore, the larger the Henry's constant, the smaller the concentration of dissolved gases in the liquid.
2. Henry's constant increases (and thus the fraction of a dissolved gas in the liquid decreases) with increasing temperature. Therefore, the dissolved gases in a liquid can be driven off by heating the liquid (Fig. 14–15).
3. The concentration of a gas dissolved in a liquid is proportional to the partial pressure of the gas. Therefore, the amount of gas dissolved in a liquid can be increased by increasing the pressure of the gas. This can be used to advantage in the carbonation of soft drinks with  $\text{CO}_2$  gas.

Strictly speaking, the result obtained from Eq. 14–18 for the mole fraction of dissolved gas is valid for the liquid layer just beneath the interface and not necessarily the entire liquid. The latter will be the case only when thermodynamic phase equilibrium is established throughout the entire liquid body.

### EXAMPLE 14–2 Mole Fraction of Dissolved Air in Water

Determine the mole fraction of air dissolved in water at the surface of a lake whose temperature is  $17^\circ\text{C}$  (Fig. 14–16). Take the atmospheric pressure at lake level to be 92 kPa.

**SOLUTION** The mole fraction of air dissolved in water at the surface of a lake is to be determined.

**Assumptions** 1 Both the air and water vapor are ideal gases. 2 Air is weakly soluble in water so that Henry's law is applicable.

**Properties** The saturation pressure of water at  $17^\circ\text{C}$  is 1.96 kPa (Table A–9). Henry's constant for air dissolved in water at 290 K is  $H = 62,000$  bar (Table 14–6).

**Analysis** This example is similar to the previous example. Again the air at the water surface is saturated, and thus the partial pressure of water vapor in the air at the lake surface is the saturation pressure of water at  $17^\circ\text{C}$ ,

$$P_{\text{vapor}} = P_{\text{sat} @ 17^\circ\text{C}} = 1.96 \text{ kPa}$$

**FIGURE 14–15**

Dissolved gases in a liquid can be driven off by heating the liquid.

**FIGURE 14–16**  
Schematic for Example 14–2.

Assuming both the air and vapor to be ideal gases, the partial pressure of dry air is determined to be

$$P_{\text{dry air}} = P - P_{\text{vapor}} = 92 - 1.96 = 90.04 \text{ kPa} = 0.9004 \text{ bar}$$

Note that with little loss in accuracy (an error of about 2 percent), we could have ignored the vapor pressure since the amount of vapor in air is so small. Then the mole fraction of air in the water becomes

$$y_{\text{dry air, liquid state}} = \frac{P_{\text{dry air, gas side}}}{H} = \frac{0.9004 \text{ bar}}{62,000 \text{ bar}} = 1.45 \times 10^{-5}$$

which is very small, as expected. Therefore, the concentration of air in water just below the air-water interface is 1.45 moles per 100,0000 moles. But obviously this is enough oxygen for fish and other creatures in the lake. Note that the amount of air dissolved in water decreases with increasing depth.

We mentioned earlier that the use of Henry's law is limited to dilute gas-liquid solutions; that is, a liquid with a small amount of gas dissolved in it. Then the question that arises naturally is, what do we do when the gas is highly soluble in the liquid (or solid), such as ammonia in water? In this case the linear relationship of Henry's law does not apply, and the mole fraction of a gas dissolved in the liquid (or solid) is usually expressed as a function of the partial pressure of the gas in the gas phase and the temperature. An approximate relation in this case for the *mole fractions* of a species on the *liquid* and *gas sides* of the interface is given by **Raoult's law** as

$$P_{i, \text{gas side}} = y_{i, \text{gas side}} P = y_{i, \text{liquid side}} P_{i, \text{sat}}(T) \quad (14-19)$$

where  $P_{i, \text{sat}}(T)$  is the *saturation pressure* of the species  $i$  at the interface temperature and  $P$  is the *total pressure* on the gas phase side. Tabular data are available in chemical handbooks for common solutions such as the ammonia-water solution that is widely used in absorption-refrigeration systems.

Gases may also dissolve in *solids*, but the diffusion process in this case can be very complicated. The dissolution of a gas may be independent of the structure of the solid, or it may depend strongly on its porosity. Some dissolution processes (such as the dissolution of hydrogen in titanium, similar to the dissolution of  $\text{CO}_2$  in water) are *reversible*, and thus maintaining the gas content in the solid requires constant contact of the solid with a reservoir of that gas. Some other dissolution processes are *irreversible*. For example, oxygen gas dissolving in titanium forms  $\text{TiO}_2$  on the surface, and the process does not reverse itself.

The concentration of the gas species  $i$  in the solid at the interface  $C_{i, \text{solid side}}$  is proportional to the *partial pressure* of the species  $i$  in the gas  $P_{i, \text{gas side}}$  on the gas side of the interface and is expressed as

$$C_{i, \text{solid side}} = S \times P_{i, \text{gas side}} (\text{kmol/m}^3) \quad (14-20)$$

where  $S$  is the **solubility**. Expressing the pressure in bars and noting that the unit of molar concentration is kmol of species  $i$  per  $\text{m}^3$ , the unit of solubility is  $\text{kmol/m}^3 \cdot \text{bar}$ . Solubility data for selected gas-solid combinations are given in Table 14-7. The product of the *solubility* of a gas and the *diffusion coefficient*

**TABLE 14-7**

**Solubility of selected gases and solids (for gas  $i$ ,  $S = C_{i, \text{solid side}} / P_{i, \text{gas side}}$ ) (from Barrer, 1941)**

| Gas           | Solid          | $T, \text{K}$ | $S \text{ kmol/m}^3 \cdot \text{bar}$ |
|---------------|----------------|---------------|---------------------------------------|
| $\text{O}_2$  | Rubber         | 298           | 0.00312                               |
| $\text{N}_2$  | Rubber         | 298           | 0.00156                               |
| $\text{CO}_2$ | Rubber         | 298           | 0.04015                               |
| He            | $\text{SiO}_2$ | 293           | 0.00045                               |
| $\text{H}_2$  | Ni             | 358           | 0.00901                               |

of the gas in a solid is referred to as the **permeability**  $\mathcal{P}$ , which is a measure of the ability of the gas to penetrate a solid. That is,  $\mathcal{P} = \mathcal{S}D_{AB}$  where  $D_{AB}$  is the diffusivity of the gas in the solid. Permeability is inversely proportional to thickness and has the unit kmol/s-bar.

Finally, if a process involves the *sublimation* of a pure solid (such as ice or solid CO<sub>2</sub>) or the *evaporation* of a pure liquid (such as water) in a different medium such as air, the mole (or mass) fraction of the substance in the liquid or solid phase is simply taken to be 1.0, and the partial pressure and thus the mole fraction of the substance in the gas phase can readily be determined from the saturation data of the substance at the specified temperature. Also, the assumption of thermodynamic equilibrium at the interface is very reasonable for pure solids, pure liquids, and solutions, except when chemical reactions are occurring at the interface.

### EXAMPLE 14–3 Diffusion of Hydrogen Gas into a Nickel Plate

Consider a nickel plate that is in contact with hydrogen gas at 358 K and 300 kPa. Determine the molar and mass density of hydrogen in the nickel at the interface (Fig. 14–17).

**SOLUTION** A nickel plate is exposed to hydrogen. The molar and mass density of hydrogen in the nickel at the interface is to be determined.

**Assumptions** Nickel and hydrogen are in thermodynamic equilibrium at the interface.

**Properties** The molar mass of hydrogen is  $M = 2 \text{ kg/kmol}$  (Table A–1). The solubility of hydrogen in nickel at 358 K is 0.00901 kmol/m<sup>3</sup>·bar (Table 14–7).

**Analysis** Noting that 300 kPa = 3 bar, the molar density of hydrogen in the nickel at the interface is determined from Eq. 14–20 to be

$$\begin{aligned} C_{\text{H}_2, \text{ solid side}} &= \mathcal{S} \times P_{\text{H}_2, \text{ gas side}} \\ &= (0.00901 \text{ kmol/m}^3 \cdot \text{bar})(3 \text{ bar}) = \mathbf{0.027 \text{ kmol/m}^3} \end{aligned}$$

It corresponds to a mass density of

$$\begin{aligned} \rho_{\text{H}_2, \text{ solid side}} &= C_{\text{H}_2, \text{ solid side}} M_{\text{H}_2} \\ &= (0.027 \text{ kmol/m}^3)(2) = \mathbf{0.054 \text{ kg/m}^3} \end{aligned}$$

That is, there will be 0.027 kmol (or 0.054 kg) of H<sub>2</sub> gas in each m<sup>3</sup> volume of nickel adjacent to the interface.

FIGURE 14–17

Schematic for Example 14–3.

### EXAMPLE 14–4 Gas Leak from a Vessel through a Rubber Plug

Consider a 4-L vessel filled with carbon dioxide gas at 25°C and 5 atm (Fig. 14–18). A 20-mm-diameter circular rubber plug with a thickness of 10 mm is used to contain the gas inside the vessel. Determine the rate of mass loss of carbon dioxide gas from the vessel through the rubber plug.

**SOLUTION** A circular rubber plug with specified dimensions is used to contain carbon dioxide gas inside a vessel. The rate of gas loss from the vessel through the rubber plug is to be determined.

FIGURE 14–18

Schematic for Example 14–4.

**Assumptions** 1 Mass diffusion is steady and one-dimensional. 2 There are no chemical reactions in the rubber plug that result in the generation or depletion of carbon dioxide.

**Properties** The binary diffusion coefficient for CO<sub>2</sub> in the rubber at 25°C or 298 K is  $D_{AB} = 1.1 \times 10^{-10}$  m<sup>2</sup>/s (Table 14–3b). The molar mass of CO<sub>2</sub> is  $M = 44.01$  kg/kmol (Table A–1). The solubility of CO<sub>2</sub> in the rubber at 25°C = 298 K is 0.04015 kmol/m<sup>3</sup>·bar (Table 14–7).

**Analysis** The mass density of CO<sub>2</sub> (for 5 atm) in the rubber at the interface is determined from

$$\begin{aligned}\rho_{A,1} &= SP_{A,1} \\ &= (0.04015 \text{ kmol/m}^3\cdot\text{bar})(5 \text{ atm}) \left( \frac{44.01 \text{ kg}}{1 \text{ kmol}} \right) \left( \frac{1.01325 \text{ bar}}{1 \text{ atm}} \right) \\ &= 8.952 \text{ kg/m}^3\end{aligned}$$

On the opposite side, the mass density of CO<sub>2</sub> is zero,  $\rho_{A,2} = 0$ . Then the rate of carbon dioxide gas loss through the rubber plug becomes

$$\begin{aligned}\dot{m}_{\text{diff}} &= D_{AB}A \frac{\rho_{A,1} - \rho_{A,2}}{L} = D_{AB} \left( \frac{\pi D^2}{4} \right) \frac{\rho_{A,1} - \rho_{A,2}}{L} \\ &= (1.1 \times 10^{-10} \text{ m}^2/\text{s}) \frac{\pi(0.02 \text{ m})^2}{4} \frac{(8.952 - 0) \text{ kg/m}^3}{0.01 \text{ m}} \\ &= \mathbf{3.09 \times 10^{-11} \text{ kg/s}}$$

This corresponds to about 1 gram of CO<sub>2</sub> per year.

**Discussion** Using the ideal gas relation, the mass of CO<sub>2</sub> gas in the vessel can be shown to be 36 g. A loss of 1 g of CO<sub>2</sub> corresponds to about 3 percent of the total initial mass, which may be significant. Therefore, alternatives should be considered for long-term storage.

## 14–5 • STEADY MASS DIFFUSION THROUGH A WALL

Many practical mass transfer problems involve the diffusion of a species through a plane-parallel medium that does not involve any homogeneous chemical reactions under *one-dimensional steady* conditions. Such mass transfer problems are analogous to the steady one-dimensional heat conduction problems in a plane wall with no heat generation and can be analyzed similarly. In fact, many of the relations developed in Chapter 3 can be used for mass transfer by replacing temperature by mass (or molar) fraction, thermal conductivity by  $\rho D_{AB}$  (or  $CD_{AB}$ ), and heat flux by mass (or molar) flux (Table 14–8).

Consider a solid plane wall (medium *B*) of area *A*, thickness *L*, and density  $\rho$ . The wall is subjected on both sides to different concentrations of a species *A* to which it is permeable. The boundary surfaces at  $x = 0$  and  $x = L$  are located within the solid adjacent to the interfaces, and the mass fractions of *A* at those surfaces are maintained at  $w_{A,1}$  and  $w_{A,2}$ , respectively, at all times (Fig. 14–19). The mass fraction of species *A* in the wall varies in the *x*-direction only and can be expressed as  $w_A(x)$ . Therefore, mass transfer through the wall in this case can be modeled as *steady* and *one-dimensional*. Here we determine

TABLE 14–8

Analogy between heat conduction and mass diffusion in a stationary medium

|                 | <i>Mass Diffusion</i> |                      |
|-----------------|-----------------------|----------------------|
| Heat Conduction | Mass Basis            | Molar Basis          |
| <i>T</i>        | <i>w<sub>i</sub></i>  | <i>y<sub>i</sub></i> |
| <i>k</i>        | $\rho D_{AB}$         | $CD_{AB}$            |
| $\dot{q}$       | <i>j<sub>i</sub></i>  | $\bar{j}_i$          |
| $\alpha$        | $D_{AB}$              | $D_{AB}$             |
| <i>L</i>        | <i>L</i>              | <i>L</i>             |

the rate of mass diffusion of species A through the wall using a similar approach to that used in Chapter 3 for heat conduction.

The concentration of species A at any point does not change with time since operation is steady, and there is no production or destruction of species A since no chemical reactions are occurring in the medium. Then the **conservation of mass** principle for species A can be expressed as *the mass flow rate of species A through the wall at any cross section is the same*. That is

$$\dot{m}_{\text{diff},A} = j_A A = \text{constant} \quad (\text{kg/s})$$

Then Fick's law of diffusion becomes

$$j_A = \frac{\dot{m}_{\text{diff},A}}{A} = -\rho D_{AB} \frac{dw_A}{dx} = \text{constant}$$

Separating the variables in this equation and integrating across the wall from  $x = 0$ , where  $w(0) = w_{A,1}$ , to  $x = L$ , where  $w(L) = w_{A,2}$ , we get

$$\frac{\dot{m}_{\text{diff},A}}{A} \int_0^L dx = - \int_{w_{A,1}}^{w_{A,2}} \rho D_{AB} dw_A \quad (14-21)$$

where the mass transfer rate  $\dot{m}_{\text{diff},A}$  and the wall area  $A$  are taken out of the integral sign since both are constants. If the density  $\rho$  and the mass diffusion coefficient  $D_{AB}$  vary little along the wall, they can be assumed to be constant. The integration can be performed in that case to yield

$$\dot{m}_{\text{diff},A, \text{wall}} = \rho D_{AB} A \frac{w_{A,1} - w_{A,2}}{L} = D_{AB} A \frac{\rho_{A,1} - \rho_{A,2}}{L} \quad (\text{kg/s}) \quad (14-22)$$

This relation can be rearranged as

$$\dot{m}_{\text{diff},A, \text{wall}} = \frac{w_{A,1} - w_{A,2}}{L/\rho D_{AB} A} = \frac{w_{A,1} - w_{A,2}}{R_{\text{diff}, \text{wall}}} \quad (14-23)$$

where

$$R_{\text{diff}, \text{wall}} = \frac{L}{\rho D_{AB} A}$$

is the **diffusion resistance** of the wall, in s/kg, which is analogous to the electrical or conduction resistance of a plane wall of thickness  $L$  and area  $A$  (Fig. 14-20). Thus, we conclude that *the rate of mass diffusion through a plane wall is proportional to the average density, the wall area, and the concentration difference across the wall, but is inversely proportional to the wall thickness*. Also, once the rate of mass diffusion is determined, the mass fraction  $w_A(x)$  at any location  $x$  can be determined by replacing  $w_{A,2}$  in Eq. 14-22 by  $w_A(x)$  and  $L$  by  $x$ .

The preceding analysis can be repeated on a molar basis with this result,

$$\dot{N}_{\text{diff},A, \text{wall}} = CD_{AB} A \frac{y_{A,1} - y_{A,2}}{L} = D_{AB} A \frac{C_{A,1} - C_{A,2}}{L} = \frac{y_{A,1} - y_{A,2}}{R_{\text{diff}, \text{wall}}} \quad (14-24)$$

where  $R_{\text{diff}, \text{wall}} = L/CD_{AB} A$  is the **molar diffusion resistance** of the wall in s/kmol. Note that mole fractions are accompanied by molar concentrations and mass fractions are accompanied by density. Either relation can be used to determine the diffusion rate of species A across the wall, depending on

**FIGURE 14-19**

Schematic for steady one-dimensional mass diffusion of species A through a plane wall.

(a) Heat flow

(b) Current flow

(c) Mass flow

**FIGURE 14-20**

Analogy between thermal, electrical, and mass diffusion resistance concepts.

**FIGURE 14-21**

One-dimensional mass diffusion through a cylindrical or spherical shell.

whether the mass or molar fractions of species A are known at the boundaries. Also, the concentration gradients on both sides of an interface are different, and thus diffusion resistance networks cannot be constructed in an analogous manner to thermal resistance networks.

In developing these relations, we assumed the density and the diffusion coefficient of the wall to be nearly constant. This assumption is reasonable when a small amount of species A diffuses through the wall and thus *the concentration of A is small*. The species A can be a gas, a liquid, or a solid. Also, the wall can be a plane layer of a liquid or gas provided that it is *stationary*.

The analogy between heat and mass transfer also applies to *cylindrical* and *spherical* geometries. Repeating the approach outlined in Chapter 3 for heat conduction, we obtain the following analogous relations for steady one-dimensional mass transfer through nonreacting cylindrical and spherical layers (Fig. 14-21)

$$\dot{m}_{\text{diff}, A, \text{cyl}} = 2\pi L \rho D_{AB} \frac{w_{A,1} - w_{A,2}}{\ln(r_2/r_1)} = 2\pi L D_{AB} \frac{\rho_{A,1} - \rho_{A,2}}{\ln(r_2/r_1)} \quad (14-25)$$

$$\dot{m}_{\text{diff}, A, \text{sph}} = 4\pi r_1 r_2 \rho D_{AB} \frac{w_{A,1} - w_{A,2}}{r_2 - r_1} = 4\pi r_1 r_2 D_{AB} \frac{\rho_{A,1} - \rho_{A,2}}{r_2 - r_1} \quad (14-26)$$

or, on a molar basis,

$$\dot{N}_{\text{diff}, A, \text{cyl}} = 2\pi L C D_{AB} \frac{y_{A,1} - y_{A,2}}{\ln(r_2/r_1)} = 2\pi L D_{AB} \frac{C_{A,1} - C_{A,2}}{\ln(r_2/r_1)} \quad (14-27)$$

$$\dot{N}_{\text{diff}, A, \text{sph}} = 4\pi r_1 r_2 C D_{AB} \frac{y_{A,1} - y_{A,2}}{r_2 - r_1} = 4\pi r_1 r_2 D_{AB} \frac{C_{A,1} - C_{A,2}}{r_2 - r_1} \quad (14-28)$$

Here,  $L$  is the length of the cylinder,  $r_1$  is the inner radius, and  $r_2$  is the outer radius for the cylinder or the sphere. Again, the boundary surfaces at  $r = r_1$  and  $r = r_2$  are located within the solid adjacent to the interfaces, and the mass fractions of A at those surfaces are maintained at  $w_{A,1}$  and  $w_{A,2}$ , respectively, at all times. (We could make similar statements for the density, molar concentration, and mole fraction of species A at the boundaries.)

We mentioned earlier that the concentration of the gas species in a solid at the interface is proportional to the partial pressure of the adjacent gas and was expressed as  $C_{A, \text{solid side}} = S_{AB} P_{A, \text{gas side}}$  where  $S_{AB}$  is the *solubility* (in  $\text{kmol}/(\text{m}^3 \cdot \text{bar})$ ) of the gas A in the solid B. We also mentioned that the product of solubility and the diffusion coefficient is called the *permeability*,  $\mathcal{P}_{AB} = S_{AB} D_{AB}$  (in  $\text{kmol}/(\text{m} \cdot \text{s} \cdot \text{bar})$ ). Then the molar flow rate of a gas through a solid under steady one-dimensional conditions can be expressed in terms of the partial pressures of the adjacent gas on the two sides of the solid by replacing  $C_A$  in these relations by  $S_{AB} P_A$  or  $\mathcal{P}_{AB} P_A / D_{AB}$ . In the case of a *plane wall*, for example, it gives (Fig. 14-22)

$$\dot{N}_{\text{diff}, A, \text{wall}} = D_{AB} S_{AB} A \frac{P_{A,1} - P_{A,2}}{L} = \mathcal{P}_{AB} A \frac{P_{A,1} - P_{A,2}}{L} \quad (\text{kmol/s}) \quad (14-29)$$

where  $P_{A,1}$  and  $P_{A,2}$  are the *partial pressures* of gas A on the two sides of the wall. Similar relations can be obtained for cylindrical and spherical walls by following the same procedure. Also, if the permeability is given on a mass basis (in  $\text{kg}/(\text{m} \cdot \text{s} \cdot \text{bar})$ ), then Eq. 14-29 gives the diffusion mass flow rate.

**FIGURE 14-22**

The diffusion rate of a gas species through a solid can be determined from a knowledge of the partial pressures of the gas on both sides and the permeability of the solid to that gas.

Noting that 1 kmol of an ideal gas at the standard conditions of 0°C and 1 atm occupies a volume of 22.414 m<sup>3</sup>, the volume flow rate of the gas through the wall by diffusion can be determined from

$$\dot{V}_{\text{diff}, A} = 22.414 \dot{N}_{\text{diff}, A} \quad (\text{standard m}^3/\text{s, at } 0^\circ\text{C and 1 atm})$$

The volume flow rate at other conditions can be determined from the ideal gas relation  $P_A \dot{V} = \dot{N}_A R_u T$ .

### EXAMPLE 14–5 Diffusion of Hydrogen through a Spherical Container

Pressurized hydrogen gas is stored at 358 K in a 4.8-m-outer-diameter spherical container made of nickel (Fig. 14–23). The shell of the container is 6 cm thick. The molar concentration of hydrogen in the nickel at the inner surface is determined to be 0.087 kmol/m<sup>3</sup>. The concentration of hydrogen in the nickel at the outer surface is negligible. Determine the mass flow rate of hydrogen by diffusion through the nickel container.

**SOLUTION** Pressurized hydrogen gas is stored in a spherical container. The diffusion rate of hydrogen through the container is to be determined.

**Assumptions** 1 Mass diffusion is *steady* and *one-dimensional* since the hydrogen concentration in the tank and thus at the inner surface of the container is practically constant, and the hydrogen concentration in the atmosphere and thus at the outer surface is practically zero. Also, there is thermal symmetry about the center. 2 There are no chemical reactions in the nickel shell that result in the generation or depletion of hydrogen.

**Properties** The binary diffusion coefficient for hydrogen in the nickel at the specified temperature is  $1.2 \times 10^{-12}$  m<sup>2</sup>/s (Table 14–3b).

**Analysis** We can consider the total molar concentration to be constant ( $C = C_A + C_B \approx C_B = \text{constant}$ ), and the container to be a *stationary* medium since there is no diffusion of nickel molecules ( $\dot{N}_B = 0$ ) and the concentration of the hydrogen in the container is extremely low ( $C_A \ll 1$ ). Then the molar flow rate of hydrogen through this spherical shell by diffusion can readily be determined from Eq. 14–28 to be

$$\begin{aligned}\dot{N}_{\text{diff}} &= 4\pi r_1 r_2 D_{AB} \frac{C_{A,1} - C_{A,2}}{r_2 - r_1} \\ &= 4\pi(2.34 \text{ m})(2.40 \text{ m})(1.2 \times 10^{-12} \text{ m}^2/\text{s}) \frac{(0.087 - 0) \text{ kmol/m}^3}{(2.40 - 2.34) \text{ m}} \\ &= 1.228 \times 10^{-10} \text{ kmol/s}\end{aligned}$$

The mass flow rate is determined by multiplying the molar flow rate by the molar mass of hydrogen, which is  $M = 2 \text{ kg/kmol}$ ,

$$\dot{m}_{\text{diff}} = M \dot{N}_{\text{diff}} = (2 \text{ kg/kmol})(1.228 \times 10^{-10} \text{ kmol/s}) = 2.46 \times 10^{-10} \text{ kg/s}$$

Therefore, hydrogen will leak out through the shell of the container by diffusion at a rate of  $2.46 \times 10^{-10}$  kg/s or 7.8 g/year. Note that the concentration of hydrogen in the nickel at the inner surface depends on the temperature and pressure of the hydrogen in the tank and can be determined as explained in Example 14–3. Also, the assumption of zero hydrogen concentration in nickel at the outer surface is reasonable since there is only a trace amount of hydrogen in the atmosphere (0.5 part per million by mole numbers).

**FIGURE 14–23**  
Schematic for Example 14–5.

## 14–6 • WATER VAPOR MIGRATION IN BUILDINGS

Moisture greatly influences the performance and durability of building materials, and thus moisture transmission is an important consideration in the construction and maintenance of buildings.

The *dimensions* of wood and other hygroscopic substances change with moisture content. For example, a variation of 4.5 percent in moisture content causes the volume of white oak wood to change by 2.5 percent. Such cyclic changes of dimensions weaken the joints and can jeopardize the structural integrity of building components, causing “squeaking” at the minimum. Excess moisture can also cause changes in the *appearance* and *physical properties* of materials: *corrosion* and *rusting* in metals, *rotting* in woods, and *peeling of paint* on the interior and exterior wall surfaces. Soaked wood with a water content of 24 to 31 percent is observed to decay rapidly at temperatures 10 to 38°C. Also, *molds* grow on wood surfaces at relative humidities above 85 percent. The expansion of water during freezing may damage the cell structure of porous materials.

Moisture content also affects the *effective conductivity* of porous mediums such as soils, building materials, and insulations, and thus heat transfer through them. Several studies have indicated that heat transfer increases almost linearly with moisture content, at a rate of 3 to 5 percent for each percent increase in moisture content by volume. Insulation with 5 percent moisture content by volume, for example, increases heat transfer by 15 to 25 percent relative to dry insulation (ASHRAE *Handbook of Fundamentals*, 1993, Chap. 20) (Fig. 14–24). Moisture migration may also serve as a transfer mechanism for latent heat by alternate evaporation and condensation. During a hot and humid day, for example, water vapor may migrate through a wall and condense on the inner side, releasing the heat of vaporization, with the process reversing during a cool night. Moisture content also affects the *specific heat* and thus the heat storage characteristics of building materials.

Moisture migration in the walls, floors, or ceilings of buildings and in other applications is controlled by either **vapor barriers** or **vapor retarders**. *Vapor barriers* are materials that are impermeable to moisture, such as sheet metals, heavy metal foils, and thick plastic layers, and they effectively bar the vapor from migrating. *Vapor retarders*, on the other hand, *retard* or *slow down* the flow of moisture through the structures but do not totally eliminate it. Vapor retarders are available as solid, flexible, or coating materials, but they usually consist of a thin sheet or coating. Common forms of vapor retarders are *reinforced plastics or metals*, *thin foils*, *plastic films*, *treated papers*, *coated felts*, and *polymeric or asphaltic paint coatings*. In applications such as the building of walls where vapor penetration is unavoidable because of numerous openings such as electrical boxes, telephone lines, and plumbing passages, vapor retarders are used instead of vapor barriers to allow the vapor that somehow leaks in to exit to the outside instead of trapping it in. Vapor retarders with a permeance of  $57.4 \times 10^{-9} \text{ kg/s-m}^2$  are commonly used in residential buildings.

The insulation on *chilled water lines* and other impermeable surfaces that are always cold must be wrapped with a *vapor barrier jacket*, or such cold surfaces must be insulated with a material that is impermeable to moisture. This is because moisture that migrates through the insulation to the cold surface condenses and remains there indefinitely with no possibility of vaporizing

**FIGURE 14–24**

A 5 percent moisture content can increase heat transfer through wall insulation by 25 percent.

and moving back to the outside. The accumulation of moisture in such cases may render the insulation useless, resulting in excessive energy consumption.

Mechanical pipe insulation systems are commonly applied to cold piping surfaces, in most industrial and commercial buildings in order to limit the heat losses and prevent water vapor condensation on the pipe exterior surfaces. Due to the fact that the surface temperature of these pipelines is normally below the ambient dew point temperature, water vapor diffuses inside the pipe insulation systems and often condenses when it reaches the pipe exterior surfaces. The water droplets accumulated in the pipe insulation system increase its overall thermal conductivity by thermal bridging the cells or the fibers of the insulation material. The moisture ingress into pipe insulation threatens the thermal performance and the overall efficiency of the building mechanical system. This phenomenon is also responsible for the mold growth inside occupied spaces and causes the pipelines to be more vulnerable to corrosion. Although a wide range of vapor barriers are used for preventing water vapor penetration into pipe insulation, common experience in the field shows that water vapor will inevitably ingress into the insulation materials from the end joints or from the cracks created during insulation installation. How to account for the moisture ingress on pipe insulation service life and thermal performance is still an open question.

Thermal conductivity is one of the most important properties for evaluating the thermal performance of the pipe insulation systems. The thermal performance of pipe insulation systems is affected by local ambient conditions and might vary gradually with time. Most published data are extrapolated from flat slab configurations of the insulation materials, but the measured thermal conductivity from flat slabs might over or under estimate the actual thermal conductivity of cylindrical-shaped-pipe insulation systems due to radial configuration and longitudinal split joints. A methodology for measuring thermal conductivity of cylindrical-shaped-pipe insulation systems exists in the ASTM standards but it is based on a heated pipe approach with outward heat flow. If the average temperature of the pipe insulation system is below ambient temperature, then a more accurate prediction of the pipe insulation actual thermal conductivity is needed for the design of insulation systems in chiller pipe applications. For a detailed review on pipe insulation thermal conductivity under dry and wet condensing conditions with moisture ingress refer to Cai et al. (2014).

Cremaschi et al. (2012) at Oklahoma State University have developed a novel experimental apparatus to measure the thermal conductivity of pipe insulation systems at ambient and below ambient conditions for dry non-condensing conditions and wet conditions with moisture ingress. The apparatus was validated for dry non-condensing conditions with two pipe insulation systems, cellular glass and Polyisocyanurate (PIR), used to benchmark their measurements against data available in the public domain. The thermal conductivity of additional three pipe insulation materials, that is, fiberglass, flexible elastomeric, and phenolic, was also measured at several insulation temperatures at below ambient and in dry non-condensing ambient conditions. Correlations of the pipe insulation thermal conductivity were developed based on insulation specimen average temperature and wall thicknesses. In subsequent series of experiments, Cai et al. (2012) measured the thermal conductivity of pipe insulation systems at below ambient temperature in wet conditions with moisture ingress. Fiberglass and phenolic pipe insulation were tested to investigate the moisture effects on the material thermal conductivity. The data showed that these two types of pipe insulation systems had quite different water absorption, rates due

**TABLE 14-9**

Saturation pressure of water at various temperatures

| Temperature, °C | Saturation Pressure, Pa |

| 50              | 12,350                  |
| 100             | 101,330                 |
| 200             | $1.55 \times 10^6$      |
| 300             | $8.58 \times 10^6$      |

to different characteristics of the material and its structure. A serious degradation of fiberglass pipe insulation thermal performance was observed, and the thermal conductivity increased by as much as 3 times when the moisture content was about 12 percent in volume. Tested at a different condition, the thermal conductivity of phenolic pipe insulation increased to 1.6 times of the original value and the moisture content was 5% in volume.

Atmospheric air can be viewed as a mixture of dry air and water vapor, and the atmospheric pressure is the sum of the pressure of dry air and the pressure of water vapor, which is called the **vapor pressure**  $P_v$ . Air can hold a certain amount of moisture only, and the ratio of the actual amount of moisture in the air at a given temperature to the maximum amount air can hold at that temperature is called the **relative humidity**  $\phi$ . The relative humidity ranges from 0 for dry air to 100 percent for *saturated* air (air that cannot hold any more moisture). The partial pressure of water vapor in saturated air is called the **saturation pressure**  $P_{\text{sat}}$ . Table 14-9 lists the saturation pressure at various temperatures.

The amount of moisture in the air is completely specified by the temperature and the relative humidity, and the vapor pressure is related to relative humidity  $\phi$  by

$$P_v = \phi P_{\text{sat}} \quad (14-30)$$

where  $P_{\text{sat}}$  is the saturation (or boiling) pressure of water at the specified temperature. Then the mass flow rate of moisture through a plane layer of thickness  $L$  and normal area  $A$  can be expressed as

$$\dot{m}_v = \mathcal{P}A \frac{P_{v,1} - P_{v,2}}{L} = \mathcal{P}A \frac{\phi_1 P_{\text{sat},1} - \phi_2 P_{\text{sat},2}}{L} \quad (\text{kg/s}) \quad (14-31)$$

where  $\mathcal{P}$  is the vapor permeability of the material, which is usually expressed on a mass basis in the unit ng/s·m·Pa, where ng =  $10^{-12}$  kg and 1 Pa =  $10^{-5}$  bar. Note that vapor migrates or diffuses from a region of higher vapor pressure toward a region of lower vapor pressure.

The permeability of most construction materials is usually expressed for a given thickness instead of per unit thickness. It is called the **permeance**  $\mathcal{M}$ , which is the ratio of the permeability of the material to its thickness. That is,

$$\text{Permeance} = \frac{\text{Permeability}}{\text{Thickness}} \quad (14-32)$$

$$\mathcal{M} = \frac{\mathcal{P}}{L} \quad (\text{kg/s} \cdot \text{m}^2 \cdot \text{Pa})$$

The reciprocal of permeance is called (unit) **vapor resistance** and is expressed as

$$\text{Vapor resistance} = \frac{1}{\text{Permeance}}$$

$$R_v = \frac{1}{\mathcal{M}} = \frac{L}{\mathcal{P}} \quad (\text{s} \cdot \text{m}^2 \cdot \text{Pa/kg}) \quad (14-33)$$

Note that vapor resistance represents the resistance of a material to water vapor transmission.

It should be pointed out that the amount of moisture that enters or leaves a building by *diffusion* is usually negligible compared to the amount that enters with *infiltrating air* or leaves with *exfiltrating air*. The primary cause of interest in the moisture diffusion is its impact on the performance and longevity of building materials.

The overall vapor resistance of a *composite* building structure that consists of several layers in series is the sum of the resistances of the individual layers and is expressed as

$$R_{v,\text{total}} = R_{v,1} + R_{v,2} + \dots + R_{v,n} = \sum R_{v,i} \quad (14-34)$$

Then the rate of vapor transmission through a composite structure can be determined in an analogous manner to heat transfer from

$$\dot{m}_v = A \frac{\Delta P_v}{R_{v,\text{total}}} \quad (\text{kg/s}) \quad (14-35)$$

Vapor permeance of common building materials is given in Table 14–10.

### EXAMPLE 14–6 Condensation and Freezing of Moisture in Walls

The condensation and even freezing of moisture in walls without effective vapor retarders is a real concern in cold climates, and it undermines the effectiveness of insulations. Consider a wood frame wall that is built around 38 mm × 90 mm (2 × 4 nominal) wood studs. The 90-mm-wide cavity between the studs is filled with glass fiber insulation. The inside is finished with 13-mm gypsum wallboard and the outside with 13-mm wood fiberboard and 13-mm × 200-mm wood bevel lapped siding. Using manufacturer's data, the thermal and vapor resistances of various components for a unit wall area are determined to be

| Construction                        | R-Value,<br>$\text{m}^2\cdot\text{K}/\text{W}$ | $R_{v,\text{Value}},$<br>$\text{s}\cdot\text{m}^2\cdot\text{Pa}/\text{ng}$ |

The indoor conditions are 20°C and 60 percent relative humidity while the outside conditions are –16°C and 70 percent relative humidity. Determine if condensation or freezing of moisture will occur in the insulation.

**SOLUTION** The thermal and vapor resistances of different layers of a wall are given. The possibility of condensation or freezing of moisture in the wall is to be investigated.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the wall is one-dimensional. 3 Thermal and vapor resistances of different layers of the wall and the heat transfer coefficients are constant.

**Properties** The thermal and vapor resistances are as given in the problem statement. The saturation pressures of water at 20°C and –16°C are 2339 Pa and 151 Pa, respectively (Table 14–9).

**Analysis** The schematic of the wall as well as the different elements used in its construction are shown in Figure 14–25. Condensation is most likely to

| Building paper, unit mass of 0.16–0.68 kg/m <sup>2</sup> | 0.1–2400   |

\*Data vary greatly. Consult manufacturer for more accurate data. Multiply by  $1.41 \times 10^{-6}$  to convert to  $\text{lbm}/\text{s}\cdot\text{ft}^2\cdot\text{psi}$ . Also, 1 ng =  $10^{-12}$  kg.

FIGURE 14–25  
Schematic for Example 14–6.

occur at the coldest part of insulation, which is the part adjacent to the exterior sheathing. Noting that the total thermal resistance of the wall is  $3.05 \text{ m}^2\cdot\text{K/W}$ , the rate of heat transfer through a unit area  $A = 1 \text{ m}^2$  of the wall is

$$\dot{Q}_{\text{wall}} = A \frac{T_i - T_o}{R_{\text{total}}} = (1 \text{ m}^2) \frac{[20 - (-16)^\circ\text{C}]}{3.05 \text{ m}^2\cdot\text{K/W}} = 11.8 \text{ W}$$

The thermal resistance of the exterior part of the wall beyond the insulation is  $0.03 + 0.14 + 0.23 = 0.40 \text{ m}^2\cdot\text{K/W}$ . Then the temperature of the insulation–outer sheathing interface is

$$T_I = T_o + \dot{Q}_{\text{wall}} R_{\text{ext}} = -16^\circ\text{C} + (11.8 \text{ W})(0.40 \text{ K/W}) = -11.3^\circ\text{C}$$

The saturation pressure of water at  $-11.3^\circ\text{C}$  is 234 Pa, as shown in Table 14–9, and if there is condensation or freezing, the vapor pressure at the insulation–outer sheathing interface will have to be this value. The vapor pressure at the indoors and the outdoors is

$$P_{v,1} = \phi_1 P_{\text{sat},1} = 0.60 \times (2340 \text{ Pa}) = 1404 \text{ Pa}$$

$$P_{v,2} = \phi_2 P_{\text{sat},2} = 0.70 \times (151 \text{ Pa}) = 106 \text{ Pa}$$

Then the rate of moisture flow through the interior and exterior parts of the wall becomes

$$\begin{aligned} \dot{m}_{v, \text{interior}} &= A \left( \frac{\Delta P}{R_v} \right)_{\text{interior}} = A \frac{P_{v,I} - P_{v,I}}{R_{v, \text{interior}}} \\ &= (1 \text{ m}^2) \frac{(1404 - 234) \text{ Pa}}{(0.012 + 0.0004) \text{ Pa}\cdot\text{m}^2\cdot\text{s/ng}} = 94,355 \text{ ng/s} = 94.4 \mu\text{g/s} \end{aligned}$$

$$\begin{aligned} \dot{m}_{v, \text{exterior}} &= A \left( \frac{\Delta P}{R_v} \right)_{\text{exterior}} = A \frac{P_{v,I} - P_{v,2}}{R_{v, \text{exterior}}} \\ &= (1 \text{ m}^2) \frac{(234 - 106) \text{ Pa}}{(0.019 + 0.0138) \text{ Pa}\cdot\text{m}^2\cdot\text{s/ng}} = 3902 \text{ ng/s} = 3.9 \mu\text{g/s} \end{aligned}$$

That is, moisture is flowing toward the interface at a rate of  $94.4 \mu\text{g/s}$  but flowing from the interface to the outdoors at a rate of only  $3.9 \mu\text{g/s}$ . Noting that the interface pressure cannot exceed 234 Pa, these results indicate that moisture is freezing in the insulation at a rate of

$$\dot{m}_{v, \text{freezing}} = \dot{m}_{v, \text{interior}} - \dot{m}_{v, \text{exterior}} = 94.4 - 3.9 = \mathbf{90.5 \mu\text{g/s}}$$

**Discussion** This result corresponds to 7.82 g during a 24-h period, which can be absorbed by the insulation or sheathing, and then flows out when the conditions improve. However, excessive condensation (or frosting at temperatures below  $0^\circ\text{C}$ ) of moisture in the walls during long cold spells can cause serious problems. This problem can be avoided or minimized by installing vapor barriers on the interior side of the wall, which will limit the moisture flow rate to  $3.9 \mu\text{g/s}$ . Note that if there were no condensation or freezing, the flow rate of moisture through a  $1 \text{ m}^2$  section of the wall would be  $28.7 \mu\text{g/s}$  (can you verify this?).

## 14-7 • TRANSIENT MASS DIFFUSION

The steady analysis discussed earlier is useful when determining the leakage rate of a species through a stationary layer. But sometimes we are interested in the diffusion of a species into a body during a limited time before steady operating conditions are established. Such problems are studied using **transient analysis**. For example, the surface of a mild steel component is commonly hardened by packing the component in a carbonaceous material in a furnace at high temperature. During the short time period in the furnace, the carbon molecules diffuse through the surface of the steel component, but they penetrate to a depth of only a few millimeters. The carbon concentration decreases exponentially from the surface to the inner parts, and the result is a steel component with a very hard surface and a relatively soft core region (Fig. 14-26).

The same process is used in the gem industry to color clear stones. For example, a clear sapphire is given a brilliant blue color by packing it in titanium and iron oxide powders and baking it in an oven at about 2000°C for about a month. The titanium and iron molecules penetrate less than 0.5 mm in the sapphire during this process. Diffusion in solids is usually done at high temperatures to take advantage of the high diffusion coefficients at high temperatures and thus to keep the diffusion time at a reasonable level. Such diffusion or “doping” is also commonly practiced in the production of n- or p-type semiconductor materials used in the manufacture of electronic components. Drying processes such as the drying of coal, timber, food, and textiles constitute another major application area of transient mass diffusion.

Transient mass diffusion in a stationary medium is analogous to transient heat transfer provided that the solution is dilute and thus the density of the medium  $\rho$  is constant. In Chapter 4 we presented analytical and graphical solutions for one-dimensional transient heat conduction problems in solids with constant properties, no heat generation, and uniform initial temperature. The analogous one-dimensional transient mass diffusion problems satisfy these requirements:

1. The *diffusion coefficient is constant*. This is valid for an isothermal medium since  $D_{AB}$  varies with temperature (corresponds to constant thermal diffusivity).
2. There are *no homogeneous reactions* in the medium that generate or deplete the diffusing species A (corresponds to no heat generation).
3. Initially ( $t = 0$ ) the concentration of species A is *constant* throughout the medium (corresponds to uniform initial temperature).

Then the solution of a mass diffusion problem can be obtained directly from the analytical or graphical solution of the corresponding heat conduction problem given in Chapter 4. The analogous quantities between heat and mass transfer are summarized in Table 14-11 for easy reference. For the case of a semi-infinite medium with constant surface concentration, for example, the solution can be expressed in an analogous manner to Eq. 4-45 as

$$\frac{C_A(x, t) - C_{A,i}}{C_{A,s} - C_{A,i}} = \operatorname{erfc}\left(\frac{x}{2\sqrt{D_{AB}t}}\right) \quad (14-36)$$

where  $C_{A,i}$  is the initial concentration of species A at time  $t = 0$  and  $C_{A,s}$  is the concentration at the inner side of the exposed surface of the medium. By

**FIGURE 14-26**

The surface hardening of a mild steel component by the diffusion of carbon molecules is a transient mass diffusion process.

**TABLE 14-11**

Analogy between the quantities that appear in the formulation and solution of transient heat conduction and transient mass diffusion in a stationary medium

| Heat Conduction  | Mass Diffusion   |
|--|--|
| $T$  | $C, y, \rho$ or $w$  |
| $\alpha$   | $D_{AB}$   |
| $\theta = \frac{T(x, t) - T_\infty}{T_i - T_\infty}, \theta_{\text{mass}} = \frac{w_A(x, t) - w_{A,\infty}}{w_{A,i} - w_{A,\infty}}$ |  |
| $\frac{T(x, t) - T_s}{T_i - T_s}$  | $\frac{w_A(x, t) - w_A}{w_{A,i} - w_A}$                      |
| $\eta = \frac{x}{2\sqrt{\alpha t}}$  | $\eta_{\text{mass}} = \frac{x}{2\sqrt{D_{AB}t}}$             |
| $\text{Bi} = \frac{h_{\text{conv}} L}{k}$  | $\text{Bi}_{\text{mass}} = \frac{h_{\text{mass}} L}{D_{AB}}$ |
| $\tau = \frac{\alpha t}{L^2}$  | $\tau = \frac{D_{AB}t}{L^2}$                                 |

**FIGURE 14-27**

The concentration profile of species A in a semi-infinite medium during transient mass diffusion and the penetration depth.

using the definitions of molar fraction, mass fraction, and density, it can be shown that for dilute solutions,

$$\frac{C_A(x, t) - C_{A,i}}{C_{A,s} - C_{A,i}} = \frac{\rho_A(x, t) - \rho_{A,i}}{\rho_{A,s} - \rho_{A,i}} = \frac{w_A(x, t) - w_{A,i}}{w_{A,s} - w_{A,i}} = \frac{y_A(x, t) - y_{A,i}}{y_{A,s} - y_{A,i}} \quad (14-37)$$

since the total density or total molar concentration of dilute solutions is usually constant ( $\rho = \text{constant}$  or  $C = \text{constant}$ ). Therefore, other measures of concentration can be used in Eq. 14-36.

A quantity of interest in mass diffusion processes is the depth of diffusion at a given time. This is usually characterized by the **penetration depth** defined as *the location x where the tangent to the concentration profile at the surface ( $x = 0$ ) intercepts the  $C_A = C_{A,i}$  line*, as shown in Figure 14-27. Obtaining the concentration gradient at  $x = 0$  by differentiating Eq. 14-36, the penetration depth is determined to be

$$\delta_{\text{diff}} = \frac{C_{A,s} - C_{A,i}}{-(dC_A/dx)|_{x=0}} = \frac{C_{A,s} - C_{A,i}}{(C_{A,s} - C_{A,i})/\sqrt{\pi D_{AB}t}} = \sqrt{\pi D_{AB}t} \quad (14-38)$$

Therefore, the penetration depth is proportional to the square root of both the diffusion coefficient and time. The diffusion coefficient of zinc in copper at 1000°C, for example, is  $5.0 \times 10^{-13} \text{ m}^2/\text{s}$  (Table 14-3). Then the penetration depth of zinc in copper in 10 h is

$$\begin{aligned} \delta_{\text{diff}} &= \sqrt{\pi D_{AB}t} = \sqrt{\pi(5.0 \times 10^{-13} \text{ m}^2/\text{s})(10 \times 3600 \text{ s})} \\ &= 0.00024 \text{ m} = 0.24 \text{ mm} \end{aligned}$$

That is, zinc will penetrate to a depth of about 0.24 mm in an appreciable amount in 10 h, and there will hardly be any zinc in the copper block beyond a depth of 0.24 mm.

The diffusion coefficients in solids are typically very low (on the order of  $10^{-9}$  to  $10^{-15} \text{ m}^2/\text{s}$ ), and thus the diffusion process usually affects a thin layer at the surface. A solid can conveniently be treated as a semi-infinite medium during transient mass diffusion regardless of its size and shape when the penetration depth is small relative to the thickness of the solid. When this is not the case, solutions for one-dimensional transient mass diffusion through a plane wall, cylinder, and sphere can be obtained from the solutions of analogous heat conduction problems using the Heisler charts or one-term solutions presented in Chapter 4.

**FIGURE 14-28**

Schematic for Example 14-7.

### EXAMPLE 14-7 Hardening of Steel by the Diffusion of Carbon

The surface of a mild steel component is commonly hardened by packing the component in a carbonaceous material in a furnace at a high temperature for a predetermined time. Consider such a component with a uniform initial carbon concentration of 0.15 percent by mass. The component is now packed in a carbonaceous material and is placed in a high-temperature furnace. The diffusion coefficient of carbon in steel at the furnace temperature is given to be  $4.8 \times 10^{-10} \text{ m}^2/\text{s}$ , and the equilibrium concentration of carbon in the iron at the interface is determined from equilibrium data to be 1.2 percent by mass. Determine how long the component should be kept in the furnace for the mass concentration of carbon 0.5 mm below the surface to reach 1 percent (Fig. 14-28).

**SOLUTION** A steel component is to be surface hardened by packing it in a carbonaceous material in a furnace. The length of time the component should be kept in the furnace is to be determined.

**Assumptions** Carbon penetrates into a very thin layer beneath the surface of the component, and thus the component can be modeled as a semi-infinite medium regardless of its thickness or shape.

**Properties** The relevant properties are given in the problem statement.

**Analysis** This problem is analogous to the one-dimensional transient heat conduction problem in a semi-infinite medium with specified surface temperature, and thus can be solved accordingly. Using mass fraction for concentration since the data are given in that form, the solution can be expressed as

$$\frac{w_A(x, t) - w_{A,i}}{w_{A,s} - w_{A,i}} = \operatorname{erfc}\left(\frac{x}{2\sqrt{D_{AB}t}}\right)$$

Substituting the specified quantities gives

$$\frac{0.01 - 0.0015}{0.012 - 0.0015} = 0.81 = \operatorname{erfc}\left(\frac{x}{2\sqrt{D_{AB}t}}\right)$$

The argument whose complementary error function is 0.81 is determined from Table 4–4 to be 0.17. That is,

$$\frac{x}{2\sqrt{D_{AB}t}} = 0.17$$

Then solving for the time  $t$  gives

$$t = \frac{x^2}{4D_{AB}(0.17)^2} = \frac{(0.0005 \text{ m})^2}{4 \times (4.8 \times 10^{-10} \text{ m}^2/\text{s})(0.17)^2} = 4505 \text{ s} = \mathbf{1 \text{ h } 15 \text{ min}}$$

**Discussion** The steel component in this case must be held in the furnace for 1 h and 15 min to achieve the desired level of hardening. The diffusion coefficient of carbon in steel increases exponentially with temperature, and thus this process is commonly done at high temperatures to keep the diffusion time at a reasonable level.

## 14–8 • DIFFUSION IN A MOVING MEDIUM

To this point we have limited our consideration to mass diffusion in a *stationary medium*, and thus the only motion involved was the creeping motion of molecules in the direction of decreasing concentration, and there was no motion of the mixture as a whole. Many practical problems, such as the evaporation of water from a lake under the influence of the wind or the mixing of two fluids as they flow in a pipe, involve diffusion in a **moving medium** where the bulk motion is caused by an external force. Mass diffusion in such cases is complicated by the fact that chemical species are transported both by *diffusion* and by the bulk motion of the medium (i.e., *convection*). The velocities and mass flow rates of species in a moving medium consist of two components: one due to *molecular diffusion* and one due to *convection* (Fig. 14–29).

Diffusion in a moving medium, in general, is difficult to analyze since various species can move at different velocities in different directions. Turbulence complicates the things even more. To gain a firm understanding of the physical

**FIGURE 14–29**

In a moving medium, mass transfer is due to both diffusion and convection.

mechanism while keeping the mathematical complexities to a minimum, we limit our consideration to systems that involve only *two components* (species A and B) in *one-dimensional flow* (velocity and other properties change in one direction only, say the *x*-direction). We also assume the total density (or molar concentration) of the medium remains constant. That is,  $\rho = \rho_A + \rho_B = \text{constant}$  (or  $C = C_A + C_B = \text{constant}$ ) but the densities of species A and B may vary in the *x*-direction.

Several possibilities are summarized in Figure 14–30. In the trivial case (case *a*) of a *stationary homogeneous mixture*, there will be no mass transfer by molecular diffusion or convection since there is no concentration gradient or bulk motion. The next case (case *b*) corresponds to the *flow of a well-mixed fluid mixture* through a pipe. Note that there is no concentration gradients and thus molecular diffusion in this case, and all species move at the bulk flow velocity of  $V$ . The mixture in the third case (case *c*) is *stationary* ( $V = 0$ ) and thus it corresponds to ordinary molecular diffusion in stationary mediums, which we discussed before. Note that the velocity of a species at a location in this case is simply the **diffusion velocity**, which is the average velocity of a group of molecules at that location moving under the influence of concentration gradient. Finally, the last case (case *d*) involves both *molecular diffusion* and *convection*, and the velocity of a species in this case is equal to the sum of the bulk flow velocity and the diffusion velocity. Note that the flow and the diffusion velocities can be in the same or opposite directions, depending on

|  |    |  | <b>Species</b>     | <b>Density</b>                             | <b>Velocity</b>               | <b>Mass flow rate</b>  |
|--|---|--|--------------------|--|-------------------------------|--|
| (a) Homogeneous mixture without bulk motion<br>(no concentration gradients and thus no diffusion)  |   |  | Species A          | $\rho_A = \text{constant}$                 | $V_A = 0$                     | $\dot{m}_A = 0$  |
|  |   |  | Species B          | $\rho_B = \text{constant}$                 | $V_B = 0$                     | $\dot{m}_B = 0$  |
|  |   |  | Mixture of A and B | $\rho = \rho_A + \rho_B = \text{constant}$ | $V = 0$                       | $\dot{m} = 0$  |
| (b) Homogeneous mixture with bulk motion<br>(no concentration gradients and thus no diffusion)     |  |  | Species A          | $\rho_A = \text{constant}$                 | $V_A = V$                     | $\dot{m}_A = \rho_A V_A A$                                   |
|  |   |  | Species B          | $\rho_B = \text{constant}$                 | $V_B = V$                     | $\dot{m}_B = \rho_B V_B A$                                   |
|  |   |  | Mixture of A and B | $\rho = \rho_A + \rho_B = \text{constant}$ | $V = V$                       | $\dot{m} = \rho V A$<br>$= \dot{m}_A + \dot{m}_B$            |
| (c) Nonhomogeneous mixture without bulk motion<br>(stationary medium with concentration gradients) |  |  | Species A          | $\rho_A \neq \text{constant}$              | $V_A = V_{\text{diff},A}$     | $\dot{m}_A = \rho_A V_{\text{diff},A} A$                     |
|  |   |  | Species B          | $\rho_B \neq \text{constant}$              | $V_B = V_{\text{diff},B}$     | $\dot{m}_B = \rho_B V_{\text{diff},B} A$                     |
|  |   |  | Mixture of A and B | $\rho = \rho_A + \rho_B = \text{constant}$ | $V = 0$                       | $\dot{m} = \rho V A = 0$<br>(thus $\dot{m}_A = -\dot{m}_B$ ) |
| (d) Nonhomogeneous mixture with bulk motion<br>(moving medium with concentration gradients)        |  |  | Species A          | $\rho_A \neq \text{constant}$              | $V_A = V + V_{\text{diff},A}$ | $\dot{m}_A = \rho_A V_{\text{diff},A} A$                     |
|  |   |  | Species B          | $\rho_B \neq \text{constant}$              | $V_B = V + V_{\text{diff},B}$ | $\dot{m}_B = \rho_B V_{\text{diff},B} A$                     |
|  |   |  | Mixture of A and B | $\rho = \rho_A + \rho_B = \text{constant}$ | $V = V$                       | $\dot{m} = \rho V A$<br>$= \dot{m}_A + \dot{m}_B$            |

FIGURE 14–30

Various quantities associated with a mixture of two species A and B at a location  $x$  under one-dimensional flow or no-flow conditions. (The density of the mixture  $\rho = \rho_A + \rho_B$  is assumed to remain constant.)

the direction of the concentration gradient. The diffusion velocity of a species is *negative* when the bulk flow is in the positive  $x$ -direction and the concentration gradient is positive (i.e., the concentration of the species increases in the  $x$ -direction).

Noting that the mass flow rate at any flow section is expressed as  $\dot{m} = \rho V A$  where  $\rho$  is the density,  $V$  is the velocity, and  $A$  is the cross-sectional area, the conservation of mass relation for the flow of a mixture that involves two species  $A$  and  $B$  can be expressed as

$$\dot{m} = \dot{m}_A + \dot{m}_B$$

or

$$\rho V A = \rho_A V_A A + \rho_B V_B A$$

Cancelling  $A$  and solving for  $V$  gives

$$V = \frac{\rho_A V_A + \rho_B V_B}{\rho} = \frac{\rho_A}{\rho} V_A + \frac{\rho_B}{\rho} V_B = w_A V_A + w_B V_B \quad (14-39)$$

where  $V$  is called the **mass-average velocity** of the flow, which is the velocity that would be measured by a velocity sensor such as a pitot tube, a turbine device, or a hot wire anemometer inserted into the flow.

The special case  $V = 0$  corresponds to a **stationary medium**, which can now be defined more precisely as *a medium whose mass-average velocity is zero*. Therefore, mass transport in a stationary medium is by diffusion only, and zero mass-average velocity indicates that there is no bulk fluid motion.

When there is *no concentration gradient* (and thus no molecular mass diffusion) in the fluid, the velocity of all species will be equal to the *mass-average velocity of the flow*. That is,  $V = V_A = V_B$ . But when there is a concentration gradient, there will also be a simultaneous flow of species in the direction of decreasing concentration at a diffusion velocity of  $V_{\text{diff}}$ . Then the average velocity of the species  $A$  and  $B$  can be determined by superimposing the average flow velocity and the diffusion velocity as (Fig. 14-31)

$$V_A = V + V_{\text{diff}, A} \quad (14-40)$$

$$V_B = V + V_{\text{diff}, B}$$

Similarly, we apply the superposition principle to the species mass flow rates to get

$$\begin{aligned} \dot{m}_A &= \rho_A V_A A = \rho_A (V + V_{\text{diff}, A}) A = \rho_A V A + \rho_A V_{\text{diff}, A} A = \dot{m}_{\text{conv}, A} + \dot{m}_{\text{diff}, A} \\ \dot{m}_B &= \rho_B V_B A = \rho_B (V + V_{\text{diff}, B}) A = \rho_B V A + \rho_B V_{\text{diff}, B} A = \dot{m}_{\text{conv}, B} + \dot{m}_{\text{diff}, B} \end{aligned} \quad (14-41)$$

Using Fick's law of diffusion, the total mass fluxes  $j = \dot{m}/A$  can be expressed as

$$j_A = \rho_A V + \rho_A V_{\text{diff}, A} = \frac{\rho_A}{\rho} \rho V - \rho D_{AB} \frac{dw_A}{dx} = w_A (j_A + j_B) - \rho D_{AB} \frac{dw_A}{dx} \quad (14-42)$$

$$j_B = \rho_B V + \rho_B V_{\text{diff}, B} = \frac{\rho_B}{\rho} \rho V - \rho D_{BA} \frac{dw_B}{dx} = w_B (j_A + j_B) - \rho D_{BA} \frac{dw_B}{dx}$$

(a) No concentration gradient

(b) Mass concentration gradient and thus mass diffusion

**FIGURE 14-31**

The velocity of a species at a point is equal to the sum of the bulk flow velocity and the diffusion velocity of that species at that point.

Note that the diffusion velocity of a species is negative when the molecular diffusion occurs in the negative  $x$ -direction (opposite to flow direction). The mass diffusion rates of the species  $A$  and  $B$  at a specified location  $x$  can be expressed as

$$\begin{aligned}\dot{m}_{\text{diff}, A} &= \rho_A V_{\text{diff}, A} A = \rho_A (V_A - V) A \\ \dot{m}_{\text{diff}, B} &= \rho_B V_{\text{diff}, B} A = \rho_B (V_B - V) A\end{aligned}\quad (14-43)$$

By substituting the  $V$  relation from Eq. 14-39 into Eq. 14-43, it can be shown that at any cross section

$$\dot{m}_{\text{diff}, A} + \dot{m}_{\text{diff}, B} = 0 \rightarrow \dot{m}_{\text{diff}, A} = -\dot{m}_{\text{diff}, B} \rightarrow -\rho A D_{AB} \frac{dw_A}{dx} = \rho A D_{BA} \frac{dw_B}{dx} \quad (14-44)$$

which indicates that the rates of diffusion of species  $A$  and  $B$  must be equal in magnitude but opposite in sign. This is a consequence of the assumption  $\rho = \rho_A + \rho_B = \text{constant}$ , and it indicates that *anytime the species A diffuses in one direction, an equal amount of species B must diffuse in the opposite direction to maintain the density (or the molar concentration) constant*. This behavior is closely approximated by dilute gas mixtures and dilute liquid or solid solutions. For example, when a small amount of gas diffuses into a liquid, it is reasonable to assume the density of the liquid to remain constant.

Note that for a binary mixture,  $w_A + w_B = 1$  at any location  $x$ . Taking the derivative with respect to  $x$  gives

$$\frac{dw_A}{dx} = -\frac{dw_B}{dx} \quad (14-45)$$

Thus we conclude from Eq. 14-44 that (Fig. 14-32)

$$D_{AB} = D_{BA} \quad (14-46)$$

That is, in the case of constant total concentration, the diffusion coefficient of species  $A$  into  $B$  is equal to the diffusion coefficient of species  $B$  into  $A$ .

We now repeat the analysis presented above with molar concentration  $C$  and the molar flow rate  $\dot{N}$ . The conservation of matter in this case is expressed as

$$\dot{N} = \dot{N}_A + \dot{N}_B$$

or

$$\rho \bar{V} A = \rho_A \bar{V}_A A + \rho_B \bar{V}_B A \quad (14-47)$$

Canceling  $A$  and solving for  $\bar{V}$  gives

$$\bar{V} = \frac{C_A \bar{V}_A + C_B \bar{V}_B}{C} = \frac{C_A}{C} \bar{V}_A + \frac{C_B}{C} \bar{V}_B = y_A \bar{V}_A + y_B \bar{V}_B \quad (14-48)$$

where  $\bar{V}$  is called the **molar-average velocity** of the flow. Note that  $\bar{V} \neq V$  unless the mass and molar fractions are the same. The molar flow rates of species are determined similarly to be

$$\begin{aligned}\dot{N}_A &= C_A V_A A = C_A (\bar{V} + \bar{V}_{\text{diff}, A}) A = C_A \bar{V} A + C_A \bar{V}_{\text{diff}, A} A = \dot{N}_{\text{conv}, A} + \dot{N}_{\text{diff}, A} \\ \dot{N}_B &= C_B V_B A = C_B (\bar{V} + \bar{V}_{\text{diff}, B}) A = C_B \bar{V} A + C_B \bar{V}_{\text{diff}, B} A = \dot{N}_{\text{conv}, B} + \dot{N}_{\text{diff}, B}\end{aligned}\quad (14-49)$$

**FIGURE 14-32**

In a binary mixture of species  $A$  and  $B$  with  $\rho = \rho_A + \rho_B = \text{constant}$ , the rates of mass diffusion of species  $A$  and  $B$  are equal magnitude and opposite in direction.

Using Fick's law of diffusion, the total molar fluxes  $\bar{j} = \dot{N}/A$  and diffusion molar flow rates  $\dot{N}_{\text{diff}}$  can be expressed as

$$\bar{j}_A = C_A \bar{V} + C_A \bar{V}_{\text{diff}, A} = \frac{C_A}{C} C \bar{V} - CD_{AB} \frac{dy_A}{dx} = y_A (\bar{j}_A + \bar{j}_B) - CD_{AB} \frac{dy_A}{dx} \quad (14-50)$$

$$\bar{j}_B = C_B \bar{V} + C_B \bar{V}_{\text{diff}, B} = \frac{C_B}{C} C \bar{V} - CD_{BA} \frac{dy_B}{dx} = y_B (\bar{j}_A + \bar{j}_B) - CD_{BA} \frac{dy_B}{dx}$$

and

$$\begin{aligned} \dot{N}_{\text{diff}, A} &= C_A \bar{V}_{\text{diff}, A} A = C_A (V_A - \bar{V}) A \\ \dot{N}_{\text{diff}, B} &= C_B \bar{V}_{\text{diff}, B} A = C_B (V_B - \bar{V}) A \end{aligned} \quad (14-51)$$

By substituting the  $\bar{V}$  relation from Eq. 14-48 into these two equations, it can be shown that

$$\dot{N}_{\text{diff}, A} + \dot{N}_{\text{diff}, B} = 0 \rightarrow \dot{N}_{\text{diff}, A} = -\dot{N}_{\text{diff}, B} \quad (14-52)$$

which again indicates that the rates of diffusion of species *A* and *B* must be equal in magnitude but opposite in sign.

It is important to note that when working with molar units, a medium is said to be stationary when the *molar-average velocity* is zero. The average velocity of the molecules will be zero in this case, but the apparent velocity of the mixture as measured by a velocimeter placed in the flow will not necessarily be zero because of the different masses of different molecules. In a *mass-based stationary medium*, for each unit mass of species *A* moving in one direction, a unit mass of species *B* moves in the opposite direction. In a *mole-based stationary medium*, however, for each mole of species *A* moving in one direction, one mole of species *B* moves in the opposite direction. But this may result in a net mass flow rate in one direction that can be measured by a velocimeter since the masses of different molecules are different.

You may be wondering whether to use the mass analysis or molar analysis in a problem. The two approaches are equivalent, and either approach can be used in mass transfer analysis. But sometimes it may be easier to use one of the approaches, depending on what is given. When mass-average velocity is known or can easily be obtained, obviously it is more convenient to use the mass-based formulation. When the *total pressure* and *temperature* of a mixture are constant, however, it is more convenient to use the molar formulation, as explained in the following three cases-gas mixtures at constant pressure and temperature, Stefan Flow, and Equimolar Counterdiffusion.

## Special Case: Gas Mixtures at Constant Pressure and Temperature

Consider a gas mixture whose total pressure and temperature are constant throughout. When the mixture is homogeneous, the mass density  $\rho$ , the molar density (or concentration)  $C$ , the gas constant  $R$ , and the molar mass  $M$  of the mixture are the same throughout the mixture. But when the concentration of one or more gases in the mixture is not constant, setting the stage for mass diffusion, then the mole fractions  $y_i$  of the species will vary throughout

the mixture. As a result, the gas constant  $R$ , the molar mass  $M$ , and the mass density  $\rho$  of the mixture will also vary since, assuming ideal gas behavior,

$$M = \sum y_i M_i, R = \frac{R_u}{M}, \text{ and } \rho = \frac{P}{RT}$$

where  $R_u = 8.314 \text{ kJ/kmol}\cdot\text{K}$  is the universal gas constant. Therefore, the assumption of *constant mixture density* ( $\rho = \text{constant}$ ) in such cases will not be accurate unless the gas or gases with variable concentrations constitute a very small fraction of the mixture. However, the *molar density*  $C$  of a mixture *remains constant* when the mixture pressure  $P$  and temperature  $T$  are constant since

$$P = \rho RT = \rho \frac{R_u}{M} T = CR_u T \quad (14-53)$$

The condition  $C = \text{constant}$  offers considerable simplification in mass transfer analysis, and thus it is more convenient to use the molar formulation when dealing with gas mixtures at constant total pressure and temperature (Fig. 14-33).

### Diffusion of Vapor through a Stationary Gas: Stefan Flow

Many engineering applications such as heat pipes, cooling ponds, and the familiar perspiration involve condensation, evaporation, and transpiration in the presence of a noncondensable gas, and thus the *diffusion* of a vapor through a stationary (or stagnant) gas. To understand and analyze such processes, consider a liquid layer of species  $A$  in a tank surrounded by a gas of species  $B$ , such as a layer of liquid water in a tank open to the atmospheric air (Fig. 14-34), at constant pressure  $P$  and temperature  $T$ . Equilibrium exists between the liquid and vapor phases at the interface ( $x = 0$ ), and thus the vapor pressure at the interface must equal the saturation pressure of species  $A$  at the specified temperature. We assume the gas to be insoluble in the liquid, and both the gas and the vapor to behave as ideal gases.

If the surrounding gas at the top of the tank ( $x = L$ ) is not saturated, the vapor pressure at the interface will be greater than the vapor pressure at the top of the tank ( $P_{A,0} > P_{A,L}$  and thus  $y_{A,0} > y_{A,L}$  since  $y_A = P_A/P$ ), and this pressure (or concentration) difference will drive the vapor upward from the air–water interface into the stagnant gas. The upward flow of vapor will be sustained by the evaporation of water at the interface. Under steady conditions, the molar (or mass) flow rate of vapor throughout the stagnant gas column remains constant. That is,

$$\bar{j}_A = \dot{N}_A / A = \text{constant} \quad (\text{or } j_A = \dot{m}_A / A = \text{constant})$$

The pressure and temperature of the gas–vapor mixture are said to be constant, and thus the molar density of the mixture must be constant throughout the mixture, as shown earlier. That is,  $C = C_A + C_B = \text{constant}$ , and it is more convenient to work with mole fractions or molar concentrations in this case instead of mass fractions or densities since  $\rho \neq \text{constant}$ .

Noting that  $y_A + y_B = 1$  and that  $y_{A,0} > y_{A,L}$ , we must have  $y_{B,0} < y_{B,L}$ . That is, the mole fraction of the gas must be decreasing downward by the same amount that the mole fraction of the vapor is increasing. Therefore, gas must

**FIGURE 14-33**

When the total pressure  $P$  and temperature  $T$  of a binary mixture of ideal gases is held constant, then the molar concentration  $C$  of the mixture remains constant.

**FIGURE 14-34**

Diffusion of a vapor  $A$  through a stagnant gas  $B$ .

be diffusing from the top of the column toward the liquid interface. However, the gas is said to be *insoluble* in the liquid, and thus there can be no net mass flow of the gas downward. Then under steady conditions, there must be an *upward bulk fluid motion* with an average velocity  $V$  that is just large enough to balance the diffusion of air downward so that the net molar (or mass) flow rate of the gas at any point is zero. In other words, the upward bulk motion offsets the downward diffusion, and for each air molecule that moves downward, there is another air molecule that moves upward. As a result, the air appears to be *stagnant* (it does not move). That is,

$$\bar{j}_B = \dot{N}_B/A = 0 \text{ (or } j_B = \dot{m}_B/A = 0\text{)}$$

The diffusion medium is no longer stationary because of the bulk motion. The implication of the bulk motion of the gas is that it transports vapor as well as the gas upward with a velocity of  $V$ , which results in *additional* mass flow of vapor upward. Therefore, the molar flux of the vapor can be expressed as

$$\bar{j}_A = \dot{N}_A/A = \bar{j}_{A,\text{conv}} + \bar{j}_{A,\text{diff}} = y_A(\bar{j}_A + \bar{j}_B) - CD_{AB} \frac{dy_A}{dx} \quad (14-54)$$

Noting that  $\bar{j}_B = 0$ , it simplifies to

$$\bar{j}_A = y_A \bar{j}_A - CD_{AB} \frac{dy_A}{dx} \quad (14-55)$$

Solving for  $\bar{j}_A$  gives

$$\bar{j}_A = -\frac{CD_{AB}}{1 - y_A} \frac{dy_A}{dx} \longrightarrow -\frac{1}{1 - y_A} \frac{dy_A}{dx} = \frac{\bar{j}_A}{CD_{AB}} = \text{constant} \quad (14-56)$$

since  $\bar{j}_A = \text{constant}$ ,  $C = \text{constant}$ , and  $D_{AB} = \text{constant}$ . Separating the variables and integrating from  $x = 0$ , where  $y_A(0) = y_{A,0}$ , to  $x = L$ , where  $y_A(L) = y_{A,L}$  gives

$$-\int_{A,0}^{y_{A,L}} \frac{dy_A}{1 - y_A} = \int_0^L \frac{\bar{j}_A}{CD_{AB}} dx \quad (14-57)$$

Performing the integrations,

$$\ln \frac{1 - y_{A,L}}{1 - y_{A,0}} = \frac{\bar{j}_A}{CD_{AB}} L \quad (14-58)$$

Then the molar flux of vapor  $A$ , which is the *evaporation rate of species A per unit interface area*, becomes

$$\bar{j}_A = \dot{N}_A/A = \frac{CD_{AB}}{L} \ln \frac{1 - y_{A,L}}{1 - y_{A,0}} \text{ (kmol/s·m}^2\text{)} \quad (14-59)$$

This relation is known as **Stefan's law**, and the *induced convective flow* described that enhances mass diffusion is called the **Stefan flow**. Noting that  $y_A = P_A/P$  and  $C = P/R_u T$  for an ideal gas mixture, the evaporation rate of species  $A$  can also be expressed as

$$\dot{N}_A = \frac{D_{AB}PA}{LR_u T} \ln \frac{P - P_{A,L}}{P - P_{A,0}} \text{ (kmol/s)} \quad (14-60)$$

An expression for the variation of the mole fraction of  $A$  with  $x$  can be determined by performing the integration in Eq. 14–57 to the upper limit of  $x$  where  $y_A(x) = y_A$  (instead of to  $L$  where  $y_A(L) = y_{A,L}$ ). It yields

$$\ln \frac{1 - y_A}{1 - y_{A,0}} = \frac{\bar{j}_A}{CD_{AB}} x$$

Substituting the  $\bar{j}_A$  expression from Eq. 14–59 into this relation and rearranging gives

$$\frac{1 - y_A}{1 - y_{A,0}} = \left( \frac{1 - y_{A,L}}{1 - y_{A,0}} \right)^{x/L} \quad \text{and} \quad \frac{y_B}{y_{B,0}} = \left( \frac{y_{B,L}}{y_{B,0}} \right)^{x/L} \quad (14-61)$$

The second relation for the variation of the mole fraction of the stationary gas  $B$  is obtained from the first one by substituting  $1 - y_A = y_B$  since  $y_A + y_B = 1$ .

To maintain isothermal conditions in the tank during evaporation, heat must be supplied to the tank at a rate of

$$\dot{Q} = \dot{m}_A h_{fg,A} = j_A A_s h_{fg,A} = (\bar{j}_A M_A) A_s h_{fg,A} \quad (\text{kJ/s}) \quad (14-62)$$

where  $A_s$  is the surface area of the liquid–vapor interface,  $h_{fg,A}$  is the latent heat of vaporization, and  $M_A$  is the molar mass of species  $A$ .

## Equimolar Counterdiffusion

Consider two large reservoirs connected by a channel of length  $L$ , as shown in Figure 14–35. The entire system contains a binary mixture of gases  $A$  and  $B$  at a uniform temperature  $T$  and pressure  $P$  throughout. The concentrations of species are maintained constant in each of the reservoirs such that  $y_{A,0} > y_{A,L}$  and  $y_{B,0} < y_{B,L}$ . The resulting concentration gradients will cause the species  $A$  to diffuse in the positive  $x$ -direction and the species  $B$  in the opposite direction. Assuming the gases to behave as ideal gases and thus  $P = CR_u T$ , the total molar concentration of the mixture  $C$  will remain constant throughout the mixture since  $P$  and  $T$  are constant. That is,

$$C = C_A + C_B = \text{constant} \quad (\text{kmol/m}^3)$$

This requires that for each molecule of  $A$  that moves to the right, a molecule of  $B$  moves to the left, and thus the molar flow rates of species  $A$  and  $B$  must be equal in magnitude and opposite in sign. That is,

$$\dot{N}_A = -\dot{N}_B \quad \text{or} \quad \dot{N}_A + \dot{N}_B = 0 \quad (\text{kmol/s})$$

This process is called **equimolar counterdiffusion** for obvious reasons. The net molar flow rate of the mixture for such a process, and thus the molar-average velocity, is zero since

$$\dot{N} = \dot{N}_A + \dot{N}_B = 0 \quad \longrightarrow \quad C \bar{V} = 0 \quad \longrightarrow \quad \bar{V} = 0$$

Therefore, the mixture is *stationary* on a molar basis and thus mass transfer is by diffusion only (there is no mass transfer by convection) so that

$$\bar{j}_A = \dot{N}_A/A = -CD_{AB} \frac{dy_A}{dx} \quad \text{and} \quad \bar{j}_B = \dot{N}_B/A = -CD_{BA} \frac{dy_B}{dx} \quad (14-63)$$

Under steady conditions, the molar flow rates of species  $A$  and  $B$  can be determined directly from Eq. 14–24 developed earlier for one-dimensional steady diffusion in a stationary medium, noting that  $P = CR_u T$  and thus  $C = P/R_u T$

**FIGURE 14–35**

Equimolar isothermal counterdiffusion of two gases  $A$  and  $B$ .

for each constituent gas and the mixture. For one-dimensional flow through a channel of uniform cross sectional area  $A$  with no homogeneous chemical reactions, they are expressed as

$$\begin{aligned}\dot{N}_{\text{diff}, A} &= CD_{AB}A \frac{y_{A,1} - y_{A,2}}{L} = D_{AB}A \frac{C_{A,1} - C_{A,2}}{L} = \frac{D_{AB}}{R_u T} A \frac{P_{A,0} - P_{A,L}}{L} \\ \dot{N}_{\text{diff}, B} &= CD_{BA}A \frac{y_{B,1} - y_{B,2}}{L} = D_{BA}A \frac{C_{B,1} - C_{B,2}}{L} = \frac{D_{BA}}{R_u T} A \frac{P_{B,0} - P_{B,L}}{L}\end{aligned}\quad (14-64)$$

These relations imply that the mole fraction, molar concentration, and the partial pressure of either gas vary linearly during equimolar counterdiffusion.

It is interesting to note that the mixture is *stationary* on a molar basis, but it is not stationary on a mass basis unless the molar masses of  $A$  and  $B$  are equal. Although the net molar flow rate through the channel is zero, the net mass flow rate of the mixture through the channel is not zero and can be determined from

$$\dot{m} = \dot{m}_A + \dot{m}_B = \dot{N}_A M_A + \dot{N}_B M_B = \dot{N}_A (M_A + M_B) \quad (14-65)$$

since  $\dot{N}_B = -\dot{N}_A$ . Note that the direction of net mass flow rate is the flow direction of the gas with the larger molar mass. A velocity measurement device such as an anemometer placed in the channel will indicate a velocity of  $V = \dot{m}/\rho_A$  where  $\rho$  is the total density of the mixture at the site of measurement.

### EXAMPLE 14-8 Venting of Helium into the Atmosphere by Diffusion

The pressure in a pipeline that transports helium gas at a rate of 2 kg/s is maintained at 1 atm by venting helium to the atmosphere through a 5-mm-internal-diameter tube that extends 15 m into the air, as shown in Figure 14-36. Assuming both the helium and the atmospheric air to be at 25°C, determine (a) the mass flow rate of helium lost to the atmosphere through the tube, (b) the mass flow rate of air that infiltrates into the pipeline, and (c) the flow velocity at the bottom of the tube where it is attached to the pipeline that will be measured by an anemometer in steady operation.

**SOLUTION** The pressure in a helium pipeline is maintained constant by venting to the atmosphere through a long tube. The mass flow rates of helium and air through the tube and the net flow velocity at the bottom are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Helium and atmospheric air are ideal gases. 3 No chemical reactions occur in the tube. 4 Air concentration in the pipeline and helium concentration in the atmosphere are negligible so that the mole fraction of the helium is 1 in the pipeline and 0 in the atmosphere (we will check this assumption later).

**Properties** The diffusion coefficient of helium in air (or air in helium) at normal atmospheric conditions is  $D_{AB} = 7.2 \times 10^{-5} \text{ m}^2/\text{s}$  (Table 14-2). The molar masses of air and helium are 29 and 4 kg/kmol, respectively (Table A-1).

**Analysis** This is a typical equimolar counterdiffusion process since the problem involves two large reservoirs of ideal gas mixtures connected to each other

FIGURE 14-36

Schematic for Example 14-8.

by a channel, and the concentrations of species in each reservoir (the pipeline and the atmosphere) remain constant.

(a) The flow area, which is the cross sectional area of the tube, is

$$A = \pi D^2/4 = \pi(0.005 \text{ m})^2/4 = 1.963 \times 10^{-5} \text{ m}^2$$

Noting that the pressure of helium is 1 atm at the bottom of the tube ( $x = 0$ ) and 0 at the top ( $x = L$ ), its molar flow rate is determined from Eq. 14–64 to be

$$\begin{aligned}\dot{N}_{\text{helium}} &= \dot{N}_{\text{diff}, A} = \frac{D_{AB} A}{R_u T} \frac{P_{A, 0} - P_{A, L}}{L} \\ &= \frac{(7.20 \times 10^{-5} \text{ m}^2/\text{s})(1.963 \times 10^{-5} \text{ m}^2)}{(8.314 \text{ kPa} \cdot \text{m}^3/\text{kmol} \cdot \text{K})(298 \text{ K})} \left( \frac{1 \text{ atm} - 0}{15 \text{ m}} \right) \left( \frac{101.3 \text{ kPa}}{1 \text{ atm}} \right) \\ &= 3.85 \times 10^{-12} \text{ kmol/s}\end{aligned}$$

Therefore,

$$\dot{m}_{\text{helium}} = (\dot{N}M)_{\text{helium}} = (3.85 \times 10^{-12} \text{ kmol/s})(4 \text{ kg/kmol}) = \mathbf{1.54 \times 10^{-11} \text{ kg/s}}$$

which corresponds to about 0.5 g per year.

(b) Noting that  $\dot{N}_B = -\dot{N}_A$  during an equimolar counterdiffusion process, the molar flow rate of air into the helium pipeline is equal to the molar flow rate of helium. The mass flow rate of air into the pipeline is

$$\dot{m}_{\text{air}} = (\dot{N}M)_{\text{air}} = (-3.85 \times 10^{-12} \text{ kmol/s})(29 \text{ kg/kmol}) = \mathbf{-112 \times 10^{-12} \text{ kg/s}}$$

The mass fraction of air in the helium pipeline is

$$w_{\text{air}} = \frac{|\dot{m}_{\text{air}}|}{\dot{m}_{\text{total}}} = \frac{112 \times 10^{-12} \text{ kg/s}}{(2 + 112 \times 10^{-12} - 1.54 \times 10^{-11}) \text{ kg/s}} = 5.6 \times 10^{-11} \approx 0$$

which validates our original assumption of negligible air in the pipeline.

(c) The net mass flow rate through the tube is

$$\dot{m}_{\text{net}} = \dot{m}_{\text{helium}} + \dot{m}_{\text{air}} = 1.54 \times 10^{-11} - 112 \times 10^{-12} = -9.66 \times 10^{-11} \text{ kg/s}$$

The mass fraction of air at the bottom of the tube is very small, as shown above, and thus the density of the mixture at  $x = 0$  can simply be taken to be the density of helium, which is

$$\rho \equiv \rho_{\text{helium}} = \frac{P}{RT} = \frac{101.325 \text{ kPa}}{(2.0769 \text{ kPa} \cdot \text{m}^3/\text{kg} \cdot \text{K})(298 \text{ K})} = 0.1637 \text{ kg/m}^3$$

Then the average flow velocity at the bottom part of the tube becomes

$$V = \frac{\dot{m}}{\rho A} = \frac{-9.66 \times 10^{-11} \text{ kg/s}}{(0.1637 \text{ kg/m}^3)(1.963 \times 10^{-5} \text{ m}^2)} = \mathbf{-3.01 \times 10^{-5} \text{ m/s}}$$

which is difficult to measure by even the most sensitive velocity measurement devices. The negative sign indicates flow in the negative  $x$ -direction (toward the pipeline).

**EXAMPLE 14–9 Measuring Diffusion Coefficient by the Stefan Tube**

A 3-cm-diameter Stefan tube is used to measure the binary diffusion coefficient of water vapor in air at 20°C at an elevation of 1600 m where the atmospheric pressure is 83.5 kPa. The tube is partially filled with water, and the distance from the water surface to the open end of the tube is 40 cm (Fig. 14–37). Dry air is blown over the open end of the tube so that water vapor rising to the top is removed immediately and the concentration of vapor at the top of the tube is zero. In 15 days of continuous operation at constant pressure and temperature, the amount of water that has evaporated is measured to be 1.23 g. Determine the diffusion coefficient of water vapor in air at 20°C and 83.5 kPa.

**SOLUTION** The amount of water that evaporates from a Stefan tube at a specified temperature and pressure over a specified time period is measured. The diffusion coefficient of water vapor in air is to be determined.

**Assumptions** 1 Water vapor and atmospheric air are ideal gases. 2 The amount of air dissolved in liquid water is negligible. 3 Heat is transferred to the water from the surroundings to make up for the latent heat of vaporization so that the temperature of water remains constant at 20°C.

**Properties** The saturation pressure of water at 20°C is 2.34 kPa (Table A–9).

**Analysis** The vapor pressure at the air–water interface is the saturation pressure of water at 20°C, and the mole fraction of water vapor (species A) at the interface is determined from

$$y_{\text{vapor}, 0} = y_{A, 0} = \frac{P_{\text{vapor}, 0}}{P} = \frac{2.34 \text{ kPa}}{83.5 \text{ kPa}} = 0.0280$$

Dry air is blown on top of the tube and, thus,  $y_{\text{vapor}, L} = y_{A, L} = 0$ . Also, the total molar density throughout the tube remains constant because of the constant temperature and pressure conditions and is determined to be

$$C = \frac{P}{R_u T} = \frac{83.5 \text{ kPa}}{(8.314 \text{ kPa}\cdot\text{m}^3/\text{kmol}\cdot\text{K})(293 \text{ K})} = 0.0343 \text{ kmol/m}^3$$

The cross-sectional area of the tube is

$$A = \pi D^2/4 = \pi(0.03 \text{ m})^2/4 = 7.069 \times 10^{-4} \text{ m}^2$$

The evaporation rate is given to be 1.23 g per 15 days. Then the molar flow rate of vapor is determined to be

$$\begin{aligned} \dot{N}_A &= \dot{N}_{\text{vapor}} = \frac{\dot{m}_{\text{vapor}}}{M_{\text{vapor}}} = \frac{1.23 \times 10^{-3} \text{ kg}}{(15 \times 24 \times 3600 \text{ s})(18 \text{ kg/kmol})} \\ &= 5.27 \times 10^{-11} \text{ kmol/s} \end{aligned}$$

Finally, substituting the information above into Eq. 14–59 we get

$$\frac{5.27 \times 10^{-1} \text{ kmol/s}}{7.069 \times 10^{-4} \text{ m}^2} = \frac{(0.0343 \text{ kmol/m}^3)D_{AB}}{0.4 \text{ m}} \ln \frac{1 - 0}{1 - 0.028}$$

which gives

$$D_{AB} = 3.06 \times 10^{-5} \text{ m}^2/\text{s}$$

for the binary diffusion coefficient of water vapor in air at 20°C and 83.5 kPa.

**FIGURE 14–37**  
Schematic for Example 14–9.

**FIGURE 14–38**

Schematic for Example 14–10.

**PtD EXAMPLE 14–10****Prevention of Health Hazards from Toxic Exposure**

Chloroform ( $M = 119.38 \text{ kg/kmol}$ ) is classified as a hazardous material because prolonged exposure to it is harmful to health. Inhalation of large amount of chloroform may cause liver and kidney damage. The permissible exposure limit (PEL) of chloroform, established by the Occupational Safety and Health Administration (OSHA), is  $240 \text{ mg/m}^3$ . A lab technician, working in a lab space of  $30 \text{ m}^3$ , has poured liquid chloroform into 10 test tubes with inner diameter of 25 mm. Each test tube holds equal amount of liquid chloroform at a level of 1 cm from the top (Fig. 14–38). The chloroform vapor pressure is 21 kPa, and evaporation of chloroform to the surrounding air is occurring at  $25^\circ\text{C}$  and 1 atm. If the diffusion coefficient of chloroform in air is  $D_{AB} = 0.104 \text{ cm}^2/\text{s}$ , determine whether or not it is safe for the technician to remain in the lab for an hour during the evaporation of chloroform from the test tubes.

**SOLUTION** In this example, the concepts of Prevention through Design (PtD) are applied in conjunction with the concepts of diffusion in a moving medium.

**Assumptions** 1 Steady operating conditions exist. 2 Chloroform vapor and atmospheric air are ideal gases. 3 The amount of air dissolved in liquid chloroform is negligible. 4 Temperatures of air and chloroform remain constant at  $25^\circ\text{C}$ .

**Properties** The molar mass of chloroform is given as  $M = 119.38 \text{ kg/kmol}$ . The diffusion coefficient of chloroform in air is given as  $D_{AB} = 0.104 \text{ cm}^2/\text{s}$ .

**Analysis** The vapor pressure of chloroform at  $25^\circ\text{C}$  is given as  $P_{A,0} = 21 \text{ kPa}$ , and the mole fraction of chloroform vapor (species A) at the interface is determined from

$$y_{A,0} = \frac{P_{A,0}}{P} = \frac{21 \text{ kPa}}{101.325 \text{ kPa}} = 0.20725$$

The total molar density throughout the tube remains constant because of the constant temperature and pressure conditions and is determined to be

$$C = \frac{P}{R_u T} = \frac{101.325 \text{ kPa}}{(8.314 \text{ kPa}\cdot\text{m}^3/\text{kmol}\cdot\text{K})(273 + 25)\text{K}} = 0.0409 \text{ kmol/m}^3$$

Then, the diffusion rate per unit interface area for one test tube is

$$\begin{aligned} \frac{\dot{N}_A}{A} &= \frac{CD_{AB}}{L} \ln\left(\frac{1 - y_{A,L}}{1 - y_{A,0}}\right) \\ &= \frac{(0.0409 \text{ kmol/m}^3)(0.104 \text{ cm}^2/\text{s})(1 \times 10^{-4} \text{ m}^2/\text{cm}^2)}{0.01 \text{ m}} \ln\left(\frac{1 - 0}{1 - 0.20725}\right) \\ &= 9.8789 \times 10^{-6} \text{ kmol/s}\cdot\text{m}^2 \end{aligned}$$

The evaporation rate of chloroform from one test tube is

$$\begin{aligned} \dot{m} &= MD^2 \frac{\pi}{4} \frac{\dot{N}_A}{A} \\ &= (119.38 \text{ kg/kmol})(0.025 \text{ m})^2 \frac{\pi}{4} (9.8789 \times 10^{-6} \text{ kmol/s}\cdot\text{m}^2) \\ &= 5.789 \times 10^{-7} \text{ kg/s} \\ &= 34.734 \text{ mg/min} \end{aligned}$$

The total rate of chloroform being evaporated from ten test tubes to the surrounding air is

$$\dot{m}_{\text{total}} = 10(34.734 \text{ mg/min}) = 347.34 \text{ mg/min}$$

For a lab space of  $30 \text{ m}^3$ , the time for the chloroform to reach the PEL (permissible exposure limit) from the evaporation is

$$\text{Time} = \text{PEL} \times \frac{\text{Lab space}}{\dot{m}_{\text{total}}} = (240 \text{ mg/m}^3) \left( \frac{30 \text{ m}^3}{347.34 \text{ mg/min}} \right) = 20.7 \text{ min} < 60 \text{ min}$$

**Discussion** It takes 20 minutes and 44 seconds for the evaporated chloroform to reach the PEL established by the OSHA. Therefore, it would not be safe for the technician to remain in the lab for an hour. Substances that can release toxic vapors should be handled under a fume hood.

## 14–9 • MASS CONVECTION

So far we have considered *mass diffusion*, which is the transfer of mass due to a concentration gradient. Now we consider *mass convection* (or *convective mass transfer*), which is the transfer of mass between a surface and a moving fluid due to both *mass diffusion* and *bulk fluid motion*. We mentioned earlier that fluid motion enhances heat transfer considerably by removing the heated fluid near the surface and replacing it by the cooler fluid farther away. Likewise, fluid motion enhances mass transfer considerably by removing the high-concentration fluid near the surface and replacing it by the lower-concentration fluid farther away. In the limiting case of no bulk fluid motion, mass convection reduces to mass diffusion, just as convection reduces to conduction. The analogy between heat and mass convection holds for both *forced* and *natural* convection, *laminar* and *turbulent* flow, and *internal* and *external* flow.

Like heat convection, mass convection is also complicated because of the complications associated with fluid flow such as the *surface geometry*, *flow regime*, *flow velocity*, and the *variation of the fluid properties* and *composition*. Therefore, we have to rely on experimental relations to determine mass transfer. Also, mass convection is usually analyzed on a *mass basis* rather than on a molar basis. Therefore, we will present formulations in terms of mass concentration (density  $\rho$  or mass fraction  $w$ ) instead of molar concentration (molar density  $C$  or mole fraction  $y$ ). But the formulations on a molar basis can be obtained using the relation  $C = \rho/M$  where  $M$  is the molar mass. Also, for simplicity, we will restrict our attention to convection in fluids that are (or can be treated as) *binary mixtures*.

Consider the flow of air over the free surface of a water body such as a lake under isothermal conditions. If the air is not saturated, the concentration of water vapor will vary from a maximum at the water surface where the air is always saturated to the free steam value far from the surface. In heat convection, we defined the region in which temperature gradients exist as the *thermal boundary layer*. Similarly, in mass convection, we define the region of the fluid in which concentration gradients exist as the **concentration boundary layer**, as shown in Figure 14–39. In **external flow**, the thickness of the concentration boundary layer  $\delta_c$  for a species  $A$  at a specified location on the surface is defined as the normal distance  $y$  from the surface at which

$$\frac{\rho_{A,s} - \rho_A}{\rho_{A,s} - \rho_{A,\infty}} = 0.99$$

where  $\rho_{A,s}$  and  $\rho_{A,\infty}$  are the densities of species  $A$  at the surface (on the fluid side) and the free stream, respectively.

$$\text{Heat transfer: } \text{Pr} = \frac{\nu}{\alpha}$$

$$\text{Mass transfer: } \text{Sc} = \frac{\nu}{D_{AB}}$$

FIGURE 14-41

In mass transfer, the Schmidt number plays the role of the Prandtl number in heat transfer.

FIGURE 14-42

### Ernst Heinrich Wilhelm Schmidt

(1892–1975), a German engineer, was born at Vögelsen, Germany. One of his early research efforts was a careful measurement of the radiation properties of solids, which caused him to propose and develop the use of aluminum foil as an effective radiation shield. He was the first to measure the velocity and temperature field in a free convection boundary layer and the large heat-transfer coefficients occurring in droplet condensation. The dimensionless **Schmidt number** which characterizes fluid flows in which there are simultaneous momentum and mass diffusion convection processes was named after him.

*Photo Deutsches Museum.*

In **internal flow**, we have a **concentration entrance region** where the concentration profile develops, in addition to the hydrodynamic and thermal entry regions (Fig. 14-40). The concentration boundary layer continues to develop in the flow direction until its thickness reaches the tube center and the boundary layers merge. The distance from the tube inlet to the location where this merging occurs is called the **concentration entry length**  $L_c$ , and the region beyond that point is called the **fully developed region**, which is characterized by

$$\frac{\partial}{\partial x} \left( \frac{\rho_{A,s} - \rho_A}{\rho_{A,s} - \rho_{A,b}} \right) = 0 \quad (14-66)$$

where  $\rho_{A,b}$  is the *bulk mean density* of species A defined as

$$\rho_{A,b} = \frac{1}{A_c V_{\text{avg}}} \int_{A_c} \rho_A u dA_c \quad (14-67)$$

Therefore, the nondimensionalized concentration difference profile as well as the mass transfer coefficient remain constant in the fully developed region. This is analogous to the friction and heat transfer coefficients remaining constant in the fully developed region.

In heat convection, the relative magnitudes of momentum and heat diffusion in the velocity and thermal boundary layers are expressed by the dimensionless *Prandtl number*, defined as (Fig. 14-41)

$$\text{Prandtl number: } \text{Pr} = \frac{\nu}{\alpha} = \frac{\text{Momentum diffusivity}}{\text{Thermal diffusivity}} \quad (14-68)$$

The corresponding quantity in mass convection is the dimensionless **Schmidt number** (Fig. 14-42), defined as

$$\text{Schmidt number: } \text{Sc} = \frac{\nu}{D_{AB}} = \frac{\text{Momentum diffusivity}}{\text{Mass diffusivity}} \quad (14-69)$$

which represents the relative magnitudes of molecular momentum and mass diffusion in the velocity and concentration boundary layers, respectively.

The relative growth of the velocity and thermal boundary layers in laminar flow is governed by the Prandtl number, whereas the relative growth of the velocity and concentration boundary layers is governed by the Schmidt number. A Prandtl number of near unity ( $\text{Pr} \approx 1$ ) indicates that momentum and heat transfer by diffusion are comparable, and velocity and thermal boundary layers almost coincide with each other. A *Schmidt number of near unity* ( $\text{Sc} \approx 1$ ) indicates that momentum and mass transfer by diffusion are comparable, and velocity and concentration boundary layers almost coincide with each other.

It seems like we need one more dimensionless number to represent the relative magnitudes of heat and mass diffusion in the thermal and concentration boundary layers. That is the **Lewis number** (Fig. 14-43), defined as (Fig. 14-44)

$$\text{Lewis number: } \text{Le} = \frac{\text{Sc}}{\text{Pr}} = \frac{\alpha}{D_{AB}} = \frac{\text{Thermal diffusivity}}{\text{Mass diffusivity}} \quad (14-70)$$

The relative thicknesses of velocity, thermal, and concentration boundary layers in laminar flow are expressed as

$$\frac{\delta_{\text{velocity}}}{\delta_{\text{thermal}}} = \text{Pr}^n, \quad \frac{\delta_{\text{velocity}}}{\delta_{\text{concentration}}} = \text{Sc}^n, \quad \text{and} \quad \frac{\delta_{\text{thermal}}}{\delta_{\text{concentration}}} = \text{Le}^n \quad (14-71)$$

where  $n = \frac{1}{3}$  for most applications in all three relations. These relations, in general, are not applicable to turbulent boundary layers since turbulent mixing in this case may dominate the diffusion processes.

Note that species transfer at the surface ( $y = 0$ ) is by diffusion only because of the *no-slip boundary condition*, and mass flux of species A at the surface can be expressed by Fick's law as (Fig. 14–45)

$$\bar{j}_A = \dot{m}_A/A_s = -\rho D_{AB} \left. \frac{\partial w_A}{\partial y} \right|_{y=0} = h_{\text{mass}} (w_{A,s} - w_{A,\infty}) \quad (\text{kg/s} \cdot \text{m}^2) \quad (14-72)$$

This is analogous to heat transfer at the surface being by conduction only and expressing it by Fourier's law.

The rate of heat convection for external flow was expressed conveniently by *Newton's law of cooling* as

$$\dot{Q}_{\text{conv}} = h_{\text{conv}} A_s (T_s - T_\infty)$$

where  $h_{\text{conv}}$  is the average heat transfer coefficient,  $A_s$  is the surface area, and  $T_s - T_\infty$  is the temperature difference across the thermal boundary layer. Likewise, the rate of mass convection can be expressed as

$$\dot{m}_{\text{conv}} = h_{\text{mass}} A_s (\rho_{A,s} - \rho_{A,\infty}) = h_{\text{mass}} \rho A_s (w_{A,s} - w_{A,\infty}) \quad (\text{kg/s}) \quad (14-73)$$

where  $h_{\text{mass}}$  is the average **mass transfer coefficient**, in  $\text{m/s}$ ;  $A_s$  is the surface area;  $\rho_{A,s} - \rho_{A,\infty}$  is the mass concentration difference of species A across the concentration boundary layer; and  $\rho$  is the average density of the fluid in the boundary layer. The product  $h_{\text{mass}} \rho$ , whose unit is  $\text{kg/m}^2 \cdot \text{s}$ , is called the *mass transfer conductance*. For internal flow we have

$$\dot{m}_{\text{conv}} = h_{\text{mass}} A_s \frac{\Delta \rho_{A,e} - \Delta \rho_{A,i}}{\ln(\Delta \rho_{A,e}/\Delta \rho_{A,i})} \quad (14-74)$$

where  $\Delta \rho_{A,e} = \rho_{A,s} - \rho_{A,e}$  and  $\Delta \rho_{A,i} = \rho_{A,s} - \rho_{A,i}$ . If the local mass transfer coefficient varies in the flow direction, the *average mass transfer coefficient* can be determined from

$$h_{\text{mass, avg}} = \frac{1}{A_s} \int_{A_s} h_{\text{mass}} dA_s$$

In heat convection analysis, it is often convenient to express the heat transfer coefficient in a nondimensionalized form in terms of the dimensionless *Nusselt number*, defined as

$$\text{Nusselt number:} \quad \text{Nu} = \frac{h_{\text{conv}} L_c}{k} \quad (14-75)$$

where  $L_c$  is the characteristic length and  $k$  is the thermal conductivity of the fluid. The corresponding quantity in mass convection is the dimensionless **Sherwood number** (Fig. 14–46), defined as (Fig. 14–47)

$$\text{Sherwood number:} \quad \text{Sh} = \frac{h_{\text{mass}} L_c}{D_{AB}} \quad (14-76)$$

where  $h_{\text{mass}}$  is the mass transfer coefficient and  $D_{AB}$  is the mass diffusivity. The Nusselt and Sherwood numbers represent the effectiveness of heat and mass convection at the surface, respectively.

**FIGURE 14–43**

**Warren Kendall Lewis** (1882–1975), an American chemical engineer, was born in Laurel, Delaware. He was an MIT professor and through coordination of chemistry, physics, and engineering into an independent discipline to serve the chemical industry, has been called the father of modern chemical engineering. The dimensionless **Lewis number** which characterizes fluid flows in which there are simultaneous heat and mass diffusion convection processes was named after him.

**FIGURE 14–44**

Lewis number is a measure of heat diffusion relative to mass diffusion.

$$-\rho D_{AB} \left. \frac{\partial w_A}{\partial y} \right|_{y=0} = h_{\text{mass}} \rho (w_{A,s} - w_{A,\infty})$$

**FIGURE 14–45**

Mass transfer at a surface occurs by diffusion because of the no-slip boundary condition, just like heat transfer occurring by conduction.

**FIGURE 14–46****Thomas Kilgore Sherwood**

(1903–1976), an American chemical engineer, was born in Columbus, Ohio. Sherwood came to MIT in 1923 for graduate work in the Chemical Engineering Department and completed his doctoral thesis under Warren K. Lewis. Sherwood's primary research area was mass transfer and its interaction with flow and with chemical reaction and industrial process operations in which those phenomena played an important part. He received numerous awards for his research contributions such as the U.S. Medal for Merit and the Lewis Award. The dimensionless **Sherwood number** which represents the ratio of convective to diffusive mass transport was named after him.

*Courtesy MIT Museum.*

$$\text{Heat transfer: } \text{Nu} = \frac{h_{\text{conv}} L_c}{k}$$

$$\text{Mass transfer: } \text{Sh} = \frac{h_{\text{mass}} L_c}{D_{AB}}$$

**FIGURE 14–47**

In mass transfer, the Sherwood number plays the role the Nusselt number plays in heat transfer.

Sometimes it is more convenient to express the heat and mass transfer coefficients in terms of the dimensionless **Stanton number** as

$$\text{Heat transfer Stanton number: } \text{St} = \frac{h_{\text{conv}}}{\rho V c_p} = \text{Nu} \frac{1}{\text{Re Pr}} \quad (14-77)$$

and

$$\text{Mass transfer Stanton number: } \text{St}_{\text{mass}} = \frac{h_{\text{mass}}}{V} = \text{Sh} \frac{1}{\text{Re Sc}} \quad (14-78)$$

where  $V$  is the free steam velocity in external flow and the bulk mean fluid velocity in internal flow.

For a given geometry, the average Nusselt number in forced convection depends on the Reynolds and Prandtl numbers, whereas the average Sherwood number depends on the Reynolds and Schmidt numbers. That is,

$$\begin{aligned} \text{Nusselt number: } & \text{Nu} = f(\text{Re}, \text{Pr}) \\ \text{Sherwood number: } & \text{Sh} = f(\text{Re}, \text{Sc}) \end{aligned}$$

where the functional form of  $f$  is the same for both the Nusselt and Sherwood numbers in a given geometry, provided that the thermal and concentration boundary conditions are of the same type. Therefore, *the Sherwood number can be obtained from the Nusselt number expression by simply replacing the Prandtl number by the Schmidt number*. This shows what a powerful tool analogy can be in the study of natural phenomena (Table 14–12).

In *natural convection mass transfer*, the analogy between the Nusselt and Sherwood numbers still holds, and thus  $\text{Sh} = f(\text{Gr}, \text{Sc})$ . But the Grashof number in this case should be determined directly from

$$\text{Gr} = \frac{g(\rho_\infty - \rho_s) L_c^3}{\rho \nu^2} = \frac{g(\Delta \rho / \rho) L_c^3}{\nu^2} \quad (14-79)$$

which is applicable to both temperature- and/or concentration-driven natural convection flows. Note that in *homogeneous* fluids (i.e., fluids with no concentration gradients), density differences are due to temperature differences only, and thus we can replace  $\Delta \rho / \rho$  by  $\beta \Delta T$  for convenience, as we did in natural convection heat transfer. However, in *nonhomogeneous* fluids, density differences are due to the *combined effects of temperature and concentration differences*, and  $\Delta \rho / \rho$  cannot be replaced by  $\beta \Delta T$  in such cases even when all we care about is heat transfer and we have no interest in mass transfer. For example, hot water at the bottom of a pond rises to the top. But when salt is placed at the bottom, as it is done in solar ponds, the salty water (brine) at the bottom will not rise because it is now heavier than the fresh water at the top (Fig. 14–48).

Concentration-driven natural convection flows are based on the densities of different species in a mixture being different. Therefore, at isothermal conditions, there will be no natural convection in a gas mixture that is composed of gases with identical molar masses. Also, the case of a hot surface facing up corresponds to diffusing fluid having a lower density than the mixture (and thus rising under the influence of buoyancy), and the case of a hot surface facing down corresponds to the diffusing fluid having a higher density. For example, the evaporation of water into air corresponds to a hot surface facing up since water vapor is lighter than the air and it tends to rise. But this is not

the case for gasoline unless the temperature of the gasoline-air mixture at the gasoline surface is so high that thermal expansion overwhelms the density differential due to higher gasoline concentration near the surface.

## Analogy Between Friction, Heat Transfer, and Mass Transfer Coefficients

Consider the flow of a fluid over a flat plate of length  $L$  with free stream conditions of  $T_\infty$ ,  $V$ , and  $w_{A,\infty}$  (Fig. 14–49). Noting that convection at the surface ( $y = 0$ ) is equal to diffusion because of the no-slip condition, the friction, heat transfer, and mass transfer conditions at the surface can be expressed as

$$\text{Wall friction: } \tau_s = \mu \frac{\partial u}{\partial y} \Big|_{y=0} = \frac{f}{2} \rho V^2 \quad (14-80)$$

$$\text{Heat transfer: } \dot{q}_s = -k \frac{\partial T}{\partial y} \Big|_{y=0} = h_{\text{heat}}(T_s - T_\infty) \quad (14-81)$$

$$\text{Mass transfer: } j_{A,s} = -\rho D_{AB} \frac{\partial w_A}{\partial y} \Big|_{y=0} = h_{\text{mass}} \rho (w_{A,s} - w_{A,\infty}) \quad (14-82)$$

These relations can be rewritten for internal flow by using *bulk mean properties* instead of free stream properties. After some simple mathematical manipulations, the three relations above can be rearranged as

$$\text{Wall friction: } \frac{d(u/V)}{d(y/L_c)} \Big|_{y=0} = \frac{f}{2} \frac{\rho VL_c}{\mu} = \frac{f}{2} \text{Re} \quad (14-83)$$

$$\text{Heat transfer: } \frac{d[(T - T_s)/(T_\infty - T_s)]}{d(y/L_c)} \Big|_{y=0} = \frac{h_{\text{heat}} L_c}{k} = \text{Nu} \quad (14-84)$$

$$\text{Mass transfer: } \frac{d[(w_A - w_{A,s})/(w_{A,\infty} - w_{A,s})]}{d(y/L_c)} \Big|_{y=0} = \frac{h_{\text{mass}} L_c}{D_{AB}} = \text{Sh} \quad (14-85)$$

The left sides of these three relations are the slopes of the normalized velocity, temperature, and concentration profiles at the surface, and the right sides are the dimensionless numbers discussed earlier.

## Special Case: $\text{Pr} \approx \text{Sc} \approx 1$ (Reynolds Analogy)

Now consider the hypothetical case in which the molecular diffusivities of momentum, heat, and mass are identical. That is,  $v = \alpha = D_{AB}$  and thus  $\text{Pr} = \text{Sc} = \text{Le} = 1$ . In this case the normalized velocity, temperature, and concentration profiles will coincide, and thus the slope of these three curves at the surface (the left sides of Eqs. 14–83 through 14–85) will be identical (Fig. 14–50). Then we can set the right sides of those three equations equal to each other and obtain

$$\frac{f}{2} \text{Re} = \text{Nu} = \text{Sh} \quad \text{or} \quad \frac{f}{2} \frac{\rho VL_c}{\nu} = \frac{h_{\text{heat}} L_c}{k} = \frac{h_{\text{mass}} L_c}{D_{AB}} \quad (14-86)$$

Noting that  $\text{Pr} = \text{Sc} = 1$ , we can also write this equation as

$$\frac{f}{2} = \frac{\text{Nu}}{\text{Re Pr}} = \frac{\text{Sh}}{\text{Re Sc}} \quad \text{or} \quad \frac{f}{2} = \text{St} = \text{St}_{\text{mass}} \quad (14-87)$$

TABLE 14–12

Analogy between the quantities that appear in the formulation and solution of heat convection and mass convection

| Heat Convection   | Mass Convection  |
|---|--|

| $\delta_{\text{thermal}}$                               | $\delta_{\text{concentration}}$                              |
| $\text{Re} = \frac{\rho VL_c}{\nu}$                     | $\text{Re} = \frac{\rho VL_c}{\nu}$                          |
| $\text{Gr} = \frac{g\beta(T_s - T_\infty)L_c^3}{\nu^2}$ | $\text{Gr} = \frac{g(\rho_\infty - \rho_s)L_c^3}{\rho\nu^2}$ |
| $\text{Pr} = \frac{\nu}{\alpha}$                        | $\text{Sc} = \frac{\nu}{D_{AB}}$                             |
| $\text{St} = \frac{h_{\text{conv}}}{\rho V C_p}$        | $\text{St}_{\text{mass}} = \frac{h_{\text{mass}}}{V}$        |
| $\text{Nu} = \frac{h_{\text{conv}} L_c}{k}$             | $\text{Sh} = \frac{h_{\text{mass}} L_c}{D_{AB}}$             |
| $\text{Nu} = f(\text{Re}, \text{Pr})$                   | $\text{Sh} = f(\text{Re}, \text{Sc})$                        |
| $\text{Nu} = f(\text{Gr}, \text{Pr})$                   | $\text{Sh} = f(\text{Gr}, \text{Sc})$                        |

FIGURE 14–48

A hot fluid at the bottom will rise and initiate natural convection currents only if its density is lower.

FIGURE 14–49

The friction, heat, and mass transfer coefficients for flow over a surface are proportional to the slope of the tangent line of the velocity, temperature, and concentration profiles, respectively, at the surface.

**FIGURE 14–50**

When the molecular diffusivities of momentum, heat, and mass are equal to each other, the velocity, temperature, and concentration boundary layers coincide.

This relation is known as the **Reynolds analogy**, and it enables us to determine the seemingly unrelated friction, heat transfer, and mass transfer coefficients when only one of them is known or measured. (Actually the original Reynolds analogy proposed by O. Reynolds in 1874 is  $\text{St} = f/2$ , which is then extended to include mass transfer.) However, it should always be remembered that the analogy is restricted to situations for which  $\text{Pr} \approx \text{Sc} \approx 1$ . Of course the first part of the analogy between friction and heat transfer coefficients can always be used for gases since their Prandtl number is close to unity.

### General Case: $\text{Pr} \neq \text{Sc} \neq 1$ (Chilton–Colburn Analogy)

The Reynolds analogy is a very useful relation, and it is certainly desirable to extend it to a wider range of  $\text{Pr}$  and  $\text{Sc}$  numbers. Several attempts have been made in this regard, but the simplest and the best known is the one suggested by Chilton and Colburn in 1934 as

$$\frac{f}{2} = \text{St} \text{Pr}^{2/3} = \text{St}_{\text{mass}} \text{Sc}^{2/3} \quad (14-88)$$

for  $0.6 < \text{Pr} < 60$  and  $0.6 < \text{Sc} < 3000$ . This equation is known as the **Chilton–Colburn analogy**. Using the definition of heat and mass Stanton numbers, the analogy between heat and mass transfer can be expressed more conveniently as (Fig. 14–51)

$$\frac{\text{St}}{\text{St}_{\text{mass}}} = \left( \frac{\text{Sc}}{\text{Pr}} \right)^{2/3}$$

$$\text{or} \quad \frac{h_{\text{heat}}}{h_{\text{mass}}} = \rho c_p \left( \frac{\text{Sc}}{\text{Pr}} \right)^{2/3} = \rho c_p \left( \frac{\alpha}{D_{AB}} \right)^{2/3} = \rho c_p \text{Le}^{2/3} \quad (14-89)$$

For air–water vapor mixtures at 298 K, the mass and thermal diffusivities are  $D_{AB} = 2.5 \times 10^{-5} \text{ m}^2/\text{s}$  and  $\alpha = 2.18 \times 10^{-5} \text{ m}^2/\text{s}$  and thus the Lewis number is  $\text{Le} = \alpha/D_{AB} = 0.872$ . (We simply use the  $\alpha$  value of dry air instead of the moist air since the fraction of vapor in the air at atmospheric conditions is low.) Then  $(\alpha/D_{AB})^{2/3} = 0.872^{2/3} = 0.913$ , which is close to unity. Also, the Lewis number is relatively insensitive to variations in temperature. Therefore, for air–water vapor mixtures, the relation between heat and mass transfer coefficients can be expressed with a good accuracy as

$$h_{\text{heat}} \cong \rho c_p h_{\text{mass}} \quad (\text{air–water vapor mixtures}) \quad (14-90)$$

where  $\rho$  and  $c_p$  are the density and specific heat of air at average conditions (or  $\rho c_p$  is the specific heat of air per unit volume). Equation 14–90 is known as the **Lewis relation** and is commonly used in air-conditioning applications. Another important consequence of  $\text{Le} \cong 1$  is that the *wet-bulb* and *adiabatic saturation temperatures* of moist air are nearly identical. In *turbulent flow*, the Lewis relation can be used even when the Lewis number is not 1 since eddy mixing in turbulent flow overwhelms any molecular diffusion, and heat and mass are transported at the same rate.

The Chilton–Colburn analogy has been observed to hold quite well in laminar or turbulent flow over plane surfaces. But this is not always the case for

**FIGURE 14–51**

When the friction or heat transfer coefficient is known, the mass transfer coefficient can be determined directly from the Chilton–Colburn analogy.

internal flow and flow over irregular geometries, and in such cases specific relations developed should be used. When dealing with flow over blunt bodies, it is important to note that  $f$  in these relations is the *skin friction coefficient*, not the total drag coefficient, which also includes the pressure drag.

## Limitation on the Heat–Mass Convection Analogy

Caution should be exercised when using the analogy in Eq. 14–88 since there are a few factors that put some shadow on the accuracy of that relation. For one thing, the Nusselt numbers are usually evaluated for smooth surfaces, but many mass transfer problems involve wavy or roughened surfaces. Also, many Nusselt relations are obtained for constant surface temperature situations, but the concentration may not be constant over the entire surface because of the possible surface dryout. The blowing or suction at the surface during mass transfer may also cause some deviation, especially during high speed blowing or suction.

Finally, the heat–mass convection analogy is valid for **low mass flux** cases in which the flow rate of species undergoing mass flow is low relative to the total flow rate of the liquid or gas mixture so that the mass transfer between the fluid and the surface does not affect the *flow velocity*. (Note that convection relations are based on *zero* fluid velocity at the surface, which is true only when there is no net mass transfer at the surface.) Therefore, the heat–mass convection analogy is not applicable when the rate of mass transfer of a species is high relative to the flow rate of that species.

Consider, for example, the evaporation and transfer of water vapor into air in an air washer, an evaporative cooler, a wet cooling tower, or just at the free surface of a lake or river (Fig. 14–52). Even at a temperature of 40°C, the vapor pressure at the water surface is the saturation pressure of 7.4 kPa, which corresponds to a mole fraction of 0.074 or a mass fraction of  $w_{A,s} = 0.047$  for the vapor. Then the mass fraction difference across the boundary layer will be, at most,  $\Delta w = w_{A,s} - w_{A,\infty} = 0.047 - 0 = 0.047$ . For the evaporation of water into air, the error involved in the low mass flux approximation is roughly  $\Delta w/2$ , which is 2.5 percent in the worst case considered above. Therefore, in processes that involve the evaporation of water into air, we can use the heat–mass convection analogy with confidence. However, the mass fraction of vapor approaches 1 as the water temperature approaches the saturation temperature, and thus the low mass flux approximation is not applicable to mass transfer in boilers, condensers, and the evaporation of fuel droplets in combustion chambers. In this chapter, we limit our consideration to low mass flux applications.

## Mass Convection Relations

Under low mass flux conditions, the mass convection coefficients can be determined by either (1) determining the friction or heat transfer coefficient and then using the Chilton–Colburn analogy or (2) picking the appropriate Nusselt number relation for the given geometry and analogous boundary conditions, replacing the Nusselt number by the Sherwood number and the Prandtl number by the Schmidt number, as shown in Table 14–13 for some representative cases. The first approach is obviously more convenient when the friction or heat transfer coefficient is already known. Otherwise,

**FIGURE 14–52**  
Evaporation from the free surface of water into air.

the second approach should be preferred since it is generally more accurate, and the Chilton–Colburn analogy offers no significant advantage in this case. Relations for convection mass transfer in other geometries can be written similarly using the corresponding heat transfer relation in Chapters 6 through 9.

**TABLE 14–13**

Sherwood number relations in mass convection for specified concentration at the surface corresponding to the Nusselt number relations in heat convection for specified surface temperature

**EXAMPLE 14–11** Mass Convection Inside a Circular Pipe

Consider a circular pipe of inner diameter  $D = 0.015\text{ m}$  whose inner surface is covered with a layer of liquid water as a result of condensation (Fig. 14–53). In order to dry the pipe, air at  $300\text{ K}$  and  $1\text{ atm}$  is forced to flow through it with an average velocity of  $1.2\text{ m/s}$ . Using the analogy between heat and mass transfer, determine the mass transfer coefficient inside the pipe for fully developed flow.

**SOLUTION** The liquid layer on the inner surface of a circular pipe is dried by blowing air through it. The mass transfer coefficient is to be determined.

**Assumptions** 1 The low mass flux model and thus the analogy between heat and mass transfer is applicable since the mass fraction of vapor in the air is low (about 2 percent for saturated air at  $300\text{ K}$ ). 2 The flow is fully developed.

**Properties** Because of low mass flux conditions, we can use dry air properties for the mixture at the specified temperature of  $300\text{ K}$  and  $1\text{ atm}$ , for which  $v = 1.58 \times 10^{-5}\text{ m}^2/\text{s}$  (Table A–15). The mass diffusivity of water vapor in the air at  $300\text{ K}$  is determined from Eq. 14–15 to be

$$D_{AB} = D_{H_2O\text{-air}} = 1.87 \times 10^{-10} \frac{T^{2.072}}{P} = 1.87 \times 10^{-10} \frac{300^{2.072}}{1} \\ = 2.54 \times 10^{-5}\text{ m}^2/\text{s}$$

**Analysis** The Reynolds number for this internal flow is

$$\text{Re} = \frac{VD}{v} = \frac{(1.2\text{ m/s})(0.015\text{ m})}{1.58 \times 10^{-5}\text{ m}^2/\text{s}} = 1139$$

which is less than 2300 and thus the flow is laminar. Therefore, based on the analogy between heat and mass transfer, the Nusselt and the Sherwood numbers in this case are  $\text{Nu} = \text{Sh} = 3.66$ . Using the definition of Sherwood number, the mass transfer coefficient is determined to be

$$h_{\text{mass}} = \frac{\text{Sh}D_{AB}}{D} = \frac{(3.66)(2.54 \times 10^{-5}\text{ m}^2/\text{s})}{0.015\text{ m}} = \mathbf{0.00620\text{ m/s}}$$

The mass transfer rate (or the evaporation rate) in this case can be determined by defining the logarithmic mean concentration difference in an analogous manner to the logarithmic mean temperature difference.

**FIGURE 14–53**

Schematic for Example 14–11.

**EXAMPLE 14–12** Analogy Between Heat and Mass Transfer

Heat transfer coefficients in complex geometries with complicated boundary conditions can be determined by mass transfer measurements on similar geometries under similar flow conditions using volatile solids such as naphthalene and dichlorobenzene and utilizing the Chilton–Colburn analogy between heat and mass transfer at low mass flux conditions. The amount of mass transfer during a specified time period is determined by weighing the model or measuring the surface recession.

During a certain experiment involving the flow of dry air at  $25^\circ\text{C}$  and  $1\text{ atm}$  at a free stream velocity of  $2\text{ m/s}$  over a body covered with a layer of naphthalene, it is observed that  $12\text{ g}$  of naphthalene has sublimated in  $15\text{ min}$  (Fig. 14–54). The surface area of the body is  $0.3\text{ m}^2$ . Both the body and the air were kept at  $25^\circ\text{C}$  during the study. The vapor pressure of naphthalene at  $25^\circ\text{C}$  is  $11\text{ Pa}$  and

**FIGURE 14–54**

Schematic for Example 14–12.

the mass diffusivity of naphthalene in air at 25°C is  $D_{AB} = 0.61 \times 10^{-5} \text{ m}^2/\text{s}$ . Determine the heat transfer coefficient under the same flow conditions over the same geometry.

**SOLUTION** Air is blown over a body covered with a layer of naphthalene, and the rate of sublimation is measured. The heat transfer coefficient under the same flow conditions over the same geometry is to be determined.

**Assumptions** 1 The low mass flux conditions exist so that the Chilton-Colburn analogy between heat and mass transfer is applicable (will be verified). 2 Both air and naphthalene vapor are ideal gases.

**Properties** The molar mass of naphthalene is 128.2 kg/kmol. Because of low mass flux conditions, we can use dry air properties for the mixture at the specified temperature of 25°C and 1 atm, at which  $\rho = 1.184 \text{ kg/m}^3$ ,  $c_p = 1007 \text{ J/kg}\cdot\text{K}$ , and  $\alpha = 2.141 \times 10^{-5} \text{ m}^2/\text{s}$  (Table A-15).

**Analysis** The incoming air is free of naphthalene, and thus the mass fraction of naphthalene at free stream conditions is zero,  $w_{A,\infty} = 0$ . Noting that the vapor pressure of naphthalene at the surface is 11 Pa, its mass fraction at the surface is determined to be

$$w_{A,s} = \frac{P_{A,s}}{P} \left( \frac{M_A}{M_{\text{air}}} \right) = \frac{11 \text{ Pa}}{101,325 \text{ Pa}} \left( \frac{128.2 \text{ kg/kmol}}{29 \text{ kg/kmol}} \right) = 4.8 \times 10^{-4}$$

which confirms that the low mass flux approximation is valid. The rate of evaporation of naphthalene in this case is

$$\dot{m}_{\text{evap}} = \frac{m}{\Delta t} = \frac{0.012 \text{ kg}}{(15 \times 60 \text{ s})} = 1.33 \times 10^{-5} \text{ kg/s}$$

Then the mass convection coefficient becomes

$$h_{\text{mass}} = \frac{\dot{m}}{\rho A_s (w_{A,s} - w_{A,\infty})} = \frac{1.33 \times 10^{-5} \text{ kg/s}}{(1.184 \text{ kg/m}^3)(0.3 \text{ m}^2)(4.8 \times 10^{-4} - 0)} \\ = 0.0780 \text{ m/s}$$

Using the analogy between heat and mass transfer, the average heat transfer coefficient is determined from Eq. 14-89 to be

$$h_{\text{heat}} = \rho c_p h_{\text{mass}} \left( \frac{\alpha}{D_{AB}} \right)^{2/3} \\ = (1.184 \text{ kg/m}^3)(1007 \text{ J/kg}\cdot\text{K})(0.0780 \text{ m/s}) \left( \frac{2.141 \times 10^{-5} \text{ m}^2/\text{s}}{0.61 \times 10^{-5} \text{ m}^2/\text{s}} \right)^{2/3} \\ = 215 \text{ W/m}^2\cdot\text{K}$$

**Discussion** Because of the convenience it offers, naphthalene has been used in numerous heat transfer studies to determine convection heat transfer coefficients.

## 14-10 • SIMULTANEOUS HEAT AND MASS TRANSFER

Many mass transfer processes encountered in practice occur isothermally, and thus they do not involve any heat transfer. But some engineering applications involve the vaporization of a liquid and the diffusion of this vapor into the surrounding gas. Such processes require the transfer of the latent

heat of vaporization  $h_{fg}$  to the liquid in order to vaporize it, and thus such problems involve simultaneous heat and mass transfer. To generalize, any mass transfer problem involving *phase change* (evaporation, sublimation, condensation, melting, etc.) must also involve *heat transfer*, and the solution of such problems needs to be analyzed by considering *simultaneous heat and mass transfer*. Some examples of simultaneous heat and mass problems are drying, evaporative cooling, transpiration (or sweat) cooling, cooling by dry ice, combustion of fuel droplets, and ablation cooling of space vehicles during reentry, and even ordinary events like rain, snow, and hail. In warmer locations, for example, the snow melts and the rain evaporates before reaching the ground (Fig. 14–55).

To understand the mechanism of simultaneous heat and mass transfer, consider the *evaporation of water* from a swimming pool into air. Let us assume that the water and the air are initially at the same temperature. If the air is saturated (a relative humidity of  $\phi = 100$  percent), there will be no heat or mass transfer as long as the isothermal conditions remain. But if the air is not saturated ( $\phi < 100$  percent), there will be a difference between the concentration of water vapor at the water-air interface (which is always saturated) and some distance above the interface (the concentration boundary layer). Concentration difference is the driving force for mass transfer, and thus this concentration difference drives the water into the air. But the water must vaporize first, and it must absorb the latent heat of vaporization in order to vaporize. Initially, the entire heat of vaporization comes from the water near the interface since there is no temperature difference between the water and the surroundings and thus there cannot be any heat transfer. The temperature of water near the surface must drop as a result of the sensible heat loss, which also drops the saturation pressure and thus vapor concentration at the interface.

This temperature drop creates temperature differences within the water at the top as well as between the water and the surrounding air. These temperature differences drive heat transfer toward the water surface from both the air and the deeper parts of the water, as shown in Figure 14–56. If the evaporation rate is high and thus the demand for the heat of vaporization is higher than the amount of heat that can be supplied from the lower parts of the water body and the surroundings, the deficit is made up from the sensible heat of the water at the surface, and thus the temperature of water at the surface drops further. The process continues until the latent heat of vaporization equals the heat transfer to the water at the surface. Once the steady operation conditions are reached and the interface temperature stabilizes, the energy balance on a thin layer of liquid at the surface can be expressed as

$$\dot{Q}_{\text{sensible, transferred}} = \dot{Q}_{\text{latent, absorbed}} \quad \text{or} \quad \dot{Q} = \dot{m}_v h_{fg} \quad (14-91)$$

where  $\dot{m}_v$  is the rate of evaporation and  $h_{fg}$  is the latent heat of vaporization of water at the surface temperature. Various expressions for  $\dot{m}_v$  under various approximations are given in Table 14–14. The mixture properties such as the specific heat  $c_p$  and molar mass  $M$  should normally be evaluated at the *mean film composition* and *mean film temperature*. However, when dealing with air–water vapor mixtures at atmospheric conditions or other low mass flux situations, we can simply use the properties of the gas with reasonable accuracy.

FIGURE 14-55

Many problems encountered in practice involve simultaneous heat and mass transfer.

FIGURE 14-56

Various mechanisms of heat transfer involved during the evaporation of water from the surface of a lake.

TABLE 14-14

Various expressions for evaporation rate of a liquid into a gas through an interface area  $A_s$  under various approximations (subscript  $v$  stands for vapor,  $s$  for liquid–gas interface, and  $\infty$  away from surface)

| Assumption  | Evaporation Rate  |
|---|---|
| General   | $\dot{m}_v = h_{\text{mass}} A_s (\rho_{v,s} - \rho_{v,\infty})$  |
| Assuming vapor to be an ideal gas,<br>$P_v = \rho_v R_v T$  | $\dot{m}_v = \frac{h_{\text{mass}} A_s}{R_v} \left( \frac{P_{v,s}}{T_s} - \frac{P_{v,\infty}}{T_\infty} \right)$                          |
| Using Chilton–Colburn analogy,<br>$h_{\text{heat}} = \rho c_p h_{\text{mass}} \text{Le}^{2/3}$        | $\dot{m}_v = \frac{h_{\text{mass}} A_s}{\rho c_p \text{Le}^{2/3} R_v} \left( \frac{P_{v,s}}{T_s} - \frac{P_{v,\infty}}{T_\infty} \right)$ |
| Using $\frac{1}{T_s} - \frac{1}{T_\infty} \approx \frac{1}{T}$ , where $T = \frac{T_s + T_\infty}{2}$ | $\dot{m}_v = \frac{h_{\text{mass}} A_s}{\rho c_p \text{Le}^{2/3}} \frac{M_v}{M} \frac{P_{v,s} - P_{v,\infty}}{P}$                         |

The  $\dot{Q}$  in Eq. 14-91 represents all forms of heat from all sources transferred to the surface, including convection and radiation from the surroundings and conduction from the deeper parts of the water due to the sensible energy of the water itself or due to heating the water body by a resistance heater, heating coil, or even chemical reactions in the water. If heat transfer from the water body to the surface as well as radiation from the surroundings is negligible, which is often the case, then the heat loss by evaporation must equal heat gain by convection. That is,

$$\dot{Q}_{\text{conv}} = \dot{m}_v h_{fg} \quad \text{or} \quad h_{\text{conv}} A_s (T_\infty - T_s) = \frac{h_{\text{conv}} A_s h_{fg}}{c_p \text{Le}^{2/3}} \frac{M_v}{M} \frac{P_{v,s} - P_{v,\infty}}{P}$$

Cancelling  $h_{\text{conv}} A_s$  from both sides of the second equation gives

$$T_s = T_\infty - \frac{h_{fg}}{c_p \text{Le}^{2/3}} \frac{M_v}{M} \frac{P_{v,s} - P_{v,\infty}}{P} \quad (14-92)$$

which is a relation for the temperature of the liquid under steady conditions.

FIGURE 14-57

Schematic for Example 14-13.

### EXAMPLE 14-13 Evaporative Cooling of a Canned Drink

During a hot summer day, a canned drink is to be cooled by wrapping it in a cloth that is kept wet continually, and blowing air to it by a fan (Fig. 14-57). If the environment conditions are 1 atm, 30°C, and 40 percent relative humidity, determine the temperature of the drink when steady conditions are reached.

**SOLUTION** Air is blown over a canned drink wrapped in a wet cloth to cool it by simultaneous heat and mass transfer. The temperature of the drink when steady conditions are reached is to be determined.

**Assumptions** 1 The low mass flux conditions exist so that the Chilton–Colburn analogy between heat and mass transfer is applicable since the mass fraction of vapor in the air is low (about 2 percent for saturated air at 25°C).

**2** Both air and water vapor at specified conditions are ideal gases (the error involved in this assumption is less than 1 percent). **3** Radiation effects are negligible.

**Properties** Because of low mass flux conditions, we can use dry air properties for the mixture at the average temperature of  $(T_\infty + T_s)/2$  which cannot be determined at this point because of the unknown surface temperature  $T_s$ . We know that  $T_s < T_\infty$  and, for the purpose of property evaluation, we take  $T_s$  to be 20°C. Then the properties of water at 20°C and the properties of dry air at the average temperature of 25°C and 1 atm are (Tables A-9 and A-15)

Water:  $h_{fg} = 2454 \text{ kJ/kg}$ ,  $P_v = 2.34 \text{ kPa}$ ; also,  $P_v = 4.25 \text{ kPa}$  at 30°C

Dry air:  $c_p = 1.007 \text{ kJ/kg}\cdot\text{°C}$ ,  $\alpha = 2.141 \times 10^{-5} \text{ m}^2/\text{s}$

The molar masses of water and air are 18 and 29 kg/kmol, respectively (Table A-1). Also, the mass diffusivity of water vapor in air at 25°C is  $D_{\text{H}_2\text{O-air}} = 2.50 \times 10^{-5} \text{ m}^2/\text{s}$  (Table 14-4).

**Analysis** Utilizing the Chilton–Colburn analogy, the surface temperature of the drink can be determined from Eq. 14-92,

$$T_s = T_\infty - \frac{h_{fg}}{c_p \text{Le}^{2/3}} \frac{M_v}{M} \frac{P_{v,s} - P_{v,\infty}}{P}$$

where the Lewis number is

$$\text{Le} = \frac{\alpha}{D_{AB}} = \frac{2.141 \times 10^{-5} \text{ m}^2/\text{s}}{2.5 \times 10^{-5} \text{ m}^2/\text{s}} = 0.856$$

Note that we could take the Lewis number to be 1 for simplicity, but we chose to incorporate it for better accuracy.

The air at the surface is saturated, and thus the vapor pressure at the surface is simply the saturation pressure of water at the surface temperature (2.34 kPa). The vapor pressure of air away from the surface is

$$P_{v,\infty} = \phi P_{\text{sat} @ T_\infty} = (0.40)P_{\text{sat} @ 30^\circ\text{C}} = (0.40)(4.25 \text{ kPa}) = 1.70 \text{ kPa}$$

Noting that the atmospheric pressure is 1 atm = 101.3 kPa, substituting gives

$$T_s = 30^\circ\text{C} - \frac{2454 \text{ kJ/kg}}{(1.007 \text{ kJ/kg}\cdot\text{K})(0.856)^{2/3}} \frac{18 \text{ kg/kmol}}{29 \text{ kg/kmol}} \frac{(2.34 - 1.70) \text{ kPa}}{101.3 \text{ kPa}}$$

$$= 19.4^\circ\text{C}$$

Therefore, the temperature of the drink can be lowered to 19.4°C by this process.

### EXAMPLE 14-14 Heat Loss from Uncovered Hot Water Baths

Hot water baths with open tops are commonly used in manufacturing facilities for various reasons. In a plant that manufactures spray paints, the pressurized paint cans are temperature tested by submerging them in hot water at 50°C in a 40-cm-deep rectangular bath and keeping them there until the cans are heated to 50°C to ensure that the cans can withstand temperatures up to 50°C during transportation and storage (Fig. 14-58). The water bath is 1 m wide and 3.5 m long, and its top surface is open to ambient air to facilitate easy observation for the workers. If the average conditions in the plant are 92 kPa,

**FIGURE 14-58**  
Schematic for Example 14-14.

25°C, and 52 percent relative humidity, determine the rate of heat loss from the top surface of the water bath by (a) radiation, (b) natural convection, and (c) evaporation. Assume the water is well agitated and maintained at a uniform temperature of 50°C at all times by a heater, and take the average temperature of the surrounding surfaces to be 20°C.

**SOLUTION** Spray paint cans are temperature tested by submerging them in an uncovered hot water bath. The rates of heat loss from the top surface of the bath by radiation, natural convection, and evaporation are to be determined.

**Assumptions** 1 The low mass flux conditions exist so that the Chilton-Colburn analogy between heat and mass transfer is applicable since the mass fraction of vapor in the air is low (about 2 percent for saturated air at 300 K). 2 Both air and water vapor at specified conditions are ideal gases (the error involved in this assumption is less than 1 percent). 3 Water is maintained at a uniform temperature of 50°C.

**Properties** Relevant properties for each mode of heat transfer are determined below in respective sections.

**Analysis** (a) The emissivity of liquid water is given in Table A-18 to be 0.95. Then the radiation heat loss from the water to the surrounding surfaces becomes

$$\begin{aligned}\dot{Q}_{\text{rad}} &= \varepsilon A_s \sigma (T_s^4 - T_{\text{surr}}^4) \\ &= (0.95)(3.5 \text{ m}^2)(5.67 \times 10^{-8} \text{ W/m}^2\cdot\text{K}^4)[(323 \text{ K})^4 - (293 \text{ K})^4] \\ &= 663 \text{ W}\end{aligned}$$

(b) The air-water vapor mixture is dilute and thus we can use dry air properties for the mixture at the average temperature of  $(T_\infty + T_s)/2 = (25 + 50)/2 = 37.5^\circ\text{C}$ . Noting that the total atmospheric pressure is  $92/101.3 = 0.9080$  atm, the properties of dry air at 37.5°C and 0.9080 atm are (Table A-15)

$$k = 0.02644 \text{ W/m}\cdot\text{K}, \quad \text{Pr} = 0.7262 \text{ (independent of pressure)}$$

$$\alpha = (2.312 \times 10^{-5} \text{ m}^2/\text{s})/0.9080 = 2.546 \times 10^{-5} \text{ m}^2/\text{s}$$

$$v = (1.679 \times 10^{-5} \text{ m}^2/\text{s})/0.9080 = 1.849 \times 10^{-5} \text{ m}^2/\text{s}$$

The properties of water at 50°C are

$$h_{fg} = 2383 \text{ kJ/kg} \quad \text{and} \quad P_v = 12.35 \text{ kPa}$$

The air at the surface is saturated, and thus the vapor pressure at the surface is simply the saturation pressure of water at the surface temperature. The vapor pressure of air far from the water surface is

$$P_{v,\infty} = \phi P_{\text{sat} @ T_\infty} = (0.52)P_{\text{sat} @ 25^\circ\text{C}} = (0.52)(3.17 \text{ kPa}) = 1.65 \text{ kPa}$$

Treating the water vapor and the air as ideal gases and noting that the total atmospheric pressure is the sum of the vapor and dry air pressures, the densities of the water vapor, dry air, and their mixture at the water-air interface and far from the surface are determined to be

$$\begin{aligned}\text{At the surface:} \quad \rho_{v,s} &= \frac{P_{v,s}}{R_v T_s} = \frac{12.35 \text{ kPa}}{(0.4615 \text{ kPa}\cdot\text{m}^3/\text{kg}\cdot\text{K})(323 \text{ K})} = 0.0829 \text{ kg/m}^3 \\ \rho_{a,s} &= \frac{P_{a,s}}{R_a T_s} = \frac{(92 - 12.35) \text{ kPa}}{(0.287 \text{ kPa}\cdot\text{m}^3/\text{kg}\cdot\text{K})(323 \text{ K})} = 0.8592 \text{ kg/m}^3 \\ \rho_s &= \rho_{v,s} + \rho_{a,s} = 0.0829 + 0.8592 = 0.9421 \text{ kg/m}^3\end{aligned}$$

Away from the surface:  $\rho_{v,\infty} = \frac{P_{v,\infty}}{R_v T_\infty} = \frac{1.65 \text{ kPa}}{(0.4615 \text{ kPa}\cdot\text{m}^3/\text{kg}\cdot\text{K})(298 \text{ K})} = 0.0120 \text{ kg/m}^3$

$$\rho_{a,\infty} = \frac{P_{a,\infty}}{R_a T_\infty} = \frac{(92 - 1.65) \text{ kPa}}{(0.287 \text{ kPa}\cdot\text{m}^3/\text{kg}\cdot\text{K})(298 \text{ K})} = 1.0564 \text{ kg/m}^3$$

$$\rho_\infty = \rho_{v,\infty} + \rho_{a,\infty} = 0.0120 + 1.0564 = 1.0684 \text{ kg/m}^3$$

The area of the top surface of the water bath is  $A_s = (3.5 \text{ m})(1 \text{ m}) = 3.5 \text{ m}^2$  and its perimeter is  $p = 2(3.5 + 1) = 9 \text{ m}$ . Therefore, the characteristic length is

$$L_c = \frac{A_s}{p} = \frac{3.5 \text{ m}^2}{9 \text{ m}} = 0.3889 \text{ m}$$

Then using densities (instead of temperatures) since the mixture is not homogeneous, the Grashof number is

$$\begin{aligned} \text{Gr} &= \frac{g(\rho_\infty - \rho_s)L_c^3}{\rho\nu^2} \\ &= \frac{(9.81 \text{ m/s}^2)(1.0684 - 0.9421 \text{ kg/m}^3)(0.3889 \text{ m})^3}{[(0.9421 + 1.0684)/2 \text{ kg/m}^3](1.849 \times 10^{-5} \text{ m}^2/\text{s})^2} \\ &= 2.121 \times 10^8 \end{aligned}$$

Recognizing that this is a natural convection problem with hot horizontal surface facing up, the Nusselt number and the convection heat transfer coefficients are determined to be

$$\text{Nu} = 0.15(\text{Gr Pr})^{1/3} = 0.15(2.121 \times 10^8 \times 0.7262)^{1/3} = 80.41$$

$$h_{\text{conv}} = \frac{\text{Nuk}}{L_c} = \frac{(80.41)(0.02644 \text{ W/m}\cdot\text{K})}{0.3889 \text{ m}} = 5.47 \text{ W/m}^2\cdot\text{K}$$

Then the natural convection heat transfer rate becomes

$$\begin{aligned} \dot{Q}_{\text{conv}} &= h_{\text{conv}} A_s (T_s - T_\infty) \\ &= (5.47 \text{ W/m}^2\cdot\text{K})(3.5 \text{ m}^2)(50 - 25)^\circ\text{C} = 479 \text{ W} \end{aligned}$$

Note that the magnitude of natural convection heat transfer is comparable to that of radiation, as expected.

(c) Utilizing the analogy between heat and mass convection, the mass transfer coefficient is determined the same way by replacing Pr by Sc. The mass diffusivity of water vapor in air at the average temperature of 310.5 K is determined from Eq. 14-15 to be

$$\begin{aligned} D_{AB} &= D_{\text{H}_2\text{O-air}} = 1.87 \times 10^{-10} \frac{T^{2.072}}{P} = 1.87 \times 10^{-10} \frac{310.5^{2.072}}{0.908} \\ &= 3.00 \times 10^{-5} \text{ m}^2/\text{s} \end{aligned}$$

The Schmidt number is

$$\text{Sc} = \frac{\nu}{D_{AB}} = \frac{1.849 \times 10^{-5} \text{ m}^2/\text{s}}{3.00 \times 10^{-5} \text{ m}^2/\text{s}} = 0.616$$

The Sherwood number and the mass transfer coefficients are determined to be

$$\text{Sh} = 0.15(\text{Gr Sc})^{1/3} = 0.15(2.121 \times 10^8 \times 0.616)^{1/3} = 76.1$$

$$h_{\text{mass}} = \frac{\text{Sh} D_{AB}}{L_c} = \frac{(76.1)(3.00 \times 10^{-5} \text{ m}^2/\text{s})}{0.3889 \text{ m}} = 0.00587 \text{ m/s}$$

Then the evaporation rate and the rate of heat transfer by evaporation become

$$\begin{aligned}\dot{m}_v &= h_{\text{mass}} A_s (\rho_{v,s} - \rho_{v,\infty}) \\ &= (0.00587 \text{ m/s})(3.5 \text{ m}^2)(0.0829 - 0.0120) \text{ kg/m}^3 \\ &= 0.00146 \text{ kg/s} = 5.24 \text{ kg/h}\end{aligned}$$

$$\dot{Q}_{\text{evap}} = \dot{m}_v h_{fg} = (0.00146 \text{ kg/s})(2383 \text{ kJ/kg}) = 3.479 \text{ kW} = \mathbf{3479 \text{ W}}$$

which is more than seven times the rate of heat transfer by natural convection.

Finally, noting that the direction of heat transfer is always from high to low temperature, all forms of heat transfer determined above are in the same direction, and the total rate of heat loss from the water to the surrounding air and surfaces is

$$\dot{Q}_{\text{total}} = \dot{Q}_{\text{rad}} + \dot{Q}_{\text{conv}} + \dot{Q}_{\text{evap}} = 663 + 479 + 3479 = 4621 \text{ W}$$

**Discussion** Note that if the water bath is heated electrically, a 4.6 kW resistance heater will be needed just to make up for the heat loss from the top surface. The total heater size will have to be larger to account for the heat losses from the side and bottom surfaces of the bath as well as the heat absorbed by the spray paint cans as they are heated to 50°C. Also note that water needs to be supplied to the bath at a rate of 5.24 kg/h to make up for the water loss by evaporation. Also, in reality, the surface temperature will probably be a little lower than the bulk water temperature, and thus the heat transfer rates will be somewhat lower than indicated here.

## SUMMARY

*Mass transfer* is the movement of a chemical species from a high concentration region toward a lower concentration one relative to the other chemical species present in the medium. Heat and mass transfer are analogous to each other, and several parallels can be drawn between them. The driving forces are the *temperature difference* in heat transfer and the *concentration difference* in mass transfer. Fick's law of mass diffusion is of the same form as Fourier's law of heat conduction. The species generation in a medium due to *homogeneous reactions* is analogous to heat generation. Also, mass convection due to bulk fluid motion is analogous to heat convection. Constant surface temperature corresponds to constant concentration at the surface, and an adiabatic wall corresponds to an impermeable wall. However, concentration is usually not a continuous function at a phase interface.

The concentration of a species *A* can be expressed in terms of density  $\rho_A$  or molar concentration  $C_A$ . It can also be expressed in dimensionless form in terms of *mass* or *molar fraction* as

$$\text{Mass fraction of species } A: \quad w_A = \frac{m_A}{m} = \frac{m_A/V}{m/V} = \frac{\rho_A}{\rho}$$

$$\text{Mole fraction of species } A: \quad y_A = \frac{N_A}{N} = \frac{N_A/V}{N/V} = \frac{C_A}{C}$$

In the case of an ideal gas mixture, the mole fraction of a gas is equal to its pressure fraction. *Fick's law* for the diffusion of a species *A* in a stationary binary mixture of species *A* and *B* in a specified direction *x* is expressed as

$$\begin{aligned}\text{Mass basis:} \quad j_{\text{diff},A} &= \frac{\dot{m}_{\text{diff},A}}{A} = -\rho D_{AB} \frac{d(\rho_A/\rho)}{dx} \\ &= -\rho D_{AB} \frac{dw_A}{dx}\end{aligned}$$

$$\begin{aligned}\text{Mole basis:} \quad j_{\text{diff},A} &= \frac{\dot{N}_{\text{diff},A}}{A} = -CD_{AB} \frac{d(C_A/C)}{dx} \\ &= -CD_{AB} \frac{dy_A}{dx}\end{aligned}$$

where  $D_{AB}$  is the *diffusion coefficient* (or *mass diffusivity*) of the species in the mixture,  $j_{\text{diff}, A}$  is the diffusive *mass flux* of species  $A$ , and  $\bar{j}_{\text{diff}, A}$  is the *molar flux*.

The mole fractions of a species  $i$  in the gas and liquid phases at the interface of a dilute mixture are proportional to each other and are expressed by *Henry's law* as

$$y_{i, \text{liquid side}} = \frac{P_{i, \text{gas side}}}{H}$$

where  $H$  is *Henry's constant*. When the mixture is not dilute, an approximate relation for the mole fractions of a species on the liquid and gas sides of the interface are expressed approximately by *Raoult's law* as

$$P_{i, \text{gas side}} = y_{i, \text{gas side}} P = y_{i, \text{liquid side}} P_{i, \text{sat}}(T)$$

where  $P_{i, \text{sat}}(T)$  is the saturation pressure of the species  $i$  at the interface temperature and  $P$  is the *total pressure* on the gas phase side.

The concentration of the gas species  $i$  in the solid at the interface  $C_{i, \text{solid side}}$  is proportional to the *partial pressure* of the species  $i$  in the gas  $P_{i, \text{gas side}}$  on the gas side of the interface and is expressed as

$$C_{i, \text{solid side}} = \mathcal{S} \times P_{i, \text{gas side}}$$

where  $\mathcal{S}$  is the *solubility*. The product of the *solubility* of a gas and the *diffusion coefficient* of the gas in a solid is referred to as the *permeability*  $\mathcal{P}$ , which is a measure of the ability of the gas to penetrate a solid.

In the absence of any chemical reactions, the mass transfer rates  $\dot{m}_{\text{diff}, A}$  through a plane wall of area  $A$  and thickness  $L$  and cylindrical and spherical shells of inner and outer radii  $r_1$  and  $r_2$  under one-dimensional steady conditions are expressed as

$$\begin{aligned}\dot{m}_{\text{diff}, A, \text{wall}} &= \rho D_{AB} A \frac{w_{A, 1} - w_{A, 2}}{L} = D_{AB} A \frac{\rho_{A, 1} - \rho_{A, 2}}{L} \\ \dot{m}_{\text{diff}, A, \text{cyl}} &= 2\pi L \rho D_{AB} \frac{w_{A, 1} - w_{A, 2}}{\ln(r_2/r_1)} = 2\pi L D_{AB} \frac{\rho_{A, 1} - \rho_{A, 2}}{\ln(r_2/r_1)} \\ \dot{m}_{\text{diff}, A, \text{sph}} &= 4\pi r_1 r_2 \rho D_{AB} \frac{w_{A, 1} - w_{A, 2}}{r_2 - r_1} \\ &= 4\pi r_1 r_2 D_{AB} \frac{\rho_{A, 1} - \rho_{A, 2}}{r_2 - r_1}\end{aligned}$$

The flow rate of a gas through a solid plane wall under steady one-dimensional conditions can also be expressed in terms of the partial pressures of the adjacent gas on the two sides of the solid as

$$\dot{N}_{\text{diff}, A, \text{wall}} = D_{AB} \mathcal{S}_{AB} A \frac{P_{A, 1} - P_{A, 2}}{L} = \mathcal{P}_{AB} A \frac{P_{A, 1} - P_{A, 2}}{L}$$

where  $P_{A, 1}$  and  $P_{A, 2}$  are the partial pressures of gas  $A$  on the two sides of the wall.

During mass transfer in a *moving medium*, chemical species are transported both by molecular diffusion and by the bulk fluid motion, and the velocities of the species are expressed as

$$V_A = V + V_{\text{diff}, A} \quad V_B = V + V_{\text{diff}, B}$$

where  $V$  is the *mass-average velocity* of the flow. It is the velocity that would be measured by a velocity sensor and is expressed as

$$V = w_A V_A + w_B V_B$$

The special case  $V = 0$  corresponds to a *stationary medium*. Using Fick's law of diffusion, the total mass fluxes  $j = \dot{m}/A$  in a moving medium are expressed as

$$j_A = \rho_A V + \rho_A V_{\text{diff}, A} = w_A(j_A + j_B) - \rho D_{AB} \frac{dw_A}{dx}$$

$$j_B = \rho_B V + \rho_B V_{\text{diff}, B} = w_B(j_A + j_B) - \rho D_{BA} \frac{dw_B}{dx}$$

The *rate of mass convection* of species  $A$  in a binary mixture is expressed in an analogous manner to Newton's law of cooling as

$$\dot{m}_{\text{conv}} = h_{\text{mass}} A_s (\rho_{A, s} - \rho_{A, \infty}) = h_{\text{mass}} \rho A_s (w_{A, s} - w_{A, \infty})$$

where  $h_{\text{mass}}$  is the average *mass transfer coefficient*, in m/s.

The counterparts of the Prandtl and Nusselt numbers in mass convection are the *Schmidt number*  $Sc$  and the *Sherwood number*  $Sh$ , defined as

$$Sc = \frac{\nu}{D_{AB}} = \frac{\text{Momentum diffusivity}}{\text{Mass diffusivity}} \quad \text{and} \quad Sh = \frac{h_{\text{mass}} L_c}{D_{AB}}$$

The relative magnitudes of heat and mass diffusion in the thermal and concentration boundary layers are represented by the *Lewis number*, defined as

$$Le = \frac{Sc}{Pr} = \frac{\alpha}{D_{AB}} = \frac{\text{Thermal diffusivity}}{\text{Mass diffusivity}}$$

Heat and mass transfer coefficients are sometimes expressed in terms of the dimensionless *Stanton number*, defined as

$$St = \frac{h_{\text{conv}}}{\rho V c_p} = Nu \frac{1}{Re Pr} \quad \text{and} \quad St_{\text{mass}} = \frac{h_{\text{mass}}}{V} = Sh \frac{1}{Re Sc}$$

where  $V$  is the free-stream velocity in external flow and the bulk mean fluid velocity in internal flow. For a given geometry and boundary conditions, the Sherwood number in natural or forced convection can be determined from the corresponding Nusselt number expression by simply replacing the Prandtl number by the Schmidt number. But in natural convection, the Grashof number should be expressed in terms of density difference instead of temperature difference.

When the molecular diffusivities of momentum, heat, and mass are identical, we have  $\nu = \alpha = D_{AB}$ , and thus  $Pr = Sc = Le = 1$ . The similarity between momentum, heat, and mass transfer in this case is given by the *Reynolds analogy*, expressed as

$$\frac{f}{2} Re = Nu = Sh \quad \text{or}$$

$$\frac{f}{2} \frac{V_\infty L}{v} = \frac{h_{\text{heat}} L}{k} = \frac{h_{\text{mass}} L}{D_{AB}} \quad \text{or} \quad \frac{f}{2} = St = St_{\text{mass}}$$

For the general case of  $Pr \neq Sc \neq 1$ , it is modified as

$$\frac{f}{2} = St Pr^{2/3} = St_{\text{mass}} Sc^{2/3}$$

which is known as the *Chilton–Colburn analogy*. The analogy between heat and mass transfer is expressed more conveniently as

$$h_{\text{heat}} = \rho c_p \text{Le}^{2/3} h_{\text{mass}} = \rho c_p (\alpha/D_{AB})^{2/3} h_{\text{mass}}$$

For air–water vapor mixtures,  $\text{Le}^{2/3} \equiv 1$ , and thus this relation simplifies further. The heat–mass convection analogy is

limited to *low mass flux* cases in which the flow rate of species undergoing mass flow is low relative to the total flow rate of the liquid or gas mixture. The mass transfer problems that involve phase change (evaporation, sublimation, condensation, melting, etc.) also involve heat transfer, and such problems are analyzed by considering heat and mass transfer simultaneously.

## PROBLEMS\*

\*Problems designated by a “C” are concept questions, and students are encouraged to answer them all. Problems designated by an “E” are in English units, and the SI users can ignore them. Problems with the icon are solved using EES, and complete solutions together with parametric studies are included on the text website. Problems with the icon are comprehensive in nature, and are intended to be solved with an equation solver such as EES. Problems with the icon are Prevention through Design problems.

### Analogy Between Heat and Mass Transfer

**14–1C** How is the concentration of a commodity defined? How is the concentration gradient defined? How is the diffusion rate of a commodity related to the concentration gradient?

**14–2C** Give examples for (a) liquid-to-gas, (b) solid-to-liquid, (c) solid-to-gas, and (d) gas-to-liquid mass transfer.

**14–3C** What is the driving force for (a) heat transfer, (b) electric current flow, (c) fluid flow, and (d) mass transfer?

**14–4C** Both Fourier's law of heat conduction and Fick's law of mass diffusion can be expressed as  $\dot{Q} = -kA(dT/dx)$ . What do the quantities  $\dot{Q}$ ,  $k$ ,  $A$ , and  $T$  represent in (a) heat conduction and (b) mass diffusion?

**14–5C** How does mass transfer differ from bulk fluid flow? Can mass transfer occur in a homogeneous medium?

**14–6C** What do (a) homogeneous reactions and (b) heterogeneous reactions represent in mass transfer? To what do they correspond in heat transfer?

### Mass Diffusion

**14–7C** Someone claims that the mass and the mole fractions for a mixture of CO<sub>2</sub> and N<sub>2</sub>O gases are identical. Do you agree? Explain.

**14–8C** Mark these statements as being True or False for a binary mixture of substances A and B.

- \_\_\_\_\_ (a) The density of a mixture is always equal to the sum of the densities of its constituents.
- \_\_\_\_\_ (b) The ratio of the density of component A to the density of component B is equal to the mass fraction of component A.
- \_\_\_\_\_ (c) If the mass fraction of component A is greater than 0.5, then at least half of the moles of the mixture are component A.
- \_\_\_\_\_ (d) If the molar masses of A and B are equal to each other, then the mass fraction of A will be equal to the mole fraction of A.
- \_\_\_\_\_ (e) If the mass fractions of A and B are both 0.5, then the molar mass of the mixture is simply the arithmetic average of the molar masses of A and B.

**14–9C** Fick's law of diffusion is expressed on the mass and mole basis as  $\dot{m}_{\text{diff}, A} = -\rho A D_{AB} (dw_A/dx)$  and  $\dot{N}_{\text{diff}, A} = -C A D_{AB} (dy_A/dx)$ , respectively. Are the diffusion coefficients  $D_{AB}$  in the two relations the same or different?

**14–10C** How does the mass diffusivity of a gas mixture change with (a) temperature and (b) pressure?

**14–11C** At a given temperature and pressure, do you think the mass diffusivity of air in water vapor will be equal to the mass diffusivity of water vapor in air? Explain.

**14–12C** At a given temperature and pressure, do you think the mass diffusivity of copper in aluminum will be equal to the mass diffusivity of aluminum in copper? Explain.

**14–13C** In a mass production facility, steel components are to be hardened by carbon diffusion. Would you carry out the hardening process at room temperature or in a furnace at a high temperature, say 900°C? Why?

**14–14** Determine the maximum mass fraction of calcium bicarbonate [Ca(HCO<sub>3</sub>)<sub>2</sub>]<sup>–</sup> in water at 350 K.

**14–15** The composition of moist air is given on a molar basis to be 78 percent N<sub>2</sub>, 20 percent O<sub>2</sub>, and 2 percent water vapor. Determine the mass fractions of the constituents of air.

*Answers:* 76.4 percent N<sub>2</sub>, 22.4 percent O<sub>2</sub>, 1.2 percent H<sub>2</sub>O

**14–16** The molar analysis of a gas mixture at 290 K and 250 kPa is 65 percent N<sub>2</sub>, 20 percent O<sub>2</sub>, and 15 percent CO<sub>2</sub>. Determine the mass fraction and partial pressure of each gas.

**14–17E** A gas mixture consists of 7 lbm of O<sub>2</sub>, 8 lbm of N<sub>2</sub>, and 10 lbm of CO<sub>2</sub>. Determine (a) the mass fraction of each component, (b) the mole fraction of each component, and (c) the average molar mass of the mixture.

**14–18** A gas mixture consists of 8 kmol of H<sub>2</sub> and 2 kmol of N<sub>2</sub>. Determine the mass of each gas and the apparent gas constant of the mixture.

**14–19** Determine the binary diffusion coefficient of CO<sub>2</sub> in air at (a) 200 K and 1 atm, (b) 400 K and 0.5 atm, and (c) 600 K and 5 atm.

**14–20** Repeat Prob. 14–19 for O<sub>2</sub> in N<sub>2</sub>.

**14–21** Determine the binary diffusion coefficient for (a) carbon dioxide in nitrogen, (b) carbon dioxide in oxygen, and (c) carbon dioxide in hydrogen at 320 K and 2 atm.

**14–22** The diffusion coefficient of hydrogen in steel is given as a function of temperature as

$$D_{AB} = 1.65 \times 10^{-6} \exp(-4630/T) \text{ (m}^2/\text{s)}$$

where  $T$  is in K. Determine the diffusion coefficients at 200 K, 500 K, 1000 K, and 1500 K.

**14–23**  Reconsider Prob. 14–22. Using EES (or other) software, plot the diffusion coefficient as a function of the temperature in the range of 200 K to 1200 K.

### Boundary Conditions

**14–24C** Consider the free surface of a lake exposed to the atmosphere. If the air at the lake surface is saturated, will the mole fraction of water vapor in air at the lake surface be the same as the mole fraction of water in the lake (which is nearly 1)?

**14–25C** When prescribing a boundary condition for mass transfer at a solid–gas interface, why do we need to specify the side of the surface (whether the solid or the gas side)? Why did we not do it in heat transfer?

**14–26C** Write three boundary conditions for mass transfer (on a mass basis) for species A at  $x = 0$  that correspond to specified temperature, specified heat flux, and convection boundary conditions in heat transfer.

**14–27C** What is an impermeable surface in mass transfer? How is it expressed mathematically (on a mass basis)? To what does it correspond in heat transfer?

**14–28C** Using solubility data of a solid in a specified liquid, explain how you would determine the mass fraction of the solid in the liquid at the interface at a specified temperature.

**14–29C** Using Henry's constant data for a gas dissolved in a liquid, explain how you would determine the mole fraction of the gas dissolved in the liquid at the interface at a specified temperature.

**14–30C** Using properties of saturated water, explain how you would determine the mole fraction of water vapor at the surface of a lake when the temperature of the lake surface and the atmospheric pressure are specified.

**14–31C** Using solubility data of a gas in a solid, explain how you would determine the molar concentration of the gas in the solid at the solid–gas interface at a specified temperature.

**14–32C** What is permeability? How is the permeability of a gas in a solid related to the solubility of the gas in that solid?

**14–33** Determine the mole fraction of carbon dioxide ( $\text{CO}_2$ ) dissolved in water at the surface of water at 300 K. The mole fraction of  $\text{CO}_2$  in air is 0.005, and the local atmosphere pressure is 100 kPa.

**14–34E** Water is sprayed into air at 80°F and 14.3 psia, and the falling water droplets are collected in a container on the floor. Determine the mass and mole fractions of air dissolved in the water.

**14–35** Consider a glass of water in a room at 20°C and 97 kPa. If the relative humidity in the room is 100 percent and the water and the air are in thermal and phase equilibrium, determine (a) the mole fraction of the water vapor in the air and (b) the mole fraction of air in the water.

**14–36E** Determine the mole fraction of the water vapor at the surface of a lake whose temperature at the surface is 70°F, and compare it to the mole fraction of water in the lake. Take the atmospheric pressure at lake level to be 13.8 psia.

**14–37** Determine the mole fraction of dry air at the surface of a lake whose temperature is 15°C. Take the atmospheric pressure at lake level to be 100 kPa.

**14–38**  Reconsider Prob. 14–37. Using EES (or other) software, plot the mole fraction of dry air at the surface of the lake as a function of the lake temperature as the temperature varies from 5°C to 25°C, and discuss the results.

**14–39** Consider a carbonated drink in a bottle at 37°C and 130 kPa. Assuming the gas space above the liquid consists of a saturated mixture of  $\text{CO}_2$  and water vapor and treating the drink as water, determine (a) the mole fraction of the water vapor in the  $\text{CO}_2$  gas and (b) the mass of dissolved  $\text{CO}_2$  in a 200-ml drink. *Answers: (a) 4.9 percent, (b) 0.28 g*

FIGURE P14–39

**14–40** Consider a rubber plate that is in contact with nitrogen gas at 298 K and 250 kPa. Determine the molar and mass densities of nitrogen in the rubber at the interface.

*Answers: 0.0039 kmol/m<sup>3</sup>, 0.1092 kg/m<sup>3</sup>*

FIGURE P14–40

**14–41** A wall made of natural rubber separates  $\text{O}_2$  and  $\text{N}_2$  gases at 25°C and 750 kPa. Determine the molar concentrations of  $\text{O}_2$  and  $\text{N}_2$  in the wall.

**14–42** Hydrogen gas at 750 kPa and 85°C is stored in a spherical nickel vessel. The vessel is situated in a surrounding of atmospheric air at 1 atm. Determine the molar and mass concentrations of hydrogen in the nickel at the inner and outer surfaces of the vessel.

**14–43** Pure nitrogen gas at 200 kPa and 25°C is flowing inside a long circular rubber pipe. The atmospheric air surrounding the pipe is at 1 atm and 25°C, with 79 percent nitrogen and 21 percent oxygen. Determine the molar concentrations of (a) nitrogen and (b) oxygen in the rubber at the inner and outer surfaces of the pipe.

**14–44** Consider a nickel wall separating hydrogen gas that is maintained on one side at 5 atm and on the opposite at 3 atm. If the temperature is constant at 85°C, determine (a) the mass densities of hydrogen gas in the nickel wall on both sides and (b) the mass densities of hydrogen outside the nickel wall on both sides.

FIGURE P14–44

**14-45** Consider a rubber membrane separating carbon dioxide gas that is maintained on one side at 2 atm and on the opposite at 1 atm. If the temperature is constant at 25°C, determine (a) the molar densities of carbon dioxide in the rubber membrane on both sides and (b) the molar densities of carbon dioxide outside the rubber membrane on both sides.

FIGURE P14-45

**14-46** A 2-mm-thick 5-L vessel made of nickel is used to store hydrogen gas at 358 K and 300 kPa. If the total inner surface area of the vessel is 1600 cm<sup>2</sup>, determine the rate of gas loss from the nickel vessel via mass diffusion. Also, determine the fraction of the hydrogen lost by mass diffusion after one year of storage.

**14-47** Hydrogen gas at 85°C is maintained at constant pressures of 5 atm and 3 atm on opposite sides of a 0.1-mm-thick nickel wall. Determine the molar diffusion rate per unit area through the nickel wall.

FIGURE P14-47

**14-48** During cold weather periods, vapor in a room diffuses through the dry wall and condenses in the adjoining insulation. This process decreases the thermal resistance and degrades the insulation. Consider a condition at which the vapor pressure in the air at 25°C inside a room is 3 kPa, and the vapor pressure in the insulation is negligible. The 3-m-high and 10-m-wide dry wall is 12-mm thick with a solubility of water vapor in the wall material of approximately 0.007 kmol/m<sup>3</sup>·bar, and diffusion

coefficient of water vapor in the wall is  $0.2 \times 10^{-9}$  m<sup>2</sup>/s. Determine the mass diffusion rate of water vapor through the wall.

FIGURE P14-48

### Steady Mass Diffusion through a Wall

**14-49C** Consider one-dimensional mass diffusion of species A through a plane wall. Does the species A content of the wall change during steady mass diffusion? How about during transient mass diffusion?

**14-50C** Write down the relations for steady one-dimensional heat conduction and mass diffusion through a plane wall, and identify the quantities in the two equations that correspond to each other.

**14-51C** Consider steady one-dimensional mass diffusion through a wall. Mark these statements as being True or False.

- \_\_\_\_\_ (a) Other things being equal, the higher the density of the wall, the higher the rate of mass transfer.
- \_\_\_\_\_ (b) Other things being equal, doubling the thickness of the wall will double the rate of mass transfer.
- \_\_\_\_\_ (c) Other things being equal, the higher the temperature, the higher the rate of mass transfer.
- \_\_\_\_\_ (d) Other things being equal, doubling the mass fraction of the diffusing species at the high concentration side will double the rate of mass transfer.

**14-52** A thin plastic membrane separates hydrogen from air. The molar concentrations of hydrogen in the membrane at the inner and outer surfaces are determined to be 0.045 and 0.002 kmol/m<sup>3</sup>, respectively. The binary diffusion coefficient of hydrogen in plastic at the operation temperature is  $5.3 \times 10^{-10}$  m<sup>2</sup>/s. Determine the mass flow rate of hydrogen by diffusion through the membrane under steady conditions if the thickness of the membrane is (a) 2 mm and (b) 0.5 mm.

**14-53** Exposure to high concentration of gaseous ammonia can cause lung damage. The acceptable short-term ammonia exposure level set by the Occupational Safety and Health Administration (OSHA) is 35 ppm for 15 minutes. Consider a vessel filled with gaseous ammonia at 30 mol/L, and a 10-cm-diameter circular plastic plug with a thickness of 2 mm is used to contain the ammonia inside the vessel. The ventilation system is capable of keeping the room safe with fresh air, provided that the rate of ammonia being released is

below 0.2 mg/s. If the diffusion coefficient of ammonia through the plug is  $1.3 \times 10^{-10} \text{ m}^2/\text{s}$ , determine whether or not the plug can safely contain the ammonia inside the vessel.

**14–54** The solubility of hydrogen gas in steel in terms of its mass fraction is given as  $w_{\text{H}_2} = 2.09 \times 10^{-4} \exp(-3950/T) P_{\text{H}_2}^{0.5}$  where  $P_{\text{H}_2}$  is the partial pressure of hydrogen in bars and  $T$  is the temperature in K. If natural gas is transported in a 1-cm-thick, 3-m-internal-diameter steel pipe at 500 kPa pressure and the mole fraction of hydrogen in the natural gas is 8 percent, determine the highest rate of hydrogen loss through a 100-m-long section of the pipe at steady conditions at a temperature of 293 K if the pipe is exposed to air. Take the diffusivity of hydrogen in steel to be  $2.9 \times 10^{-13} \text{ m}^2/\text{s}$ .

*Answer:*  $3.98 \times 10^{-14} \text{ kg/s}$

**14–55**  Reconsider Prob. 14–54. Using EES (or other) software, plot the highest rate of hydrogen loss as a function of the mole fraction of hydrogen in natural gas as the mole fraction varies from 5 to 15 percent, and discuss the results.

**14–56** Pure hydrogen gas, at  $25^\circ\text{C}$ , is flowing through an iron pipe with an inner diameter of 25 mm. The iron pipe is 10 m long and has a wall thickness of 5 mm. If the concentration of hydrogen in the iron pipe at the inner surface is  $0.1 \text{ kmol/m}^3$  and negligible at the outer surface, determine the diffusion rate of hydrogen through the pipe wall, in kg/s.

**14–57**  Reconsider Prob. 14–56. Using the EES (or other) software, evaluate the effect of pipe wall thickness on the diffusion rate of hydrogen through the pipe wall. By varying the pipe wall thickness from 0.5 to 10 mm, plot the diffusion rate of hydrogen through the pipe wall as a function of wall thickness.

**14–58** Pure helium gas is stored at  $20^\circ\text{C}$  in the cylindrical Pyrex tank of 2 m in length with an inner diameter of 12 cm and a wall thickness of 2.5 mm. A helium detector situated beside the tank has detected a steady leakage of helium at  $1.8 \times 10^{-6} \text{ g}$  over the duration of an hour. Assume that both ends of the tank are impermeable surfaces, and the concentration of helium at the tank outer surface is negligible. Determine the concentration of helium at the inner surface of the tank.

**14–59** Helium gas is stored at  $293 \text{ K}$  in a 3-m-outer-diameter spherical container made of 5-cm-thick Pyrex. The molar concentration of helium in the Pyrex is  $0.00073 \text{ kmol/m}^3$  at the inner surface and negligible at the outer surface. Determine the mass flow rate of helium by diffusion through the Pyrex container.

FIGURE P14–59

**14–60**  Hydrogen can cause fire hazards, and hydrogen gas leaking into surrounding air can lead to spontaneous ignition with extremely hot flames. Even at very low leakage rate, hydrogen can sustain combustion causing extended fire damages. Hydrogen gas is lighter than air, so if a leakage occurs it accumulates under roofs and forms explosive hazards. To prevent such hazards, buildings containing source of hydrogen must have adequate ventilation system and hydrogen sensors. Consider a metal spherical vessel, with an inner diameter of 5 m and a thickness of 3 mm, containing hydrogen gas at 2000 kPa. The vessel is situated in a room with atmospheric air at 1 atm. The ventilation system for the room is capable of keeping the air fresh, provided that the rate of hydrogen leakage is below  $5 \mu\text{g/s}$ . If the diffusion coefficient and solubility of hydrogen gas in the metal vessel are  $1.5 \times 10^{-12} \text{ m}^2/\text{s}$  and  $0.005 \text{ kmol/m}^3\text{-bar}$ , respectively, determine whether or not the vessel is safely containing the hydrogen gas.

**14–61** Helium gas is stored at  $293 \text{ K}$  and 500 kPa in a 1-cm-thick, 2-m-inner-diameter spherical tank made of fused silica ( $\text{SiO}_2$ ). The area where the container is located is well ventilated. Determine (a) the mass flow rate of helium by diffusion through the tank and (b) the pressure drop in the tank in one week as a result of the loss of helium gas.

**14–62** Pure  $\text{N}_2$  gas at 1 atm and  $25^\circ\text{C}$  is flowing through a 10-m-long, 3-cm-inner-diameter pipe made of 2-mm-thick rubber. Determine the rate at which  $\text{N}_2$  leaks out of the pipe if the medium surrounding the pipe is (a) a vacuum and (b) atmospheric air at 1 atm and  $25^\circ\text{C}$  with 21 percent  $\text{O}_2$  and 79 percent  $\text{N}_2$ .

*Answers:* (a)  $2.28 \times 10^{-10} \text{ kmol/s}$ , (b)  $4.78 \times 10^{-11} \text{ kmol/s}$

FIGURE P14–62

**14–63** You probably have noticed that balloons inflated with helium gas rise in the air the first day during a party but they fall down the next day and act like ordinary balloons filled with air. This is because the helium in the balloon slowly leaks out through the wall while air leaks in by diffusion.

Consider a balloon that is made of 0.1-mm-thick soft rubber and has a diameter of 15 cm when inflated. The pressure and temperature inside the balloon are initially 110 kPa and  $25^\circ\text{C}$ . The permeability of rubber to helium, oxygen, and nitrogen at  $25^\circ\text{C}$  are  $9.4 \times 10^{-13}$ ,  $7.05 \times 10^{-13}$ , and  $2.6 \times 10^{-13} \text{ kmol/m}\cdot\text{s}\cdot\text{bar}$ , respectively. Determine the initial rates of diffusion of helium, oxygen, and nitrogen through the balloon wall and the mass fraction of helium that escapes the balloon during the first 5 h assuming the helium pressure inside the balloon remains nearly

constant. Assume air to be 21 percent oxygen and 79 percent nitrogen by mole numbers and take the room conditions to be 100 kPa and 25°C.

**FIGURE P14–63**

**14–64** Reconsider the balloon discussed in Prob. 14–63. Assuming the volume to remain constant and disregarding the diffusion of air into the balloon, obtain a relation for the variation of pressure in the balloon with time. Using the results obtained and the numerical values given in the problem, determine how long it will take for the pressure inside the balloon to drop to 100 kPa.

#### Water Vapor Migration in Buildings

**14–65C** What are the adverse effects of excess moisture on the wood and metal components of a house and the paint on the walls?

**14–66C** How does the condensation or freezing of water vapor in the wall affect the effectiveness of the insulation in the wall? How does the moisture content affect the effective thermal conductivity of soil?

**14–67C** Moisture migration in the walls, floors, and ceilings of buildings is controlled by vapor barriers or vapor retarders. Explain the difference between the two, and discuss which is more suitable for use in the walls of residential buildings.

**14–68C** Why are the insulations on the chilled water lines always wrapped with vapor barrier jackets?

**14–69C** Consider a tank that contains moist air at 3 atm and whose walls are permeable to water vapor. The surrounding air at 1 atm pressure also contains some moisture. Is it possible for the water vapor to flow into the tank from surroundings? Explain.

**14–70C** Explain how vapor pressure of the ambient air is determined when the temperature, total pressure, and relative humidity of the air are given.

**14–71C** Express the mass flow rate of water vapor through a wall of thickness  $L$  in terms of the partial pressure of water vapor on both sides of the wall and the permeability of the wall to the water vapor.

**14–72** A glass of milk left on top of a counter in the kitchen at 15°C, 88 kPa, and 50 percent relative humidity is tightly sealed by a sheet of 0.009-mm-thick aluminum foil whose permeance is  $2.9 \times 10^{-12} \text{ kg/s}\cdot\text{m}^2\cdot\text{Pa}$ . The inner diameter of the glass is 12 cm. Assuming the air in the glass to be saturated at all times, determine how much the level of the milk in the glass will recede in 12 h. *Answer: 0.0011 mm*

**FIGURE P14–72**

**14–73** Consider a 20-cm-thick brick wall of a house. The indoor conditions are 25°C and 50 percent relative humidity while the outside conditions are 50°C and 50 percent relative humidity. Assuming that there is no condensation or freezing within the wall, determine the amount of moisture flowing through a unit surface area of the wall during a 24-h period.

**14–74** The roof of a house is 15 m × 8 m and is made of a 20-cm-thick concrete layer. The interior of the house is maintained at 25°C and 50 percent relative humidity and the local atmospheric pressure is 100 kPa. Determine the amount of water vapor that will migrate through the roof in 24 h if the average outside conditions during that period are 3°C and 30 percent relative humidity. The permeability of concrete to water vapor is  $24.7 \times 10^{-12} \text{ kg/s}\cdot\text{m}\cdot\text{Pa}$ .

**14–75** Reconsider Prob. 14–74. Using EES (or other) software, investigate the effects of temperature and relative humidity of air inside the house on the amount of water vapor that will migrate through the roof. Let the temperature vary from 15°C to 30°C and the relative humidity from 30 to 70 percent. Plot the amount of water vapor that will migrate as functions of the temperature and the relative humidity, and discuss the results.

**14–76** Reconsider Prob. 14–74. In order to reduce the migration of water vapor, the inner surface of the wall is painted with vapor retarder latex paint whose permeance is  $26 \times 10^{-12} \text{ kg/s}\cdot\text{m}^2\cdot\text{Pa}$ . Determine the amount of water

vapor that will diffuse through the roof in this case during a 24-h period.

**14-77** The diffusion of water vapor through plaster boards and its condensation in the wall insulation in cold weather are of concern since they reduce the effectiveness of insulation. Consider a house that is maintained at 20°C and 60 percent relative humidity at a location where the atmospheric pressure is 97 kPa. The inside of the walls is finished with 9.5-mm-thick gypsum wallboard. Taking the vapor pressure at the outer side of the wallboard to be zero, determine the maximum amount of water vapor that will diffuse through a 3-m × 8-m section of a wall during a 24-h period. The permeance of the 9.5-mm-thick gypsum wallboard to water vapor is  $2.86 \times 10^{-9} \text{ kg/s}\cdot\text{m}^2\cdot\text{Pa}$ .

FIGURE P14-77

**14-78** Reconsider Prob. 14-77. In order to reduce the migration of water vapor through the wall, it is proposed to use a 0.051-mm-thick polyethylene film with a permeance of  $9.1 \times 10^{-12} \text{ kg/s}\cdot\text{m}^2\cdot\text{Pa}$ . Determine the amount of water vapor that will diffuse through the wall in this case during a 24-h period.

*Answer: 26.4 g*

### Transient Mass Diffusion

**14-79C** In transient mass diffusion analysis, can we treat the diffusion of a solid into another solid of finite thickness (such as the diffusion of carbon into an ordinary steel component) as a diffusion process in a semi-infinite medium? Explain.

**14-80C** When the density of a species *A* in a semi-infinite medium is known at the beginning and at the surface, explain how you would determine the concentration of the species *A* at a specified location and time.

**14-81C** Define the penetration depth for mass transfer, and explain how it can be determined at a specified time when the diffusion coefficient is known.

**14-82** A thick wall made of natural rubber is exposed to pure oxygen gas on one side of its surface. Both the wall and oxygen gas are isothermal at 25°C, and the oxygen concentration at the wall surface is constant. Determine the time required for the oxygen concentration at  $x = 5 \text{ mm}$  to reach 5% of its concentration at the wall surface.

FIGURE P14-82

**14-83** Reconsider Prob. 14-82. Using the EES (or other) software, evaluate the oxygen concentration with varying time and distance from the wall surface. By varying the distance from the wall surface for  $0 \leq x \leq 2 \text{ cm}$ , for  $t = 10,000 \text{ s}$ ,  $50,000 \text{ s}$ , and  $150,000 \text{ s}$ , plot the oxygen concentration ratio,  $C_A(x,t)/C_{A,s}$ , as a function of the distance from the surface,  $x$ .

**14-84** Consider a piece of steel undergoing a decarburization process at 925°C. The mass diffusivity of carbon in steel at 925°C is  $1 \times 10^{-7} \text{ cm}^2/\text{s}$ . Determine the depth below the surface of the steel at which the concentration of carbon is reduced to 40% from its initial value as a result of the decarburization process for (a) an hour and (b) ten hours. Assume the concentration of carbon at the surface is zero throughout the decarburization process.

**14-85** A thick nickel wall is exposed to pure hydrogen gas at 165°C on one side of its surface. The hydrogen concentration at the wall surface is constant. Determine the hydrogen concentration at the penetration depth in percentage of its concentration at the wall surface.

FIGURE P14-85

**14-86** Reconsider Prob. 14-85. Using the EES (or other) software, evaluate the hydrogen concentration with varying time and distance from the wall surface. By varying the elapsed time for  $0 \leq t \leq 150,000 \text{ s}$ , for  $x = 0.5$ ,  $1.0$  and  $2.0 \text{ mm}$ , plot the hydrogen concentration ratio,  $C_A(x,t)/C_{A,s}$ , as a function of the elapsed time.

**14–87** A long nickel bar with a diameter of 5 cm has been stored in a hydrogen-rich environment at 358 K and 300 kPa for a long time, and thus it contains hydrogen gas throughout uniformly. Now the bar is taken into a well-ventilated area so that the hydrogen concentration at the outer surface remains at almost zero at all times. Determine how long it will take for the hydrogen concentration at the center of the bar to drop by half. The diffusion coefficient of hydrogen in the nickel bar at the room temperature of 298 K can be taken to be  $D_{AB} = 1.2 \times 10^{-12} \text{ m}^2/\text{s}$ . *Answer: 3.3 years*

**14–88** When handling corrosive and toxic substances, chemical resistant gloves should be worn. When selecting gloves to handle a substance, the suitability of the gloves should be considered. Depending on the material of the gloves, they could be easily permeable by some substances. An employee is handling tetrachloroethylene solution for a metal-cleaning process. Dermal exposure to tetrachloroethylene can cause skin irritation, and long-term exposure to it can have adverse neurological effects on humans. As a protective measure, the employee wears rubber-blend gloves while handling the tetrachloroethylene solution. The average thickness of the gloves is 0.67 mm, and the mass diffusivity of tetrachloroethylene in the gloves is  $3 \times 10^{-8} \text{ m}^2/\text{s}$ . Estimate how long can the employee's hand be in contact with the tetrachloroethylene solution before the concentration of the solution at the inner glove surface reaches 1% of the concentration at the outer surface. Is this type of glove suitable for handling tetrachloroethylene solution?

**14–89** A layer of glucose is submerged under a deep layer of water at 25°C. As the layer of glucose dissolves in the water, its density at the glucose-water interface is maintained constant. Determine (a) the time required for the glucose concentration at  $x = 1 \text{ cm}$  to reach 1% of its concentration at the glucose-water interface and (b) the penetration depth of glucose in water in the duration of time calculated in part (a).

FIGURE P14–89

**14–90** A steel part whose initial carbon content is 0.12 percent by mass is to be case-hardened in a furnace at 1150 K by exposing it to a carburizing gas. The diffusion coefficient of carbon in steel is strongly temperature dependent, and at the furnace temperature it is given to be  $D_{AB} = 7.2 \times 10^{-12} \text{ m}^2/\text{s}$ . Also, the mass fraction of carbon at the exposed surface of the steel part is maintained at 0.011 by the carbon-rich environment in the furnace. If the hardening process is to continue until the mass fraction of carbon at a depth of 0.7 mm is raised to 0.32 percent, determine how long the part should be held in the furnace.

FIGURE P14–90

**14–91** Repeat Prob. 14–90 for a furnace temperature of 500 K at which the diffusion coefficient of carbon in steel is  $D_{AB} = 2.1 \times 10^{-20} \text{ m}^2/\text{s}$ .

**14–92** A pond with an initial oxygen content of zero is to be oxygenated by forming a tent over the water surface and filling the tent with oxygen gas at 25°C and 130 kPa. Determine the mole fraction of oxygen at a depth of 1 cm from the surface after 24 h.

FIGURE P14–92

**14–93** A heated piece of steel, with a uniform initial carbon concentration of 0.20% by mass, was exposed to a carburizing atmosphere for an hour. Throughout the entire process, the carbon concentration on the surface was 0.70%. If the mass diffusivity of carbon in steel in this process was uniform at  $1 \times 10^{-11} \text{ m}^2/\text{s}$ , determine the percentage of mass concentration of carbon at 0.2 mm and 0.4 mm below the surface after the process. *Answers: 0.428 percent, 0.268 percent*

**14–94** A large pond, at a temperature of 25°C, has an initial uniform oxygen density of  $2 \text{ kg/m}^3$ . During an aeration process, the pond surface has its oxygen density suddenly increased to  $9 \text{ kg/m}^3$ . Determine the oxygen density at 5 cm below the pond surface after 100 hours of aeration process.

### Diffusion in a Moving Medium

**14–95C** What is diffusion velocity? How does it affect the mass-average velocity? Can the velocity of a species in a moving medium relative to a fixed reference point be zero in a moving medium? Explain.

**14–96C** What is the difference between mass-average velocity and mole-average velocity during mass transfer in a moving medium? If one of these velocities is zero, will the other also necessarily be zero? Under what conditions will these two velocities be the same for a binary mixture?

**14–97C** Define the following terms: mass-average velocity, diffusion velocity, stationary medium, and moving medium.

**14–98C** Consider one-dimensional mass transfer in a moving medium that consists of species A and B with  $\rho = \rho_A + \rho_B$  = constant. Mark these statements as being True or False.

- \_\_\_\_\_ (a) The rates of mass diffusion of species A and B are equal in magnitude and opposite in direction.
- \_\_\_\_\_ (b)  $D_{AB} = D_{BA}$ .
- \_\_\_\_\_ (c) During equimolar counterdiffusion through a tube, equal numbers of moles of A and B move in opposite directions, and thus a velocity measurement device placed in the tube will read zero.
- \_\_\_\_\_ (d) The lid of a tank containing propane gas (which is heavier than air) is left open. If the surrounding air and the propane in the tank are at the same temperature and pressure, no propane will escape the tank and no air will enter.

**14–99C** What is Stefan flow? Write the expression for Stefan's law and indicate what each variable represents.

**14–100** A researcher is using a 5-cm-diameter Stefan tube to measure the mass diffusivity of chloroform in air at 25°C and 1 atm. Initially, the liquid chloroform surface was 7.00 cm from the top of the tube; and after 10 hours have elapsed, the liquid chloroform surface was 7.44 cm from the top of the tube, which corresponds to 222 g of chloroform being diffused. At 25°C, the chloroform vapor pressure is 0.263 atm, and the concentration of chloroform is zero at the top of the tube. If the molar mass of chloroform is 119.39 kg/kmol, determine the mass diffusivity of chloroform in air.

FIGURE P14–100

**14–101E** A 1-in-diameter Stefan tube is used to measure the binary diffusion coefficient of water vapor in air at 80°F and 13.8 psia. The tube is partially filled with water with a distance from the water surface to the open end of the tube of 10 in. Dry air is blown over the open end of the tube so that water vapor rising to the top is removed immediately and the concentration of vapor

at the top of the tube is zero. During 10 days of continuous operation at constant pressure and temperature, the amount of water that has evaporated is measured to be 0.0025 lbm. Determine the diffusion coefficient of water vapor in air at 80°F and 13.8 psia.

**14–102** Benzene is classified by the U.S. Department of Health and Human Services (DHHS) as a carcinogen. Exposure to benzene increases the risk of cancer and other illnesses in humans. The Occupational Safety and Health Administration (OSHA) have established that action should be taken when benzene level in air reaches 0.5 ppm. A lab technician has poured liquid benzene ( $M = 78.11$  kg/kmol) into 10 test tubes with inner diameter of 25 mm. Each test tube holds equal amount of liquid benzene at a level of 1 cm from the top. The benzene vapor pressure is 10 kPa, and evaporation of benzene to the surrounding air is occurring at 25°C and 1 atm. The HVAC system for the laboratory is capable of keeping the air fresh, provided that the rate of benzene vapor being evaporated is below 3 g/h. Determine whether or not the benzene evaporation rate from all ten test tubes would present health risks to the people in the laboratory.

**14–103** The mass diffusivity of ethanol ( $\rho = 789$  kg/m<sup>3</sup> and  $M = 46$  kg/kmol) through air was determined in a Stefan tube. The tube has a uniform cross-sectional area of 0.8 cm<sup>2</sup>. Initially, the ethanol surface was 10 cm from the top of the tube; and after 10 hours have elapsed, the ethanol surface was 25 cm from the top of the tube, which corresponds to 0.0445 cm<sup>3</sup> of ethanol being evaporated. The ethanol vapor pressure is 0.0684 atm, and the concentration of ethanol is zero at the top of the tube. If the entire process was operated at 24°C and 1 atm, determine the mass diffusivity of ethanol in air.

FIGURE P14–103

**14–104** Methanol ( $\rho = 791$  kg/m<sup>3</sup> and  $M = 32$  kg/kmol) undergoes evaporation in a vertical tube with a uniform cross-sectional area of 0.8 cm<sup>2</sup>. At the top of the tube, the methanol concentration is zero, and its surface is 30 cm from the top of the tube (Fig. P14–104). The methanol vapor pressure is 17 kPa, with a mass diffusivity of  $D_{AB} = 0.162$  cm<sup>2</sup>/s in air. The evaporation process is operated at 25°C and 1 atm. (a) Determine the evaporation rate of the methanol in kg/h and (b) plot the mole fraction of methanol vapor as a function of the tube height, from the methanol surface ( $x = 0$ ) to the top of the tube ( $x = L$ ).

FIGURE P14–104

**14–105** A tank with a 2-cm-thick shell contains hydrogen gas at the atmospheric conditions of  $25^{\circ}\text{C}$  and 90 kPa. The charging valve of the tank has an internal diameter of 3 cm and extends 8 cm above the tank. If the lid of the tank is left open so that hydrogen and air can undergo equimolar counterdiffusion through the 10-cm-long passageway, determine the mass flow rate of hydrogen lost to the atmosphere through the valve at the initial stages of the process.

*Answer:*  $4.20 \times 10^{-8} \text{ kg/s}$

**14–106** Reconsider Prob. 14–105. Using EES (or other) software, plot the mass flow rate of hydrogen lost as a function of the diameter of the charging valve as the diameter varies from 1 cm to 5 cm, and discuss the results.

**14–107** An 8-cm-internal-diameter, 30-cm-high pitcher half-filled with water is left in a dry room at  $15^{\circ}\text{C}$  and 87 kPa with its top open. If the water is maintained at  $15^{\circ}\text{C}$  at all times also, determine how long it will take for the water to evaporate completely.

FIGURE P14–107

**14–108** A large tank containing ammonia at 1 atm and  $25^{\circ}\text{C}$  is vented to the atmosphere through a 2-m-long tube whose internal diameter is 1.5 cm. Determine the rate of loss of ammonia and the rate of infiltration of air into the tank.

**14–109E** The pressure in a pipeline that transports helium gas at a rate of 5 lbm/s is maintained at 14.5 psia by venting helium to the atmosphere through a 0.25-in-internal-diameter tube that extends 30 ft into the air. Assuming both the helium and the atmospheric air to be at  $80^{\circ}\text{F}$ , determine (a) the mass flow rate of helium lost to the atmosphere through the tube, (b) the mass flow rate of air that infiltrates into the pipeline, and (c) the flow velocity at the bottom of the tube where it is attached to the pipeline that will be measured by an anemometer in steady operation.

FIGURE P14–109E

**14–110E** Repeat Prob. 14–109E for a pipeline that transports carbon dioxide instead of helium.

### Mass Convection

**14–111C** What is a concentration boundary layer? How is it defined for flow over a plate?

**14–112C** What is the physical significance of the Schmidt number? How is it defined? To what dimensionless number does it correspond in heat transfer? What does a Schmidt number of 1 indicate?

**14–113C** What is the physical significance of the Lewis number? How is it defined? What does a Lewis number of 1 indicate?

**14–114C** Under what conditions will the normalized velocity, thermal, and concentration boundary layers coincide during flow over a flat plate?

**14–115C** Heat convection is expressed by Newton's law of cooling as  $\dot{Q} = hA_s(T_s - T_{\infty})$ . Express mass convection in an analogous manner on a mass basis, and identify all the quantities in the expression and state their units.

**14-116C** What is the physical significance of the Sherwood number? How is it defined? To what dimensionless number does it correspond in heat transfer? What does a Sherwood number of 1 indicate for a plane fluid layer?

**14-117C** In natural convection mass transfer, the Grashof number is evaluated using density difference instead of temperature difference. Can the Grashof number evaluated this way be used in heat transfer calculations also?

**14-118C** What is the relation  $(f/2) \text{Re} = \text{Nu} = \text{Sh}$  known as? Under what conditions is it valid? What is the practical importance of it?

**14-119C** What is the name of the relation  $f/2 = \text{St} \text{Pr}^{2/3} = \text{St}_{\text{mass}} \text{Sc}^{2/3}$  and what are the names of the variables in it? Under what conditions is it valid? What is the importance of it in engineering?

**14-120C** Using the analogy between heat and mass transfer, explain how the mass transfer coefficient can be determined from the relations for the heat transfer coefficient.

**14-121C** What is the relation  $h_{\text{heat}} = \rho c_p h_{\text{mass}}$  known as? For what kind of mixtures is it valid? What is the practical importance of it?

**14-122C** What is the low mass flux approximation in mass transfer analysis? Can the evaporation of water from a lake be treated as a low mass flux process?

**14-123** Consider a flat plate made of rubber separates carbon dioxide gas at  $25^\circ\text{C}$  and air. On the surface exposed to air, there is mass convection. Determine the mass concentration gradient of carbon dioxide at the plate surface that is exposed to air, if the mass flux of  $\text{CO}_2$  through the rubber plate is  $4.43 \times 10^{-11} \text{ kmol/s} \cdot \text{m}^2$ .

**14-124** Consider a wet concrete patio is covered with a thin layer of water film. At the surface, mass convection of water to air occurs at an average mass transfer coefficient of  $0.03 \text{ m/s}$ . If the air is at  $1 \text{ atm}$ ,  $15^\circ\text{C}$  and 35 percent relative humidity, determine the mass fraction concentration gradient of water at the surface.

**14-125** A fluid with a free stream velocity of  $2 \text{ m/s}$  is flowing over a surface of a body with characteristic length of  $2 \text{ m}$ . The flow conditions are maintained at  $298 \text{ K}$  and  $1 \text{ atm}$ , and the average mass transfer convection is  $0.015 \text{ m/s}$ . Determine the average Reynolds number, Schmidt number, Sherwood number, and friction coefficient for (a) air flowing over the surface coated with water (evaporation) and (b) air flowing over the surface coated with naphthalene (sublimation). Assume the mass diffusivity of naphthalene in air is  $0.61 \times 10^{-5} \text{ m}^2/\text{s}$ .

**14-126** The average heat transfer coefficient for air flow over an odd-shaped body is to be determined by mass transfer measurements and using the Chilton-Colburn analogy between heat and mass transfer. The experiment is conducted by blowing dry air at  $1 \text{ atm}$  at a free stream velocity of  $2 \text{ m/s}$  over a body covered with a layer of naphthalene. The surface area of

the body is  $0.75 \text{ m}^2$ , and it is observed that  $100 \text{ g}$  of naphthalene has sublimated in  $45 \text{ min}$ . During the experiment, both the body and the air were kept at  $25^\circ\text{C}$ , at which the vapor pressure and mass diffusivity of naphthalene are  $11 \text{ Pa}$  and  $D_{AB} = 0.61 \times 10^{-5} \text{ m}^2/\text{s}$ , respectively. Determine the heat transfer coefficient under the same flow conditions over the same geometry.

FIGURE P14-126

**14-127** Local convection heat transfer coefficient for air flowing parallel over a 1-m-long plate with irregular surface topology is experimentally determined to be  $h_x = 0.5 + 12x - 0.7x^3$ , where  $h_x$  is in  $\text{W}/\text{m}^2 \cdot \text{K}$ . If the plate surface is coated with water, determine the corresponding average mass convection coefficient over the entire plate. Assume properties can be evaluated at  $298 \text{ K}$  and  $1 \text{ atm}$ .

**14-128** Ethyl alcohol is spilled and spread over a flat table into a layer of approximately  $1 \text{ m}$  in diameter wide. Dry air at  $25^\circ\text{C}$  and  $1 \text{ atm}$  flows over the ethyl alcohol surface with a free stream velocity of  $1 \text{ m/s}$ . Determine the average mass transfer coefficient of ethyl alcohol in air.

**14-129** Dry air at  $15^\circ\text{C}$  and  $85 \text{ kPa}$  flows over a 2-m-long wet surface with a free stream velocity of  $3 \text{ m/s}$ . Determine the average mass transfer coefficient. *Answer:  $0.00463 \text{ m/s}$*

FIGURE P14-129

**14-130** A thin slab of solid salt ( $\text{NaCl}$ ), with dimension of  $0.15 \text{ m} \times 0.15 \text{ m}$ , is being dragged through seawater ( $v = 1.022 \times 10^{-6} \text{ m}^2/\text{s}$ ) at an average relative velocity of  $0.6 \text{ m/s}$ . The seawater at  $18^\circ\text{C}$  has a salt concentration of  $31 \text{ kg/m}^3$ , while the salt slab

has a concentration of  $35000 \text{ kg/m}^3$ . If the diffusion coefficient of salt in seawater is  $1.2 \times 10^{-9} \text{ m}^2/\text{s}$ , determine the mass convection rate of salt being dissolved in the seawater.

**14–131** In a manufacturing facility,  $40 \text{ cm} \times 40 \text{ cm}$  wet brass plates coming out of a water bath are to be dried by passing them through a section where dry air at  $1 \text{ atm}$  and  $25^\circ\text{C}$  is blown parallel to their surfaces at  $4 \text{ m/s}$ . If the plates are at  $15^\circ\text{C}$  and there are no dry spots, determine the rate of evaporation from both sides of a plate.

FIGURE P14–131

**14–132E** Air at  $80^\circ\text{F}$ ,  $1 \text{ atm}$ , and 30 percent relative humidity is blown over the surface of a  $15\text{-in} \times 15\text{-in}$  square pan filled with water at a free stream velocity of  $10 \text{ ft/s}$ . If the water is maintained at a uniform temperature of  $80^\circ\text{F}$ , determine the rate of evaporation of water and the amount of heat that needs to be supplied to the water to maintain its temperature constant.

**14–133E** Repeat Prob. 14–132E for temperature of  $60^\circ\text{F}$  for both the air and water.

**14–134** Consider a  $5\text{-m} \times 5\text{-m}$  wet concrete patio with an average water film thickness of  $0.3 \text{ mm}$ . Now wind at  $50 \text{ km/h}$  is blowing over the surface. If the air is at  $1 \text{ atm}$ ,  $15^\circ\text{C}$ , and 35 percent relative humidity, determine how long it will take for the patio to dry completely.

**14–135** Benzene ( $M = 78.11 \text{ kg/kmol}$ ) is a carcinogen, and exposure to benzene increases the risk of cancer and other illnesses in humans. A truck transporting liquid benzene was involved in an accident that spilled the liquid on a flat highway. The liquid benzene forms a pool of approximately  $10 \text{ m}$  in diameter on the highway. In this particular windy day at  $25^\circ\text{C}$  and  $1 \text{ atm}$  with an average wind velocity of  $10 \text{ m/s}$ , the liquid benzene surface is experiencing mass transfer to air by convection. Nearby at the downstream of the wind is a residential area that could be affected by the benzene vapor. Local health officials have assessed that if the benzene level in the air reaches  $500 \text{ kg}$  within the hour of the spillage, residents should be evacuated from the area. If the benzene vapor pressure is  $10 \text{ kPa}$ , estimate the mass transfer rate of benzene being convected to the air, and determine whether the residents should be evacuated or not.

FIGURE P14–135

**14–136** Air at  $40^\circ\text{C}$  and  $1 \text{ atm}$  flows over a  $5\text{-m}$ -long wet plate with an average velocity of  $2.5 \text{ m/s}$  in order to dry the surface. Using the analogy between heat and mass transfer, determine the mass transfer coefficient on the plate.

**14–137E** A 2-in-diameter spherical naphthalene ball is suspended in a room at  $1 \text{ atm}$  and  $80^\circ\text{F}$ . Determine the average mass transfer coefficient between the naphthalene and the air if air is forced to flow over naphthalene with a free stream velocity of  $15 \text{ ft/s}$ . The Schmidt number of naphthalene in air at room temperature is 2.35. *Answer:  $0.0524 \text{ ft/s}$*

**14–138** Consider a 3-mm-diameter raindrop that is falling freely in atmospheric air at  $25^\circ\text{C}$ . Taking the temperature of the raindrop to be  $9^\circ\text{C}$ , determine the terminal velocity of the raindrop at which the drag force equals the weight of the drop and the average mass transfer coefficient at that time.

**14–139E** Consider a circular pipe of inner diameter  $D = 0.7 \text{ in}$ , whose inner surface is covered with a thin layer of liquid water as a result of condensation. In order to dry the pipe, air at  $540 \text{ R}$  and  $1 \text{ atm}$  is forced to flow through it with an average velocity of  $6 \text{ ft/s}$ . Using the analogy between heat and mass transfer, determine the mass transfer coefficient inside the pipe for fully developed flow. *Answer:  $0.017 \text{ ft/s}$*

**14–140** Consider a 15-cm-internal-diameter,  $10\text{-m}$ -long circular duct whose interior surface is wet. The duct is to be dried by forcing dry air at  $1 \text{ atm}$  and  $15^\circ\text{C}$  through it at an average velocity of  $3 \text{ m/s}$ . The duct passes through a chilled room, and it remains at an average temperature of  $15^\circ\text{C}$  at all times. Determine the mass transfer coefficient in the duct.

**14–141** Reconsider Prob. 14–140. Using EES (or other) software, plot the mass transfer coefficient as a function of the air velocity as the velocity varies from  $1 \text{ m/s}$  to  $8 \text{ m/s}$ , and discuss the results.

### Simultaneous Heat and Mass Transfer

**14–142C** Does a mass transfer process have to involve heat transfer? Describe a process that involves both heat and mass transfer.

**14–143C** During evaporation from a water body to air, under what conditions will the latent heat of vaporization be equal to convection heat transfer from the air?

**14–144C** Consider a shallow body of water. Is it possible for this water to freeze during a cold and dry night even when the ambient air and surrounding surface temperatures never drop to  $0^\circ\text{C}$ ? Explain.

**14–145E** During a hot summer day, a 2-L bottle drink is to be cooled by wrapping it in a cloth kept wet continually and blowing air to it with a fan. If the environment conditions are 1 atm, 80°F, and 30 percent relative humidity, determine the temperature of the drink when steady conditions are reached.

**14–146** Jugs made of porous clay were commonly used to cool water in the past. A small amount of water that leaks out keeps the outer surface of the jug wet at all times, and hot and relatively dry air flowing over the jug causes this water to evaporate. Part of the latent heat of evaporation comes from the water in the jug, and the water is cooled as a result. If the environment conditions are 1 atm, 30°C, and 35 percent relative humidity, determine the temperature of the water when steady conditions are reached.

FIGURE P14–146

**14–147** Reconsider Prob. 14–146. Using EES (or other) software, plot the water temperature as a function of the relative humidity of air as the relative humidity varies from 10 to 100 percent, and discuss the results.

**14–148** A soaked sponge is experiencing dry air flowing over its surface. The air is at 1 atm and zero relative humidity. Determine the difference in the air temperature and the surface temperature of the sponge,  $T_\infty - T_s$ , when steady state conditions are reached, if the sponge is soaked with (a) water,  $D_{AB} = 2.42 \times 10^{-5} \text{ m}^2/\text{s}$ , and (b) ammonia,  $D_{AB} = 2.6 \times 10^{-5} \text{ m}^2/\text{s}$ . Evaluate the properties of air, water, and ammonia at 20°C, 10°C, and -40°C, respectively.

**14–149** A water-soaked 10-cm × 10-cm-square sponge is experiencing parallel dry air flow over its surface. The average convection heat transfer coefficient of dry air at 20°C flowing over the sponge surface is estimated to be 30 W/m<sup>2</sup>·K, and the sponge surface is maintained at 30°C. If the sponge is placed under an array of radiant lamps, determine (a) the rate of evaporation of water from the sponge and (b) the net radiation heat transfer rate.

FIGURE P14–149

**14–150** Consider a thin layer of liquid water on a concrete surface. The surrounding air is dry with a convection heat transfer coefficient of 50 W/m<sup>2</sup>·K. The liquid water has an emissivity of 0.95, and the air and surrounding temperature is 30°C. If the layer of liquid water has a uniform temperature of 20°C, determine the conduction heat flux through the concrete.

FIGURE P14–150

**14–151** One way of increasing heat transfer from the head on a hot summer day is to wet it. This is especially effective in windy weather, as you may have noticed. Approximating the head as a 30-cm-diameter sphere at 30°C with an emissivity of 0.95, determine the total rate of heat loss from the head at ambient air conditions of 1 atm, 25°C, 30 percent relative humidity, and 25 km/h winds if the head is (a) dry and (b) wet. Take the surrounding temperature to be 25°C.

Answers: (a) 40.5 W, (b) 385 W

FIGURE P14–151

**14–152** A 2-m-deep 20-m × 20-m heated swimming pool is maintained at a constant temperature of 30°C at a location where the atmospheric pressure is 1 atm. If the ambient air is at 20°C and 60 percent relative humidity and the effective sky temperature is 0°C, determine the rate of heat loss from the top surface of the pool by (a) radiation, (b) natural convection, and (c) evaporation. (d) Assuming the heat losses to the ground to be negligible, determine the size of the heater.

**14–153** Repeat Prob. 14–152 for a pool temperature of 25°C.

**14–154** A glass bottle washing facility uses a well agitated hot water bath at 50°C with an open top that is placed on the ground. The bathtub is 1 m high, 2 m wide, and 4 m long and is made of sheet metal so that the outer side surfaces are also at about 50°C. The bottles enter at a rate of 800 per minute at ambient temperature and leave at the water temperature. Each bottle has a mass of 150 g and removes 0.6 g of water as it leaves the bath wet. Makeup water is supplied at 15°C. If the average conditions in the plant are 1 atm, 25°C, and 50 percent relative humidity, and the average temperature of the surrounding surfaces is 15°C, determine (a) the amount of heat and water removed by the bottles themselves per second, (b) the rate of heat loss from the top surface of the water bath by radiation, natural convection, and evaporation, (c) the rate of heat loss from the side surfaces by natural convection and radiation, and (d) the rate at which heat and water must be supplied to maintain steady operating conditions. Disregard heat loss through the bottom surface of the bath and take the emissivities of sheet metal and water to be 0.61 and 0.95, respectively.

**14–155** Repeat Prob. 14–154 for a water bath temperature of 55°C.

### Review Problems

**14–156** Determine the mole fraction of the water vapor at the surface of a lake whose temperature is 15°C and compare it to the mole fraction of water in the lake. Take the atmospheric pressure at lake level to be 92 kPa.

FIGURE P14–156

**14–157** Show that for an ideal gas mixture maintained at a constant temperature and pressure, the molar concentration  $C$  of the mixture remains constant but this is not necessarily the case for the density  $\rho$  of the mixture.

**14–158E** A gas mixture in a tank at 600 R and 20 psia consists of 1 lbm of CO<sub>2</sub> and 3 lbm of CH<sub>4</sub>. Determine the volume of the tank and the partial pressure of each gas.

**14–159** Dry air whose molar analysis is 78.1 percent N<sub>2</sub>, 20.9 percent O<sub>2</sub>, and 1 percent Ar flows over a water body until it is saturated. If the pressure and temperature of air remain constant at 1 atm and 25°C during the process, determine (a) the molar analysis of the saturated air and (b) the density of air before and after the process. What do you conclude from your results?

**14–160** The diffusion coefficient of carbon in steel is given as

$$D_{AB} = 2.67 \times 10^{-5} \exp(-17,400/T) \text{ (m}^2/\text{s)}$$

where  $T$  is in K. Determine the diffusion coefficient from 300 K to 1500 K in 100 K increments and plot the results.

**14–161** Consider a 30-cm-diameter pan filled with water at 15°C in a room at 20°C, 1 atm, and 30 percent relative humidity. Determine (a) the rate of heat transfer by convection, (b) the rate of evaporation of water, and (c) the rate of heat transfer to the water needed to maintain its temperature at 15°C. Disregard any radiation effects.

**14–162** Repeat Prob. 14–161 assuming a fan blows air over the water surface at a velocity of 3 m/s. Take the radius of the pan to be the characteristic length.

**14–163** Using Henry's law, show that the dissolved gases in a liquid can be driven off by heating the liquid.

**14–164** Consider a glass of water in a room at 20°C and 100 kPa. If the relative humidity in the room is 70 percent and the water and the air are at the same temperature, determine (a) the mole fraction of the water vapor in the room air, (b) the mole fraction of the water vapor in the air adjacent to the water surface, and (c) the mole fraction of air in the water near the surface. *Answers: (a) 1.64 percent, (b) 2.34 percent, (c) 0.0015 percent*

FIGURE P14–164

**14–165** A membrane made of 0.1-mm-thick soft rubber separates pure O<sub>2</sub> at 1 atm and 25°C from air at 3 atm pressure. Determine the mass flow rate of O<sub>2</sub> through the membrane per unit area and the direction of flow.

**14–166** Consider a brick house that is maintained at 20°C and 60 percent relative humidity at a location where the atmospheric pressure is 85 kPa. The walls of the house are made of 20-cm-thick brick whose permeance is  $23 \times 10^{-12}$  kg/s·m<sup>2</sup>·Pa. Taking the vapor pressure at the outer side of the wallboard to

be zero, determine the maximum amount of water vapor that will diffuse through a 3-m  $\times$  5-m section of a wall during a 24-h period.

**14-167** A thick part made of nickel is put into a room filled with hydrogen at 3 atm and 85°C. Determine the hydrogen concentration at a depth of 2-mm from the surface after 24 h.

*Answer:*  $4.1 \times 10^{-7}$  kmol/m<sup>3</sup>

**14-168** A tanker truck carrying liquid herbicide overturned and caused a spill over a field. The liquid herbicide remained on the soil for 30 minutes before evaporating into the air. The mass diffusivity of the liquid herbicide in the soil is  $2 \times 10^{-8}$  m<sup>2</sup>/s. If a concentration of 0.1% by weight will destroy most life, determine the depth of the soil at which plant and insect life is likely to be affected by the spill.

**14-169** Oxygen gas is forced into an aquarium at 1 atm and 25°C, and the oxygen bubbles are observed to rise to the free surface in 4 s. Determine the penetration depth of oxygen into water from a bubble during this time period.

**14-170** In an experiment, a sphere of crystalline sodium chloride (NaCl) was suspended in a stirred tank filled with water at 20°C. Its initial mass was 100 g. In 10 minutes, the mass of sphere was found to have decreased by 10 percent. The density of NaCl is 2160 kg/m<sup>3</sup>. Its solubility in water at 20°C is 320 kg/m<sup>3</sup>. Use these results to obtain an average value for the mass transfer coefficient.

**14-171** Liquid toluene ( $C_6H_5CH_3$ ) was stored at 6.4°C in an open top 20-cm-diameter cylindrical container. The vapor pressure of toluene at 6.4°C is 10 mm Hg. A gentle stream of fresh air at 6.4°C and 101.3 kPa was allowed to flow over the open end of the container. The rate of evaporation of toluene into air was measured to be 60 g/day. Estimate the concentration of toluene (in g/m<sup>3</sup>) at exactly 10 mm above the liquid surface. The diffusion coefficient of toluene at 25°C is  $D_{AB} = 0.084 \times 10^{-4}$  m<sup>2</sup>/s.

**14-172** Liquid methanol is accidentally spilt on a 1 m  $\times$  1 m laboratory bench and covered the entire bench surface. A fan is providing a 20 m/s air flow parallel over the bench surface. The air is maintained at 25°C and 1 atm, and the concentration of methanol in the free stream is negligible. If the methanol vapor at the air-methanol interface has a pressure of 4000 Pa and a temperature of 25°C, determine the evaporation rate of methanol in molar basis.

**14-173E** The top section of an 8-ft-deep 100-ft  $\times$  100-ft heated solar pond is maintained at a constant temperature of 80°F at a location where the atmospheric pressure is 1 atm. If the ambient air is at 70°F and 100 percent relative humidity and wind is blowing at an average velocity of 40 mph, determine the rate of heat loss from the top surface of the pond by (a) forced convection, (b) radiation, and (c) evaporation. Take the average temperature of the surrounding surfaces to be 60°F.

**14-174E** Repeat Prob. 14-173E for a solar pond surface temperature of 90°F. *Answers:* (a) 1,060,000 Btu/h, (b) 299,400 Btu/h, (c) 3,410,000 Btu/h

**14-175E** A swimmer extends his wet arms into the windy air outside at 1 atm, 40°F, 50 percent relative humidity, and 20 mph. If the average skin temperature is 80°F, determine the rate at which water evaporates from both arms and the corresponding rate of heat transfer by evaporation. The arm can be modeled as a 2-ft-long and 3-in-diameter cylinder with adiabatic ends.

**14-176** A sphere of ice, 5 cm in diameter, is exposed to 50 km/h wind with 10 percent relative humidity. Both the ice sphere and air are at -1°C and 90 kPa. Predict the rate of evaporation of the ice in g/h by use of the following correlation for single spheres:  $Sh = [4.0 + 1.21(ReSc)^{2/3}]^{0.5}$ . Data at -1°C and 90 kPa:  $D_{air-H_2O} = 2.5 \times 10^{-5}$  m<sup>2</sup>/s<sup>3</sup>, kinematic viscosity (air) =  $1.32 \times 10^{-7}$  m<sup>2</sup>/s, vapor pressure ( $H_2O$ ) = 0.56 kPa and density (ice) = 915 kg/m<sup>3</sup>.

**14-177** Benzene-free air at 25°C and 101.3 kPa enters a 5-cm-diameter tube at an average velocity of 5 m/s. The inner surface of the 6-m-long tube is coated with a thin film of pure benzene at 25°C. The vapor pressure of benzene ( $C_6H_6$ ) at 25°C is 13 kPa, and the solubility of air in benzene is assumed to be negligible. Calculate (a) the average mass transfer coefficient in m/s, (b) the molar concentration of benzene in the outlet air, and (c) the evaporation rate of benzene in kg/h.

**14-178** Air at 52°C, 101.3 kPa, and 10 percent relative humidity enters a 5-cm-diameter tube with an average velocity of 5 m/s. The tube inner surface is wetted uniformly with water, whose vapor pressure at 52°C is 13.6 kPa. While the temperature and pressure of air remain constant, the partial pressure of vapor in the outlet air is increased to 10 kPa. Determine (a) the average mass transfer coefficient in m/s, (b) the log-mean driving force for mass transfer in molar concentration units, (c) the water evaporation rate in kg/h, and (d) the length of the tube.

### Fundamentals of Engineering (FE) Exam Problems

**14-179** The basic equation describing the diffusion of one medium through another stationary medium is

$$(a) j_A = - CD_{AB} \frac{d(C_A/C)}{dx} \quad (b) j_A = - D_{AB} \frac{d(C_A/C)}{dx}$$

$$(c) j_A = - k \frac{d(C_A/C)}{dx} \quad (d) j_A = - k \frac{dT}{dx}$$

(e) none of them

**14-180** For the absorption of a gas (like carbon dioxide) into a liquid (like water) Henry's law states that partial pressure of the gas is proportional to the mole fraction of the gas in the liquid-gas solution with the constant of proportionality being Henry's constant. A bottle of soda pop ( $CO_2-H_2O$ ) at room temperature has a Henry's constant of 17,100 kPa. If the pressure in this bottle is 120 kPa and the partial pressure of

the water vapor in the gas volume at the top of the bottle is neglected, the concentration of the CO<sub>2</sub> in the liquid H<sub>2</sub>O is

- (a) 0.003 mol-CO<sub>2</sub>/mol
- (b) 0.007 mol-CO<sub>2</sub>/mol
- (c) 0.013 mol-CO<sub>2</sub>/mol
- (d) 0.022 mol-CO<sub>2</sub>/mol
- (e) 0.047 mol-CO<sub>2</sub>/mol

**14–181** A rubber object is in contact with nitrogen (N<sub>2</sub>) at 298 K and 250 kPa. The solubility of nitrogen gas in rubber is 0.00156 kmol/m<sup>3</sup>·bar. The mass density of nitrogen at the interface is

- (a) 0.049 kg/m<sup>3</sup>
- (b) 0.064 kg/m<sup>3</sup>
- (c) 0.077 kg/m<sup>3</sup>
- (d) 0.092 kg/m<sup>3</sup>
- (e) 0.109 kg/m<sup>3</sup>

**14–182** Nitrogen gas at high pressure and 298 K is contained in a 2-m × 2-m × 2-m cubical container made of natural rubber whose walls are 4 cm thick. The concentration of nitrogen in the rubber at the inner and outer surfaces are 0.067 kg/m<sup>3</sup> and 0.009 kg/m<sup>3</sup>, respectively. The diffusion coefficient of nitrogen through rubber is 1.5 × 10<sup>-10</sup> m<sup>2</sup>/s. The mass flow rate of nitrogen by diffusion through the cubical container is

- (a) 8.24 × 10<sup>-10</sup> kg/s
- (b) 1.35 × 10<sup>-10</sup> kg/s
- (c) 5.22 × 10<sup>-9</sup> kg/s
- (d) 9.71 × 10<sup>-9</sup> kg/s
- (e) 3.58 × 10<sup>-8</sup> kg/s

**14–183** A recent attempt to circumnavigate the world in a balloon used a helium-filled balloon whose volume was 7240 m<sup>3</sup> and surface area was 1800 m<sup>2</sup>. The skin of this balloon is 2 mm thick and is made of a material whose helium diffusion coefficient is 1 × 10<sup>-9</sup> m<sup>2</sup>/s. The molar concentration of the helium at the inner surface of the balloon skin is 0.2 kmol/m<sup>3</sup> and the molar concentration at the outer surface is extremely small. The rate at which helium is lost from this balloon is

- (a) 0.26 kg/h
- (b) 1.5 kg/h
- (c) 2.6 kg/h
- (d) 3.8 kg/h
- (e) 5.2 kg/h

**14–184** Carbon at 1273 K is contained in a 7-cm-inner-diameter cylinder made of iron whose thickness is 1.2 mm. The concentration of carbon in the iron at the inner surface is 0.5 kg/m<sup>3</sup> and the concentration of carbon in the iron at the outer surface is negligible. The diffusion coefficient of carbon through iron is 3 × 10<sup>-11</sup> m<sup>2</sup>/s. The mass flow rate of carbon by diffusion through the cylinder shell per unit length of the cylinder is

- (a) 2.8 × 10<sup>-9</sup> kg/s
- (b) 5.4 × 10<sup>-9</sup> kg/s
- (c) 8.8 × 10<sup>-9</sup> kg/s
- (d) 1.6 × 10<sup>-8</sup> kg/s
- (e) 5.2 × 10<sup>-8</sup> kg/s

**14–185** The surface of an iron component is to be hardened by carbon. The diffusion coefficient of carbon in iron at 1000°C is given to be 3 × 10<sup>-11</sup> m<sup>2</sup>/s. If the penetration depth of carbon in iron is desired to be 1.0 mm, the hardening process must take at least

- (a) 1.10 h
- (b) 1.47 h
- (c) 1.86 h
- (d) 2.50 h
- (e) 2.95 h

**14–186** A natural gas (methane, CH<sub>4</sub>) storage facility uses 3-cm-diameter by 6-m-long vent tubes on its storage tanks to keep the pressure in these tanks at atmospheric value. If the

diffusion coefficient for methane in air is 0.2 × 10<sup>-4</sup> m<sup>2</sup>/s and the temperature of the tank and environment is 300 K, the rate at which natural gas is lost from a tank through one vent tube is

- (a) 13 × 10<sup>-5</sup> kg/day
- (b) 3.2 × 10<sup>-5</sup> kg/day
- (c) 8.7 × 10<sup>-5</sup> kg/day
- (d) 5.3 × 10<sup>-5</sup> kg/day
- (e) 0.12 × 10<sup>-5</sup> kg/day

**14–187** Saturated water vapor at 25°C ( $P_{\text{sat}} = 3.17 \text{ kPa}$ ) flows in a pipe that passes through air at 25°C with a relative humidity of 40 percent. The vapor is vented to the atmosphere through a 7-mm internal-diameter tube that extends 10 m into the air. The diffusion coefficient of vapor through air is 2.5 × 10<sup>-5</sup> m<sup>2</sup>/s. The amount of water vapor lost to the atmosphere through this individual tube by diffusion is

- (a) 1.02 × 10<sup>-6</sup> kg
- (b) 1.37 × 10<sup>-6</sup> kg
- (c) 2.28 × 10<sup>-6</sup> kg
- (d) 4.13 × 10<sup>-6</sup> kg
- (e) 6.07 × 10<sup>-6</sup> kg

**14–188** When the \_\_\_\_\_ is unity, one can expect the momentum and mass transfer by diffusion to be the same.

- (a) Grashof
- (b) Reynolds
- (c) Lewis
- (d) Schmidt
- (e) Sherwood

**14–189** Air flows in a 4-cm-diameter wet pipe at 20°C and 1 atm with an average velocity of 4 m/s in order to dry the surface. The Nusselt number in this case can be determined from  $\text{Nu} = 0.023\text{Re}^{0.8}\text{Pr}^{0.4}$  where  $\text{Re} = 10,550$  and  $\text{Pr} = 0.731$ . Also, the diffusion coefficient of water vapor in air is 2.42 × 10<sup>-5</sup> m<sup>2</sup>/s. Using the analogy between heat and mass transfer, the mass transfer coefficient inside the pipe for fully developed flow becomes

- (a) 0.0918 m/s
- (b) 0.0408 m/s
- (c) 0.0366 m/s
- (d) 0.0203 m/s
- (e) 0.0022 m/s

**14–190** Air flows through a wet pipe at 298 K and 1 atm, and the diffusion coefficient of water vapor in air is 2.5 × 10<sup>-5</sup> m<sup>2</sup>/s. If the heat transfer coefficient is determined to be 35 W/m<sup>2</sup>·K, the mass transfer coefficient is

- (a) 0.0326 m/s
- (b) 0.0387 m/s
- (c) 0.0517 m/s
- (d) 0.0583 m/s
- (e) 0.0707 m/s

### Design and Essay Problems

**14–191** Write an essay on diffusion caused by effects other than the concentration gradient such as thermal diffusion, pressure diffusion, forced diffusion, knudsen diffusion, and surface diffusion.

**14–192** One way of generating electricity from solar energy involves the collection and storage of solar energy in large artificial lakes of a few meters deep, called solar ponds. Solar energy is stored at the bottom part of the pond at temperatures close to boiling, and the rise of hot water to the top is prevented by planting salt to the bottom of the pond. Write an essay on the operation of solar pond power plants, and find out how much salt is used per year per m<sup>2</sup>. If the cost is not a factor, can sugar be used instead of salt to maintain the concentration gradient? Explain.

**14–193** The condensation and even freezing of moisture in building walls without effective vapor retarders is a real concern in cold climates as it undermines the effectiveness of the insulation. Investigate how the builders in your area are coping with this problem, whether they are using vapor retarders or vapor barriers in the walls, and where they are located in the walls. Prepare a report on your findings and explain the reasoning for the current practice.

**14–194** You are asked to design a heating system for a swimming pool that is 2 m deep, 25 m long, and 25 m wide. Your client desires that the heating system be large enough to raise the water temperature from 20°C to 30°C in 3 h. The heater must also be able to maintain the pool at 30°C at the outdoor design conditions of 15°C, 1 atm, 35 percent relative humidity, 40 mph winds, and effective sky temperature of 10°C. Heat losses to the ground are expected to be small and can

be disregarded. The heater considered is a natural gas furnace whose efficiency is 80 percent. What heater size (in Btu/h input) would you recommend that your client buy?

\*The unit kJ/kg·K is equivalent to kPa·m<sup>3</sup>/kg·K. The gas constant is calculated from  $R = R_u/M$ , where  $R_u = 8.31447 \text{ kJ/kmol}\cdot\text{K}$  is the universal gas constant and  $M$  is the molar mass.

Source: Specific heat values are obtained primarily from the property routines prepared by The National Institute of Standards and Technology (NIST), Gaithersburg, MD.

Sources: <sup>a</sup>Water content and freezing-point data are from ASHRAE, *Handbook of Fundamentals*, SI version (Atlanta, GA: American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc., 1993), Chap. 30. Used with permission. Freezing point is the temperature at which freezing starts for fruits and vegetables, and the average freezing temperature for other foods.

<sup>b</sup>Specific heat data are based on the specific heat values of a water and ice at 0°C and are determined from Siebel's formulas:  $c_{p, \text{fresh}} = 3.35 \times (\text{Water content}) + 0.84$ , above freezing, and  $c_{p, \text{frozen}} = 1.26 \times (\text{Water content}) + 0.84$ , below freezing.

<sup>c</sup>The latent heat of fusion is determined by multiplying the heat of fusion of water (334 kJ/kg) by the water content of the food.

**TABLE A-7**Properties of common foods (*Concluded*)

(b) Other properties

| Food                     | Water Content, % (mass) | Temperature, $T$ °C | Density, $\rho$ kg/m³ | Thermal Conductivity, $k$ W/m·K | Thermal Diffusivity, $\alpha$ m²/s | Specific Heat, $c_p$ kJ/kg·K |

Source: Data obtained primarily from ASHRAE, *Handbook of Fundamentals*, SI version (Atlanta, GA: American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc., 1993), Chap. 30, Tables 7 and 9. Used with permission.

Most specific heats are calculated from  $c_p = 1.68 + 2.51 \times (\text{Water content})$ , which is a good approximation in the temperature range of 3 to 32°C.

Most thermal diffusivities are calculated from  $\alpha = k/\rho c_p$ . Property values given here are valid for the specific water content.

**TABLE A-8**

Properties of miscellaneous materials

(Values are at 300 K unless indicated otherwise)

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\rho c_p = \nu/\text{Pr}$ . The temperatures 0.01°C, 100°C, and 374.14°C are the triple-, boiling-, and critical-point temperatures of water, respectively. The properties listed above (except the vapor density) can be used at any pressure with negligible error except at temperatures near the critical-point value.

Note 2: The unit kJ/kg·°C for specific heat is equivalent to kJ/kg·K, and the unit W/m·°C for thermal conductivity is equivalent to W/m·K.

Source: Viscosity and thermal conductivity data are from J. V. Sengers and J. T. R. Watson, *Journal of Physical and Chemical Reference Data* 15 (1986), pp. 1291–1322. Other data are obtained from various sources or calculated.

**TABLE A-10**

## Properties of saturated refrigerant-134a

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\rho c_p = \nu/Pr$ . The properties listed here (except the vapor density) can be used at any pressures with negligible error except at temperatures near the critical-point value.

Note 2: The unit kJ/kg·°C for specific heat is equivalent to kJ/kg·K, and the unit W/m·°C for thermal conductivity is equivalent to W/m·K.

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\rho c_p = \nu/\text{Pr}$ . The properties listed here (except the vapor density) can be used at any pressures with negligible error except at temperatures near the critical-point value.

Note 2: The unit kJ/kg·°C for specific heat is equivalent to kJ/kg·K, and the unit W/m·°C for thermal conductivity is equivalent to W/m·K.

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\mu c_p = \nu/\text{Pr}$ . The properties listed here (except the vapor density) can be used at any pressures with negligible error except at temperatures near the critical-point value.

Note 2: The unit kJ/kg·°C for specific heat is equivalent to kJ/kg·K, and the unit W/m·°C for thermal conductivity is equivalent to W/m·K.

Note: For ideal gases, the properties  $c_p$ ,  $k$ ,  $\mu$ , and  $Pr$  are independent of pressure. The properties  $\rho$ ,  $\nu$ , and  $\alpha$  at a pressure  $P$  (in atm) other than 1 atm are determined by multiplying the values of  $\rho$  at the given temperature by  $P$  and dividing  $\nu$  and  $\alpha$  by  $P$ .

Note: For ideal gases, the properties  $c_p$ ,  $k$ ,  $\mu$ , and  $Pr$  are independent of pressure. The properties  $\rho$ ,  $\nu$ , and  $\alpha$  at a pressure  $P$  (in atm) other than 1 atm are determined by multiplying the values of  $P$  at the given temperature by  $\rho$  and by dividing  $\nu$  and  $\alpha$  by  $P$ .

**FIGURE A-20**

The Moody chart for the friction factor for fully developed flow in circular pipes for use in the head loss relation  $\Delta P_L = f \frac{L}{D} \frac{\rho V^2}{2}$ . Friction factors in the turbulent flow are evaluated from the Colebrook equation  $\frac{1}{\sqrt{f}} = -2 \log_{10} \left( \frac{\epsilon/D}{3.7} + \frac{2.51}{Re \sqrt{f}} \right)$ .

<sup>\*</sup>The gas constant is calculated from  $R = R_u/M$ , where  $R_u = 1.9859 \text{ Btu/lbmol}\cdot\text{R} = 10.732 \text{ psia}\cdot\text{ft}^3/\text{lbmol}\cdot\text{R}$  is the universal gas constant and  $M$  is the molar mass.

Source: Specific heat values are mostly obtained from the property routines prepared by The National Institute of Standards and Technology (NIST), Gaithersburg, MD.

**TABLE A-2E**

Boiling and freezing point properties

Source: <sup>a</sup>Water content and freezing point data are from ASHRAE, *Handbook of Fundamentals*, I-P version (Atlanta, GA: American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc., 1993), Chap. 30, Table 1. Used with permission. Freezing point is the temperature at which freezing starts for fruits and vegetables, and the average freezing temperature for other foods.

<sup>b</sup>Specific heat data are based on the specific heat values of water and ice at 32°F and are determined from Siebel's formulas:  $c_{p, \text{fresh}} = 0.800 \times (\text{Water content}) + 0.200$ , above freezing, and  $c_{p, \text{frozen}} = 0.300 \times (\text{Water content}) + 0.200$ , below freezing.

<sup>c</sup>The latent heat of fusion is determined by multiplying the heat of fusion of water (143 Btu/lbm) by the water content of the food.

**TABLE A-7E**Properties of common foods (*Concluded*)

(b) Other properties

| Food                     | Water Content, % (mass) | Temperature, $T$ °F | Density, $\rho$ lbm/ft³ | Thermal Conductivity, $k$ Btu/h·ft·°F | Thermal Diffusivity, $\alpha$ ft²/s | Specific Heat, $c_p$ Btu/lbm·R |
|--------------------------|-------------------------|---------------------|-------------------------|---------------------------------------|-------------------------------------|--------------------------------|

Source: Data obtained primarily from ASHRAE, *Handbook of Fundamentals*, I-P version (Atlanta, GA: American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc., 1993), Chap. 30, Tables 7 and 9. Used with permission.

Most specific heats are calculated from  $c_p = 0.4 + 0.6 \times (\text{Water content})$ , which is a good approximation in the temperature range of 40 to 90°F. Most thermal diffusivities are calculated from  $\alpha = k/\rho c_p$ . Property values given above are valid for the specified water content.

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\rho c_p = \nu/\text{Pr}$ . The temperatures 32.02°F, 212°F, and 705.44°F are the triple-, boiling-, and critical-point temperatures of water, respectively. All properties listed above (except the vapor density) can be used at any pressures with negligible error except at temperatures near the critical-point value.

Note 2: The unit Btu/lbm·°F for specific heat is equivalent to Btu/lbm·R, and the unit Btu/h·ft·°F for thermal conductivity is equivalent to Btu/h·ft·R.

Source: Viscosity and thermal conductivity data are from J. V. Sengers and J. T. T. Watson, *Journal of Physical and Chemical Reference Data* 15 (1986), pp. 1291–1322. Other data are obtained from various sources or calculated.

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\rho c_p = \nu/\text{Pr}$ . The properties listed here (except the vapor density) can be used at any pressures with negligible error except at temperatures near the critical-point value.

Note 2: The unit Btu/lbm.°F for specific heat is equivalent to Btu/lbm-R, and the unit Btu/h-ft.°F for thermal conductivity is equivalent to Btu/h-ft-R.

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\rho c_p = \nu/\text{Pr}$ . The properties listed here (except the vapor density) can be used at any pressures with negligible error except at temperatures near the critical-point value.

Note 2: The unit Btu/lbm·°F for specific heat is equivalent to Btu/lbm·R, and the unit Btu/h·ft·°F for thermal conductivity is equivalent to Btu/h·ft·R.

Note 1: Kinematic viscosity  $\nu$  and thermal diffusivity  $\alpha$  can be calculated from their definitions,  $\nu = \mu/\rho$  and  $\alpha = k/\rho c_p = \nu/\text{Pr}$ . The properties listed here (except the vapor density) can be used at any pressures with negligible error at temperatures near the critical-point value.

Note 2: The unit Btu/lbm·°F for specific heat is equivalent to Btu/lbm-R, and the unit Btu/h·ft·°F for thermal conductivity is equivalent to Btu/h·ft·R.

Note: For ideal gases, the properties  $c_p$ ,  $k$ ,  $\mu$ , and  $Pr$  are independent of pressure. The properties  $\rho$ ,  $\nu$ , and  $\alpha$  at a pressure  $P$  (in atm) other than 1 atm are determined by multiplying the values of  $\rho$  at the given temperature by  $P$  and by dividing  $\nu$  and  $\alpha$  by  $P$ .

Note: For ideal gases, the properties *c<sub>p</sub>*, *k*, *μ*, and Pr are independent of pressure. The properties *ρ*, *ν*, and *α* at a pressure *P* (in atm) other than 1 atm are determined by multiplying the values of *ρ* at the given temperature by *P* and by dividing *ν* and *α* by *P*.

Source: U. S. Standard Atmosphere Supplements, U.S. Government Printing Office, 1966. Based on year-round mean conditions at 45° latitude and varies with the time of the year and the weather patterns. The conditions at sea level (z = 0) are taken to be  $P = 14.696$  psia,  $T = 59$  °F,  $\rho = 0.076474$  lbm/ft<sup>3</sup>,  $g = 32.1741$  ft<sup>2</sup>/s.

# INDEX

## A

- Absorptivity, 28, 736
- Air at 1 atm pressure, properties of
  - English units, 954–955
  - SI units, 927–928
- Air-conditioning, 43
- Analogies between momentum and heat transfer, 407–409
  - Chilton-Colburn analogy, 408
  - modified Reynolds analogy, 408
  - Reynolds analogy, 408
  - Stanton number, 408
- Analogy between friction, heat transfer, and mass transfer coefficients, 877
- Analogy between heat and mass transfer, 837–839
  - conduction, 838
  - convection, 839
  - differential coefficient, 838
  - Fick's law of diffusion, 838
  - Fourier's law of heat conduction, 838
  - heat generation, 838–839
  - heterogeneous reactions, 839
  - homogeneous reactions, 838
  - mass convection, 839
  - temperature, 838
- Application of Reynolds analogy, non-boiling two-phase flow, 634–635
- Approach velocity, 424
- Approximate analytical and graphical solutions, transient heat conduction, 250–251, 255–256
- Arithmetic mean temperature difference, 482
- Aspect ratio, 555
- Asymmetrical thermal radiation, 45–46
- Atmosphere at high altitude, properties of
  - English units, 956
  - SI units, 929
- Atmospheric and solar radiation, 742–747
  - diffuse solar radiation, 744
  - direct solar radiation, 744
  - effective sky temperature, 744–745
  - effective surface temperature, 743
  - total solar radiance, 743
- Average velocity and temperature, 475–476
  - hydraulic diameter, 476
  - laminar and turbulent flow in tubes, 476
  - mean temperature, 475
  - mean velocity, 475

## B

- Beef products, microorganisms, 279–283
- Beer's law, 802
- Binary diffusion coefficient, 842
- Bioheat transfer equation, 187–192
- Blackbody, 28
- Blackbody emissive power, 719
- Blackbody radiation, 28, 719–725
  - blackbody emissive power, 719
  - blackbody radiation function, 724
  - Planck's law, 719
  - spectral blackbody emissive power, 719
  - Stephan-Boltzmann law, 719
  - Wein's displacement law, 720
- Blackbody radiation function, 724
- Black surfaces, radiation heat transfer, 782–784
- Boiling, 599
- Boiling and condensation, 598–648
  - boiling heat transfer, 599–600
  - condensation heat transfer, 613–614
  - dropwise condensation, 628–629
  - film condensation, 614–626
  - film condensation inside horizontal tubes, 626–628
  - flow boiling, 612–613
  - non-boiling two-phase flow heat transfer, 629–635
  - pool boiling, 601–612
- Boiling and freezing points, properties of
  - English units, 937
  - SI units, 909
- Boiling regimes and boiling curve, 601
- Boundary and initial conditions, 82–91
  - convection boundary condition, 86–88
  - generalized boundary conditions, 89–91
  - insulated boundary, 85
  - interface boundary conditions, 89
  - radiation boundary condition, 88–89
  - specified heat boundary condition, 84–85
  - specified temperature boundary condition, 84
  - thermal symmetry, 85–86
- Boundary conditions, 845–850
  - Henry's constant, 846–847
  - Henry's law, 846
  - impermeable surface, 846
  - permeability, 849
  - Raoult's law, 848
  - solubility, 846, 848

Boundary layer, 381  
 Boundary layer approximations, 397  
 Boundary layer region, 388, 477  
 Boundary nodes, 326–330  
 Brownian motion, 844  
 Buffer layer, 391  
 Building materials, properties of  
     English units, 941–942  
     SI units, 914–915  
 Buoyancy force, 534–535  
 Burnout heat flux, 604  
 Burnout point, 604

**C**

Characteristic equation, 248  
 Characteristic values, 248  
 Chemical energy, 7  
 Chilton-Colburn analogy, 408, 878–879  
 Classification of differential equations, 117–118  
 Colebrook equation, 498  
 Combined heat transfer coefficient, 29, 145–146  
 Combined natural and forced convection, 562–566  
 Combined natural convection and radiation, 556–557  
 Combined one-dimensional heat conduction equation, 77–79  
 Common foods, properties of  
     English units, 944–945  
     SI units, 917–918  
 Compact heat exchanger, 650  
 Complementary error function, 262  
 Compressible versus incompressible flow, 384–385  
 Concentration, 836  
 Concentration boundary layer, 873  
 Concentration entrance region, 873–874  
 Concentration entry length, 874  
 Concentric cylinders, natural convection, 555–556  
 Concentric spheres, natural convection, 556  
 Condensation heat transfer, 613–614  
     dropwise condensation, 614  
     film condensation, 613–614  
 Conduction, 17–25, 838  
     Fourier's law of heat conduction, 18  
     heat capacity, 22  
     temperature gradient  
     thermal conductivity, 18, 19–22  
     thermal diffusivity, 22–25  
 Conduction resistance, 144  
 Conduction shape factor, 192  
 Conservation of energy equation, 397–399  
 Conservation of energy principle, 11  
 Conservation of mass, 851  
 Constant heat, 7  
 Constant pressure, 7  
 Constant surface heat flux, 481, 489–490  
 Constant surface temperature, 482–485, 490–491

Contact of two semi-infinite solids, 265–268  
 Continuity equation, 396  
 Controlling numerical error, 352–355  
     discretization error, 352–353  
     in numerical methods, 354–355  
     round-off error, 353–354  
 Convection, 25–27, 839  
     conservation of energy principle, 11  
     energy balance for closed systems, 12  
     energy balance for steady-flow systems, 12–13  
     first law of thermodynamics, 11–17  
     forced, 26  
     mass flow rate, 13  
     natural, 26  
     Newton's law of cooling, 26  
     surface energy balance, 13–14  
     volume flow rate, 14  
 Convection boundary condition, 86–88  
 Convection from fin tip, 175–176  
 Convection, fundamentals of, 379–422  
     analogies between momentum and heat transfer, 407–409  
     classification of fluid flows, 384–387  
     derivation of differential convection equations, 394–401  
     functional forms of friction and convection coefficients, 406–407  
     heat and momentum transfer in turbulent flow, 392–394  
     laminar and turbulent flows, 390–392  
     mechanism, 380–383  
     microscale heat transfer, 410–412  
     nondimensionalized convection equations and similarity, 405–406  
     solutions of convection equations for flat plate, 401–405  
     thermal boundary layer, 389–390  
     velocity boundary layer, 387–389  
 Convection heat transfer coefficient, 381  
 Convection, physical mechanism of, 380–383  
     boundary layer, 381  
     convection heat transfer coefficient, 381  
     Newton's law of cooling, 380  
     no-slip condition, 381  
     Nusselt number, 382  
 Cooling of finned surfaces ( $T_s = \text{constant}$ ), 548–549  
 Cooling of PCBs ( $q_s = \text{constant}$ ), 549–550  
 Counter flow heat exchanger, 650, 664–665  
 Critical Reynolds number, 392  
 Crossed string method, 780–782  
 Cross-flow heat exchanger configuration, 651  
 Cylindrical coordinates, general heat conduction equation, 81

**D**

Darcy friction factor, 487  
 Darcy-Weisbach friction factor, 487–488  
 Density, 839–840

Derivation of differential convection equations, 394–401  
 boundary layer approximations, 397  
 conservation of energy equation, 397–399  
 continuity equation, 396  
 mass balance, 395  
 momentum balance, 396  
 momentum equations, 395–397  
 x-momentum equation, 397

Derivatives in differential equations, 116–117

Developing laminar flow in the entrance region, 492–496

Developing turbulent flow in entrance region, 500

Differential coefficient, 838

Differential equations, 115–120, 311–314  
 classification, 117–118  
 derivatives, 116–117  
 finite difference formulation of differential equations, 311–314  
 general solution, 119–120  
 integration, 117  
 solutions, 118–119  
 variables, 115–116

Diffuse gray surfaces, radiation heat transfer, 784–796  
 methods of solving radiation problems, 787–788  
 net transfer, radiation heat, between any two surfaces, 786–787  
 net transfer, radiation heat, to or from surface, 785–786  
 radiosity, 784–785  
 reradiating surface, 786  
 space resistance, 786  
 three-surface enclosures, radiation heat transfer, 790–796  
 two-surface enclosures, radiation heat transfer, 788–789

Diffuse reflection, 738

Diffuse solar radiation, 744

Diffusion in moving medium, 861–873  
 diffusion of vapor through stationary gas, 866–868  
 diffusion velocity, 862  
 equimolar counterdiffusion, 868–873  
 gas mixtures at constant temperature and pressure, 865  
 mass-average velocity, 863  
 molar-average velocity, 864  
 moving medium, 861  
 stationary medium, 863  
 Stefan's flow, 867–868  
 Stefan's law, 867

Diffusion of vapor through stationary gas, 866–868

Diffusion resistance, 851

Diffusion velocity, 862

Diffusive mass flux, 842

Diffusive molar flux, 842

Direct method, conduction, 323

Direct solar radiation, 744

Discretization error, 352–353

Double-pane window, 568

Double-pipe heat exchanger, 650

Draft, 45

Drag and heat transfer in external flow, 424–427  
 approach velocity, 424  
 drag coefficient, 425  
 free stream velocity, 424  
 friction and pressure drag, 424–426  
 heat transfer, 426–427  
 pressure drag, 425  
 separated region, 426  
 skin friction drag, 425  
 upstream velocity, 424  
 wake, 426

Drag coefficient, 425

Dropwise condensation, 614, 628–629

Dynamic viscosity, 388

**E**

Eddies, 392

Eddy diffusivity of heat, 394

Eddy diffusivity of momentum, 394

Eddy thermal conductivity, 393

Eddy thermal diffusivity, 394

Eddy viscosity, 393

Edge-of-glass *U*-factor of window, 570–571

Effective emissivity, 199

Effectiveness-NTU method, 672–685  
 definition, 673  
 heat transfer effectiveness, 673  
 number of transfer units NTU, 676

Effective thermal conductivity, 553

Effect of vapor velocity, 622

Effective sky temperature, 744–745

Effective surface temperature, 743

Eigenfunction, 248

Eigenvalues, 248

Electromagnetic radiation, 716

Electromagnetic spectrum, 717

Electromagnetic waves, 716

Emissivity and absorptivity of gases and gas mixtures, 803–809

Emissivity correction factor, 804

Emissivity of surfaces, 930–931

Emitted radiation intensity, 727–728

Enclosures, natural convection, 552–562  
 aspect ratio, 555  
 combined natural convection and radiation, 556–557  
 concentric cylinders, 555–556  
 concentric spheres, 556  
 effective thermal conductivity, 553  
 horizontal rectangular enclosures, 553–554  
 inclined rectangular enclosures, 554–555  
 vertical rectangular enclosures, 555

Energy, and heat transfer, 6–11  
 chemical energy, 7  
 enthalpy, 7

Energy, and heat transfer (*Continued*)

heat, 9  
 heat flux, 10  
 heat transfer rate, 9  
 internal energy, 6  
 latent energy, 7  
 latent heat, 7  
 nuclear energy, 7  
 sensible energy, 6  
 sensible heat, 6  
 specific heats of gases, liquids, and solids, 7–10  
 thermal energy 9  
 total energy, 6

Energy balance for closed systems, 12

Energy balance for steady-flow systems, 12–13

Energy balance method, conduction, 314

Energy equation, 403–405

Engineering, and heat transfer, 4–6  
 modeling, 5–6

Engineering equation solver (EES), 41

Engineering software packages, 40–41

Enhancement of heat transfer in pool boiling, 609–610

Enthalpy, 7

Entrance region, 477–480

boundary layer region, 477  
 entry lengths, 479–480  
 hydrodynamic entrance region, 477  
 thermal entrance region, 478  
 thermal entry length, 478  
 thermally fully developed region, 478  
 velocity boundary layer, 477

Entry lengths, 479–480

Equation of motion and Grashof number, 537–540

Equimolar counterdiffusion, 868–873

Evaporation, 599

Evaporative heat loss, 812

Excessive air motion, 45

Explicit method, transient heat conduction, 335

External flow, 873

External forced convection, 423–472

drag and heat transfer in external flow, 424–427  
 flow across cylinders and spheres, 437–445  
 flow across tube banks, 445–451  
 parallel flow over flat plates, 427–436

**F**

Fick's law of diffusion, 838, 841

Film boiling, 603–604, 607–608

Film condensation, 613–614, 614–626

effect of vapor velocity, 622

flow regimes, 616

heat transfer correlations for film condensation, 616–622

modified latent heat of vaporization, 615

presence of noncondensable gases in condensers, 622

superheated vapor, 615

Film condensation inside horizontal tubes, 626–628

Fin 171–187

effectiveness, 178–181

efficiency, 176–178

equation, 171–176

length, 181–187

Fin equation, 171–176

convection from fin tip, 175–176

infinitely long fin, 173–174

negligible heat loss from fin tip, 174

specific temperature, 174–175

Finite difference formulation of differential equations, 311–314

finite distance form, 312

nodal points, 312

nodes, 312

Finite distance form, 312

First law of thermodynamics, 11–17

Flat plate with unheated starting length, 431–432

Flow across cylinders and spheres, 437–445

heat transfer coefficient, 441–445

surface roughness, effect, 439–440

Flow across tube banks, 445–451

pressure drop, 448–449

Flow boiling, 600, 612–613

Flow regimes, 616

Flow through tube annulus, 500–501

Fluid flow classifications, 384–387

compressible versus incompressible flow, 384–385

internal versus external flow, 384

laminar versus turbulent flow, 385

natural (unforced) versus forced flow, 385

one-, two-, and three-dimensional flows, 386–387

steady versus unsteady flow, 385–386

viscous versus inviscid regions of flow, 384

Forced convection, 26

Forced diffusion, 844

Fouling factor, overall heat transfer coefficient, 656

Fourier-Biot equation, 80–81

Fourier number, 246

Fourier's law of heat conduction, 18, 71, 838

Frame *U*-factor, 571

Free stream velocity, 424

Friction and pressure drag, 424–426

Friction coefficient, 389, 428–429

Fully developed region, 874

Fully developed transitional flow heat transfer, 497–498

Functional forms of friction and convection coefficients, 406–407

**G**

Gases at 1 atm pressure, properties of

English units, 954–955

SI units, 927–928

Gas mixtures at constant temperature and pressure, 865

General heat conduction equation, 79–82

cylindrical coordinates, 81

rectangular coordinates, 79–81

spherical coordinates, 81–82

Generalized boundary conditions, 89–91

Generalized thermal resistance networks, 158–160

General solution, differential equations, 119–120

General thermal analysis, 480–485

arithmetic mean temperature difference, 482

constant surface heat flux, 481

constant surface temperature, 482–485

log mean temperature difference, 484

Grashof number, 539–540

Greenhouse effect, 742

## H

Head loss, 488

Heat and momentum transfer in turbulent flow, 392–394

eddies, 392

eddy diffusivity of heat, 394

eddy diffusivity of momentum, 394

eddy thermal conductivity, 393

eddy thermal diffusivity, 394

eddy viscosity, 393

kinematic eddy viscosity, 394

Reynolds stress, 393

turbulent shear stress, 393

turbulent stress, 393

turbulent thermal conductivity, 393

turbulent viscosity, 393

Heat capacity, 22

Heat capacity rate, 661–662

Heat conduction in cylinders and spheres, 161–167

multilayered cylinders and spheres, 163–167

Heat conduction equation, 67–141

boundary and initial conditions, 82–91

differential equations, 115–120

general heat conduction equation, 79–82

introduction, 68–73

heat generation, 72–73

heat generation in a solid, 104–112

multidimensional heat transfer, 70–71

one-dimensional heat conduction equation, 73–79

solution of steady one-dimensional heat conduction

problems, 91–104

steady versus transient heat transfer, 69–70

variable thermal conductivity, 112–115

Heat exchangers, 649–714

analysis, 660–662

effectiveness-NTU method, 672–685

human cardiovascular system as counter-current, 689–694

log mean temperature difference method, 662–672

overall heat transfer coefficient, 653–660

selection, 685–689

types, 650–653

Heat flux, 10

Heat generation, 72–73, 838–839

Heat generation in a solid, 104–112

Heat transfer, 426–427

Heat transfer, basics, 1–66

conduction, 17–25

convection, 25–27

energy, 6–11

engineering, 4–6

first law of thermodynamics, 11–17

mechanisms, 18

prevention through design, 35–38

radiation, 27–30

simultaneous mechanisms, 30–35

thermal comfort, 43–49

thermodynamics, 2–4

Heat transfer, boiling, 599–600

boiling, 599

evaporation, 599

flow boiling, 600

pool boiling, 600

saturation, 600

subcool, 600

Heat transfer coefficient, 429–431, 441–445

Heat transfer coefficient, convection 382

Heat transfer correlations for film condensation, 616–622

horizontal tube banks, 621–622

horizontal tubes and spheres, 621

inclined planes, 620–621

vertical plates, 616–620

vertical tubes, 621

Heat transfer correlations in pool boiling, 604

Heat transfer effectiveness, 673

Heat transfer enhancement, 501

Heat transfer from finned surfaces, 170–187

fin effectiveness, 178–181

fin efficiency, 176–178

fin equation, 171–176

proper length, 181–187

Heat transfer from human body, 810–814

evaporative heat loss, 812

latent heat loss, 812

mean radiation temperature, 811

operative temperature, 811

unit thermal resistance of clothing, 811

Heat transfer in common configurations, 192–197

Heat transfer in transition region, 512–517

Heat transfer, plane walls, 143–152

multilayer plane walls, 148–152

overall heat transfer coefficient, 147

thermal resistance concept, 144–146

thermal resistance network, 146–148

Heat transfer rate, 9  
 Heat transfer through walls and roofs, 197–207  
 Heat transfer through windows, 566–577  
   double-pane window, 568  
   edge-of-glass *U*-factor of window, 570–571  
   frame *U*-factor, 571  
   interior and exterior surface heat transfer coefficients, 571–572  
   overall transfer coefficient, 567  
   overall *U*-factor of windows, 572–574  
   spacers, 570  
   *U*-factor, 567  
 Heisler charts, 251–254  
 Henry's constant, 846–847  
 Henry's law, 846  
 Heterogeneous reactions, 839  
 Homogeneous reactions, 838  
 Horizontal cylinders and spheres, 544  
 Horizontal plates, 544  
 Horizontal rectangular enclosures, 553–554  
 Horizontal tube banks, heat transfer correlations for, 621–622  
 Horizontal tubes and spheres, heat transfer correlations for, 621  
 Human cardiovascular system as counter-current heat exchanger, 689–694  
 Hydraulic diameter, 476  
 Hydrodynamic entrance region, 477

**I**

Ideal gas mixtures, 841–845  
 Impermeable surface, 846  
 Implicit method, transient heat conduction, 335  
 Incident radiation, 729  
 Inclined planes, 543–544  
 Inclined rectangular enclosures, 554–555  
 Incompressible substance, 8  
 Infinitely long fin, 173–174  
 Infrared spectrum, 718  
 Insulated boundary, 85  
 Insulating materials, properties of  
   English units, 943  
   SI units, 916  
 Integration, differential equations, 117  
 Interface boundary conditions, 89  
 Interior and exterior surface heat transfer coefficients, 571–572  
 Internal energy, 6  
 Internal flow, 873  
 Internal forced convection, 473–532  
   average velocity and temperature, 475–476  
   entrance region, 477–480  
   general thermal analysis, 480–485  
   introduction, 474  
   laminar flow in tubes, 485–496  
   transitional flow in tubes, 507–517  
   turbulent flow in tubes, 496–507

Internal versus external flow, 384  
 Irradiation, 729, 736  
 Irregular boundaries, 330–334  
 Irrotational flow region, 388  
 Iterative method, conduction, 323–324

**K**

Kinematic eddy viscosity, 394  
 Kinematic viscosity, 388  
 Kirchhoff's law, 28, 739–741  
 Knudson diffusion, 844

**L**

Lag phase, 276  
 Laminar and turbulent flow in tubes, 476  
 Laminar and turbulent flows, 390–392  
   buffer layer, 391  
   critical Reynolds number, 392

**Errata Sheet**

**Last Update: December 1, 2014**

**Chapter 4**

- p. 243, 1<sup>st</sup> line of Analysis for Example 4-2: Change “The characteristic length and the Biot number of the metal plate are” to “With a metal plate thickness of  $2L = 2$  cm, the characteristic length of the plate is”
- p. 244, 3<sup>rd</sup> line of Discussion for Example 4-2: Change “velocities **less** than...” to “velocities **greater** than...”
- p. 262, 1<sup>st</sup> line below Eq. 4-42: Change “functionsrom” to “functions”

**Chapter 5**

- p. 378, Prob. 5-153: Change “(e)  $T_6 = (T_2 + T_5 + T_7 + T_{10}) / 2$ ” to “(e)  $T_6 = (T_1 + T_2 + T_9 + T_{10}) / 4$ ”

**Chapter 6**

- p. 393, 13<sup>th</sup> line above Eq. (6-15): Add “overbar” on “ $u' v'$ ”, two places
- p. 393, 10<sup>th</sup> line above Eq. (6-15): Add “overbar” on “ $v' T'$ ”
- p. 393, 9<sup>th</sup> line above Eq. (6-15): Add “overbar” on “ $u' v' \neq 0$ ”, “ $u' = 0$ ”, “ $v' = 0$ ”, and “ $u' v' = 0$ ”
- p. 393, 7<sup>th</sup> & 8<sup>th</sup> lines above Eq. (6-15): Add “overbar” on “ $u' v'$ ”
- p. 393, Eq. (6-15): Change “ $\overline{vT}$ ” to “ $\overline{v'T'}$ ”
- p. 405, 1<sup>st</sup> line above Eq. (6-64): Change “Eqs. 6-28, 6-29, ...” to “Eqs. 6-21, 6-28,...”
- p. 406, 3<sup>rd</sup> line: Change “Nu” to “Pr”, two places
- p. 423, Prob. 6-114: Add the following to the problem “(e)  $Nu = C_f Re^{1/2} Pr^{1/3}$ ”

**Chapter 7**

- p. 426, Eq. (7-2): Change the first “+” to “=”
- p. 430, below Eq. (7-17): Delete the first two lines, it is repeated twice.
- p. 431, 2<sup>nd</sup> line above Eq. (7-23): Change “Eq. 7-21” to “Eq. 7-19”
- p. 431, 1<sup>st</sup> line above Eq. (7-23): Change “Eq. 7-22” to “Eq. 7-20”
- p. 463, Problem 7-79, 5<sup>th</sup> line: Delete “and” at the end of this line

**Chapter 9**

- p. 542, Table 9-1, Eq. (9-22): Change “0.59” to “0.54”
- p. 542, Table 9-1, Eq. (9-23): Change “0.1” to “0.15”

**Web Chapter 16**

- p. 16-28, 3<sup>rd</sup> line: Change "Table 16-11 for" to "Table 16-11 (given in page 16-26) for"

## COOLING OF ELECTRONIC EQUIPMENT

**E**lectronic equipment has made its way into practically every aspect of modern life, from toys and appliances to high-power computers. The reliability of the electronics of a system is a major factor in the overall reliability of the system. Electronic components depend on the passage of electric current to perform their duties, and they become potential sites for excessive heating, since the current flow through a resistance is accompanied by heat generation. Continued miniaturization of electronic systems has resulted in a dramatic increase in the amount of heat generated per unit volume, comparable in magnitude to those encountered at nuclear reactors and the surface of the sun. Unless properly designed and controlled, high rates of heat generation result in high operating temperatures for electronic equipment, which jeopardizes its safety and reliability.

The failure rate of electronic equipment increases exponentially with temperature. Also, the high thermal stresses in the solder joints of electronic components mounted on circuit boards resulting from temperature variations are major causes of failure. Therefore, thermal control has become increasingly important in the design and operation of electronic equipment.

In this chapter, we discuss several cooling techniques commonly used in electronic equipment such as conduction cooling, natural convection and radiation cooling, forced-air cooling, liquid cooling, and immersion cooling. This chapter is intended to familiarize the reader with these techniques and put them into perspective. The reader interested in an in-depth coverage of any of these topics can consult numerous other sources available, such as those listed in the references.

## 15–1 ■ INTRODUCTION AND HISTORY

The field of electronics deals with the construction and utilization of devices that involve current flow through a vacuum, a gas, or a semiconductor. This exciting field of science and engineering dates back to 1883, when Thomas Edison invented the vacuum diode. The **vacuum tube** served as the foundation of the electronics industry until the 1950s, and played a central role in the development of radio, TV, radar, and the digital computer. Of the several computers developed in this era, the largest and best known is the ENIAC (Electronic Numerical Integrator and Computer), which was built at the University of Pennsylvania in 1946. It had over 18,000 vacuum tubes and occupied a room  $7\text{ m} \times 14\text{ m}$  in size. It consumed a large amount of power, and its reliability was poor because of the high failure rate of the vacuum tubes.

The invention of the **bipolar transistor** in 1948 marked the beginning of a new era in the electronics industry and the obsolescence of vacuum tube technology. Transistor circuits performed the functions of the vacuum tubes with greater reliability, while occupying negligible space and consuming negligible power compared with vacuum tubes. The first transistors were made from germanium, which could not function properly at temperatures above  $100^\circ\text{C}$ . Soon they were replaced by silicon transistors, which could operate at much higher temperatures.

The next turning point in electronics occurred in 1959 with the introduction of the **integrated circuits** (IC), where several components such as diodes, transistors, resistors, and capacitors are placed in a single chip. The number of components packed in a single chip has been increasing steadily since then at an amazing rate, as shown in Fig. 15–1. The continued miniaturization of electronic components has resulted in *medium-scale integration* (MSI) in the 1960s with 50 to 1000 components per chip, *large-scale integration* (LSI) in the 1970s with 1000 to 100,000 components per chip, and *very large-scale integration* (VLSI) in the 1980s with 100,000 to 10,000,000 components per chip. Today it is not unusual to have a chip  $3\text{ cm} \times 3\text{ cm}$  in size with several million components on it.

The development of the **microprocessor** in the early 1970s by the Intel Corporation marked yet another beginning in the electronics industry. The accompanying rapid development of large-capacity memory chips in this decade made it possible to introduce capable personal computers for use at work or at home at an affordable price. Electronics has made its way into practically everything from watches to household appliances to automobiles. Today it is difficult to imagine a new product that does not involve any electronic parts.

The current flow through a resistance is always accompanied by *heat generation* in the amount of  $I^2R$ , where  $I$  is the electric current and  $R$  is the resistance. When the transistor was first introduced, it was touted in the newspapers as a device that “produces no heat.” This certainly was a fair statement, considering the huge amount of heat generated by vacuum tubes. Obviously, the little heat generated in the transistor was no match to that generated in its predecessor. But when thousands or even millions of such components are packed in a small volume, the heat generated increases to such high levels that its removal becomes a formidable task and a major concern for the safety and reliability of the electronic devices. The heat fluxes encountered in electronic devices range from less than  $1\text{ W/cm}^2$  to more than  $100\text{ W/cm}^2$ .

**FIGURE 15–1**

The increase in the number of components packed on a chip over the years.

Heat is generated in a resistive element for as long as current continues to flow through it. This creates a *heat build-up* and a subsequent *temperature rise* at and around the component. The temperature of the component will continue rising until the component is destroyed unless heat is transferred away from it. The temperature of the component will remain constant when the rate of heat removal from it equals the rate of heat generation.

Individual electronic components have *no moving parts*, and thus nothing to wear out with time. Therefore, they are inherently reliable, and it seems as if they can operate safely for many years. Indeed, this would be the case if components operated at room temperature. But electronic components are observed to fail under prolonged use at high temperatures. Possible causes of failure are *diffusion* in semiconductor materials, *chemical reactions*, and *creep* in the bonding materials, among other things. The failure rate of electronic devices increases almost *exponentially* with the operating temperature, as shown in Fig. 15–2. The cooler the electronic device operates, the more reliable it is. A rule of thumb is that the failure rate of electronic components is halved for each 10°C reduction in their junction temperature.

## 15–2 • MANUFACTURING OF ELECTRONIC EQUIPMENT

The narrow band where two different regions of a semiconductor (such as the p-type and n-type regions) come in contact is called a **junction**. A transistor, for example, involves two such junctions, and a diode, which is the simplest semiconductor device, is based on a single p-n junction. In heat transfer analysis, the circuitry of an electronic component through which electrons flow and thus heat is generated is also referred to as the junction. That is, junctions are the sites of heat generation and thus the hottest spots in a component. In silicon-based semiconductor devices, the junction temperature is limited to 125°C for safe operation. However, lower junction temperatures are desirable for extended life and lower maintenance costs. In a typical application, numerous electronic components, some smaller than 1 μm in size, are formed from a silicon wafer into a chip.

### The Chip Carrier

The chip is housed in a **chip carrier** or substrate made of ceramic, plastic, or glass in order to protect its delicate circuitry from the detrimental effects of the environment. The chip carrier provides a rugged housing for the safe handling of the chip during the manufacturing process, as well as the connectors between the chip and the circuit board. The various components of the chip carrier are shown in Fig. 15–3. The chip is secured in the carrier by bonding it to the bottom surface. The thermal expansion coefficient of the *plastic* is about 20 times that of silicon. Therefore, bonding the silicon chip directly to the plastic case would result in such large thermal stresses that the reliability would be seriously jeopardized. To avoid this problem, a *lead frame* made of a copper alloy with a thermal expansion coefficient close to that of silicon is used as the bonding surface.

The design of the chip carrier is the *first level* in the thermal control of electronic devices, since the transfer of heat from the chip to the chip carrier is the

**FIGURE 15–2**

The increase in the failure rate of bipolar digital devices with temperature.  
(From Ref. 15.)

**FIGURE 15–3**

The components of a chip carrier.

first step in the dissipation of the heat generated on the chip. The heat generated on the chip is transferred to the case of the chip carrier by a combination of conduction, convection, and radiation. However, it is obvious from the figure that the common chip carrier is designed with the *electrical aspects* in mind, and little consideration is given to the *thermal aspects*. First of all, the cavity of the chip carrier is filled with a gas, which is a poor heat conductor, and the case is often made of materials that are also poor conductors of heat. This results in a relatively large thermal resistance between the chip and the case, called the **junction-to-case resistance**, and thus a large temperature difference. As a result, the temperature of the chip will be much higher than that of the case for a specified heat dissipation rate. The junction-to-case thermal resistance depends on the *geometry* and the *size* of the chip and the chip carrier as well as the material properties of the *bonding* and the *case*. It varies considerably from one device to another and ranges from about  $10^{\circ}\text{C}/\text{W}$  to more than  $100^{\circ}\text{C}/\text{W}$ .

*Moisture* in the cavity of the chip carrier is highly undesirable, since it causes corrosion on the wiring. Therefore, chip carriers are made of materials that prevent the entry of moisture by diffusion and are *hermetically sealed* in order to prevent the direct entry of moisture through cracks. Materials that outgas are also not permitted in the chip cavity, because such gases can also cause corrosion. In products with strict hermeticity requirements, the more expensive ceramic cases are used instead of the plastic ones.

A common type of chip carrier for high-power transistors is shown in Fig. 15-4. The transistor is formed on a small silicon chip housed in the disk-shaped cavity, and the I/O pins come out from the bottom. The case of the transistor carrier is usually attached directly to a flange, which provides a large surface area for heat dissipation and reduces the junction-to-case thermal resistance.

It is often desirable to house more than one chip in a single chip carrier. The result is a *hybrid* or *multichip package*. Hybrid packages house several chips, individual electronic components, and ordinary circuit elements connected to each other in a single chip carrier. The result is improved performance due to the shortening of the wiring lengths, and enhanced reliability. Lower cost would be an added benefit of multichip packages if they are produced in sufficiently large quantity.

### EXAMPLE 15-1 Predicting the Junction Temperature of a Transistor

The temperature of the case of a power transistor that is dissipating 3 W is measured to be  $50^{\circ}\text{C}$ . If the junction-to-case resistance of this transistor is specified by the manufacturer to be  $15^{\circ}\text{C}/\text{W}$ , determine the temperature at the junction of the transistor.

**SOLUTION** The case temperature of a power transistor and the junction-to-case resistance are given. The junction temperature is to be determined.

**Assumptions** Steady operating conditions exist.

**Analysis** The schematic of the transistor is given in Fig. 15-5. The rate of heat transfer between the junction and the case in steady operation can be expressed as

$$\dot{Q} = \left( \frac{\Delta T}{R} \right)_{\text{junction-case}} = \frac{T_{\text{junction}} - T_{\text{case}}}{R_{\text{junction-case}}}$$

Then the junction temperature becomes

$$\begin{aligned} T_{\text{junction}} &= T_{\text{case}} + \dot{Q} R_{\text{junction-case}} \\ &= 50^\circ\text{C} + (3 \text{ W})(15^\circ\text{C/W}) \\ &= 95^\circ\text{C} \end{aligned}$$

Therefore, the temperature of the transistor junction will be  $95^\circ\text{C}$  when its case is at  $50^\circ\text{C}$ .

### EXAMPLE 15-2 Determining the Junction-to-Case Thermal Resistance

This experiment is conducted to determine the junction-to-case thermal resistance of an electronic component. Power is supplied to the component from a 15-V source, and the variations in the electric current and in the junction and the case temperatures with time are observed. When things are stabilized, the current is observed to be 0.1 A and the temperatures to be  $80^\circ\text{C}$  and  $55^\circ\text{C}$  at the junction and the case, respectively. Calculate the junction-to-case resistance of this component.

**SOLUTION** The power dissipated by an electronic component as well as the junction and case temperatures are measured. The junction-to-case resistance is to be determined.

**Assumptions** Steady operating conditions exist.

**Analysis** The schematic of the component is given in Fig. 15-6. The electric power consumed by this electronic component is

$$\dot{W}_e = VI = (15 \text{ V})(0.1 \text{ A}) = 1.5 \text{ W}$$

In steady operation, this is equivalent to the heat dissipated by the component. That is,

$$\dot{Q} = \left( \frac{\Delta T}{R} \right)_{\text{junction-case}} = \frac{T_{\text{junction}} - T_{\text{case}}}{R_{\text{junction-case}}} = 1.5 \text{ W}$$

Then the junction-to-case resistance is determined to be

$$R_{\text{junction-case}} = \frac{T_{\text{junction}} - T_{\text{case}}}{\dot{Q}} = \frac{(80 - 55)^\circ\text{C}}{1.5 \text{ W}} = 16.7^\circ\text{C/W}$$

**Discussion** Note that a temperature difference of  $16.7^\circ\text{C}$  will occur between the electronic circuitry and the case of the chip carrier for each W of power consumed by the component.

FIGURE 15-6

Schematic for Example 15-2.

## Printed Circuit Boards

A **printed circuit board** (PCB) is a properly wired plane board made of polymers and glass-epoxy materials on which various electronic components such

as the ICs, diodes, transistors, resistors, and capacitors are mounted to perform a certain task, as shown in Fig. 15–7. The PCBs are commonly called *cards*, and they can be replaced easily during a repair. The PCBs are plane boards, usually 10 cm wide and 15 cm long and only a few millimeters thick, and they are not suitable for heavy components such as transformers. Usually a copper cladding is added on one or both sides of the board. The cladding on one side is subjected to an etching process to form wiring strips and attachment pads for the components. The power dissipated by a PCB usually ranges from 5 W to about 30 W.

A typical electronic system involves several layers of PCBs. The PCBs are usually cooled by direct contact with a fluid such as air flowing between the boards. But when the boards are placed in a hermetically sealed enclosure, they must be cooled by a cold plate (a heat exchanger) in contact with the edge of the boards. The *device-to-board edge thermal resistance* of a PCB is usually high (about 20 to 60°C/W) because of the small thickness of the board and the low thermal conductivity of the board material. In such cases, even a thin layer of copper cladding on one side of the board can decrease the device-to-board edge thermal resistance in the plane of the board and enhance heat transfer in that direction drastically.

In the thermal design of a PCB, it is important to pay particular attention to the components that are not tolerant of high temperatures, such as certain high-performance capacitors, and to ensure their safe operation. Often when one component on a PCB fails, the whole board fails and must be replaced.

Printed circuit boards come in three types: *single-sided*, *double-sided*, and *multilayer* boards. Each type has its own strengths and weaknesses. Single-sided PCBs have circuitry lines on one side of the board only and are suitable for low-density electronic devices (10 to 20 components). Double-sided PCBs

**FIGURE 15–7**

A printed circuit board (PCB)  
with a variety of components on it.  
*(Courtesy of Litton Systems, Inc.)*

have circuits on both sides and are best suited for intermediate-density devices. Multilayer PCBs contain several layers of circuitry and are suitable for high-density devices. They are equivalent to several PCBs sandwiched together.

The single-sided PCB has the lowest cost, as expected, and it is easy to maintain, but it occupies a lot of space. The multilayer PCB, on the other hand, allows the placement of a large number of components in a three-dimensional configuration, but it has the highest initial cost and is difficult to repair. Also, temperatures are most likely to be the highest in multilayer PCBs.

In critical applications, the electronic components are placed on boards attached to a conductive metal, called the *heat frame*, that serves as a conduction path to the edge of the circuit board and thus to the cold plate for the heat generated in the components. Such boards are said to be *conduction-cooled*. The temperature of the components in this case will depend on the location of the components on the boards: it will be highest for the components in the middle and lowest for those near the edge, as shown in Fig. 15-8.

Materials used in the fabrication of circuit boards should be (1) effective electrical insulators to prevent electrical breakdown and (2) good heat conductors to conduct away the heat generated. They should also have (3) high material strength to withstand forces and to maintain dimensional stability; (4) thermal expansion coefficients that closely match that of copper, to prevent cracking in the copper cladding during thermal cycling; (5) resistance to moisture absorption, since moisture can affect both mechanical and electrical properties and degrade performance; (6) stability in properties at temperature levels encountered in electronic applications; (7) ready availability and manufacturability; and, of course, (8) low cost. As you might have already guessed, no existing material has all of these desirable characteristics.

Glass-epoxy laminates made of an epoxy or polyimide matrix reinforced by several layers of woven glass cloth are commonly used in the production of circuit boards. Polyimide matrices are more expensive than epoxy but can withstand much higher temperatures. Polymer or polyimide films are also used without reinforcement for flexible circuits.

## The Enclosure

An electronic system is not complete without a rugged enclosure (a case or a cabinet) that will *house* the circuit boards and the necessary peripheral equipment and connectors, *protect* them from the detrimental effects of the environment, and *provide* a cooling mechanism (Fig. 15-9). In a small electronic system such as a personal computer, the enclosure can simply be an inexpensive box made of sheet metal with proper connectors and a small fan. But for a large system with several hundred PCBs, the design and construction of the enclosure are challenges for both electronic and thermal designers. An enclosure must provide *easy access* for service personnel so that they can identify and replace any defective parts easily and quickly in order to minimize down time, which can be very costly. But, at the same time, the enclosure must *prevent* any easy access by unauthorized people in order to protect the sensitive electronics from them as well as the people from possible electrical hazards. Electronic circuits are powered by low voltages (usually under 15 V), but the currents involved may be very high (sometimes a few hundred amperes).

**FIGURE 15-8**

The path of heat flow in a conduction-cooled PCB and the temperature distribution.

**FIGURE 15-9**

A cabinet-style enclosure.

**FIGURE 15-10**

Different stages involved in the production of an electronic system.  
(From Dally, 1990.)

Plug-in-type circuit boards make it very easy to replace a defective board and are commonly used in low-power electronic equipment. High-power circuit boards in large systems, however, are tightly attached to the racks of the cabinet with special brackets. A well-designed enclosure also includes switches, indicator lights, a screen to display messages and present information about the operation, and a key pad for user interface.

The printed circuit boards in a large system are plugged into a *back panel* through their edge connectors. The back panel supplies power to the PCBs and interconnects them to facilitate the passage of current from one board to another. The PCBs are assembled in an orderly manner in card racks or chassis. One or more such assemblies are housed in a *cabinet*, as shown in Fig. 15-10.

Electronic enclosures come in a wide variety of sizes and shapes. Sheet metals such as thin-gauge aluminum or steel sheets are commonly used in the production of enclosures. The thickness of the enclosure walls depends on the shock and vibration requirements. Enclosures made of thick metal sheets or by casting can meet these requirements, but at the expense of increased weight and cost.

Electronic boxes are sometimes sealed to prevent the fluid inside (usually air) from leaking out and the water vapor outside from leaking in. Sealing against moisture migration is very difficult because of the small size of the water molecule and the large vapor pressure outside the box relative to that within the box. Sealing adds to the size, weight, and cost of an electronic box, especially in space or high-altitude operation, since the box in this case must withstand the larger forces due to the higher pressure differential between inside and outside the box.

## 15–3 • COOLING LOAD OF ELECTRONIC EQUIPMENT

The first step in the selection and design of a cooling system is the determination of the heat dissipation, which constitutes the *cooling load*. The easiest way to determine the power dissipation of electronic equipment is to measure the voltage applied  $V$  and the electric current  $I$  at the entrance of the electronic device under full-load conditions and to substitute them into the relation

$$\dot{W}_e = VI = I^2R \quad (\text{W}) \quad (15-1)$$

where  $\dot{W}_e$  is the electric power consumption of the electronic device, which constitutes the *energy input* to the device.

The first law of thermodynamics requires that in *steady* operation the energy input into a system be equal to the energy output from the system. Considering that the only form of energy leaving the electronic device is heat generated as the current flows through resistive elements, we conclude that the heat dissipation or cooling load of an electronic device is equal to its power consumption. That is,  $\dot{Q} = \dot{W}_e$ , as shown in Fig. 15–11. The exception to this rule is equipment that outputs other forms of energy as well, such as the emitter tubes of a radar, radio, or TV installation emitting radiofrequency (RF) electromagnetic radiation. In such cases, the cooling load will be equal to the difference between the power consumption and the RF power emission. An equivalent but cumbersome way of determining the cooling load of an electronic device is to determine the heat dissipated by each component in the device and then to add them up.

The discovery of *superconductor* materials that can operate at room temperature will cause drastic changes in the design of electronic devices and cooling techniques, since such devices will generate hardly any heat. As a result, more components can be packed into a smaller volume, resulting in enhanced speed and reliability without having to resort to exotic cooling techniques.

Once the cooling load has been determined, it is common practice to inflate this number to leave some *safety margin*, or a “cushion,” and to make some allowance for future growth. It is not uncommon to add another card to an existing system (such as adding a fax/modem card to a PC) to perform an additional task. But we should not go overboard in being conservative, since an *oversized* cooling system will cost more, occupy more space, be heavier, and consume more power. For example, there is no need to install a large and noisy fan in an electronic system just to be “safe” when a smaller one will do. For the same reason, there is no need to use an expensive and failure-prone liquid cooling system when air cooling is adequate. We should always keep in mind that the most desirable form of cooling is *natural convection cooling*, since it does not require any moving parts, and thus it is inherently reliable, quiet, and, best of all, free.

The cooling system of an electronic device must be designed considering the actual *field* operating conditions. In critical applications such as those in the military, the electronic device must undergo extensive testing to satisfy stringent requirements for safety and reliability. Several such codes exist to specify the minimum standards to be met in some applications.

The *duty cycle* is another important consideration in the design and selection of a cooling technique. The actual power dissipated by a device can be

**FIGURE 15–11**

In the absence of other energy interactions, the heat output of an electronic device in steady operation is equal to the power input to the device.

FIGURE 15-12

The temperature change of an electronic component with time as it reaches steady operating temperature after it is turned on.

much less than the rated power, depending on its duty cycle (the fraction of time it is on). A 5-W power transistor, for example, will dissipate an average of 2 W of power if it is active only 40 percent of the time. If the chip of this transistor is 1.5 mm wide, 1.5 mm high, and 0.1 mm thick, then the heat flux on the chip will be  $(2 \text{ W})/(0.15 \text{ cm})^2 = 89 \text{ W/cm}^2$ .

An electronic device that is not running is in *thermal equilibrium* with its surroundings, and thus is at the temperature of the surrounding medium. When the device is turned on, the temperature of the components and thus the device starts rising as a result of absorbing the heat generated. The temperature of the device stabilizes at some point when the heat generated equals the heat removed by the cooling mechanism. At this point, the device is said to have reached *steady operating conditions*. The warming-up period during which the component temperature rises is called the *transient operation stage* (Fig. 15-12).

Another thermal factor that undermines the reliability of electronic devices is the thermal stresses caused by *temperature cycling*. In an experimental study (see Hilbert and Kube, 1969), the failure rate of electronic devices subjected to deliberate temperature cycling of more than  $20^\circ\text{C}$  is observed to increase eightfold. *Shock and vibration* are other common causes of failure for electronic devices and should be considered in the design and manufacturing process for increased reliability.

Most electronic devices operate for long periods of time, and thus their cooling mechanism is designed for steady operation. But electronic devices in some applications never run long enough to reach steady operation. In such cases, it may be sufficient to use a limited cooling technique, such as thermal storage for a short period, or not to use one at all. Transient operation can also be caused by large swings in the environmental conditions. A common cooling technique for transient operation is to use a double-wall construction for the enclosure of the electronic equipment, with the space between the walls filled with a wax with a suitable melting temperature. As the wax melts, it absorbs a large amount of heat and thus delays overheating of the electronic components considerably. During off periods, the wax solidifies by rejecting heat to the environment.

## 15-4 • THERMAL ENVIRONMENT

An important consideration in the selection of a cooling technique is the *environment* in which the electronic equipment is to operate. Simple *ventilation holes* on the case may be all we need for the cooling of low-power-density electronics such as a TV or a DVD player in a room, and a *fan* may be adequate for the safe operation of a home computer (Fig. 15-13). But the thermal control of the electronics of an *aircraft* will challenge thermal designers, since the environmental conditions in this case will swing from one extreme to another in a matter of minutes. The expected *duration of operation* in a hostile environment is also an important consideration in the design process. The thermal design of the electronics for an aircraft that cruises for hours each time it takes off will be quite different than that of a missile that has an operation time of a few minutes.

The thermal environment in *marine applications* is relatively stable, since the ultimate heat sink in this case is water with a temperature range of  $0^\circ\text{C}$  to  $30^\circ\text{C}$ . For *ground applications*, however, the ultimate heat sink is the atmospheric

FIGURE 15-13

Strategically located ventilation holes are adequate to cool low-power electronics such as a TV or DVD player.

air, whose temperature varies from  $-50^{\circ}\text{C}$  at polar regions to  $+50^{\circ}\text{C}$  in desert climates, and whose pressure ranges from about 70 kPa (0.69 atm) at 3000 m elevation to 107 kPa (1.06 atm) at 500 m below sea level. The combined convection and radiation heat transfer coefficient can range from  $10 \text{ W/m}^2 \cdot ^{\circ}\text{C}$  in calm weather to  $80 \text{ W/m}^2 \cdot ^{\circ}\text{C}$  in 100 km/h (62 mph) winds. Also, the surfaces of the devices facing the sun directly can be subjected to solar radiation heat flux of  $1000 \text{ W/m}^2$  on a clear day.

In *airborne applications*, the thermal environment can change from 1 atm and  $35^{\circ}\text{C}$  on the ground to 19 kPa (0.2 atm) and  $-60^{\circ}\text{C}$  at a typical cruising altitude of 12,000 m in minutes (Fig. 15-14). At supersonic velocities, the surface temperature of some part of the aircraft may rise  $200^{\circ}\text{C}$  above the environment temperature.

Electronic devices are rarely exposed to uncontrolled environmental conditions directly because of the wide variations in the environmental variables. Instead, a conditioned fluid such as air, water, or a dielectric fluid is used to serve as a local heat sink and as an intermediary between the electronic equipment and the environment, just like the air-conditioned air in a building providing thermal comfort to the human body. Conditioned air is the preferred cooling medium, since it is benign, readily available, and not prone to leakage. But its use is limited to equipment with low power densities, because of the low thermal conductivity of air. The thermal design of electronic equipment in military applications must comply with strict military standards in order to satisfy the utmost reliability requirements.

FIGURE 15-14

The thermal environment of a spacecraft changes drastically in a short time, and this complicates the thermal control of the electronics.

FIGURE 15-15

The electronics of short-range missiles may not need any cooling because of the short flight time involved.

FIGURE 15-16

The temperature of a gas having a specific heat  $c_p$  flowing at a velocity of  $V$  rises by  $V^2/2c_p$  when it is brought to a complete stop.

## 15-5 • ELECTRONICS COOLING IN DIFFERENT APPLICATIONS

The cooling techniques used in the cooling of electronic equipment vary widely, depending on the particular application. Electronic equipment designed for *airborne applications* such as airplanes, satellites, space vehicles, and missiles offers challenges to designers because it must fit into odd-shaped spaces because of the curved shape of the bodies, yet be able to provide adequate paths for the flow of fluid and heat. Most such electronic equipment are cooled by forced convection using pressurized air bled off a compressor. This compressed air is usually at a high temperature, and thus it is cooled first by expanding it through a turbine. The moisture in the air is also removed before the air is routed to the electronic boxes. But the removal process may not be adequate under rainy conditions. Therefore, electronics in some cases are placed in sealed finned boxes that are externally cooled to eliminate any direct contact with electronic components.

The electronics of short-range *missiles* do not need any cooling because of their short cruising times (Fig. 15-15). The missiles reach their destinations before the electronics reach unsafe temperatures. Long-range missiles such as cruise missiles, however, may have a flight time of several hours. Therefore, they must utilize some form of cooling mechanism. The first thing that comes to mind is to use forced convection with the air that rams the missile by utilizing its large *dynamic pressure*. However, the *dynamic temperature* of air, which is the rise in the temperature of the air as a result of the ramming effect, may be more than  $50^{\circ}\text{C}$  at speeds close to the speed of sound (Fig. 15-16).

For example, at a speed of 320 m/s, the dynamic temperature of air is

$$T_{\text{dynamic}} = \frac{V^2}{2c_p} = \frac{(320 \text{ m/s})^2}{2(1007 \text{ J/kg} \cdot ^\circ\text{C})} \left( \frac{1 \text{ J/kg}}{1 \text{ m}^2/\text{s}^2} \right) = 51^\circ\text{C} \quad (15-2)$$

Therefore, the temperature of air at a velocity of 320 m/s and a temperature of 30°C will rise to 81°C as a result of the conversion of kinetic energy to internal energy. Air at such high temperatures is not suitable for use as a cooling medium. Instead, cruise missiles are often cooled by taking advantage of the cooling capacity of the large quantities of *liquid fuel* they carry. The electronics in this case are cooled by passing the fuel through the cold plate of the electronic enclosure as it flows toward the combustion chamber.

Electronic equipment in *space vehicles* is usually cooled by a liquid circulated through the components, where heat is picked up, and then through a space radiator, where the waste heat is radiated into deep space at about 0 K. Note that radiation is the only heat transfer mechanism for rejecting heat to the vacuum environment of space, and radiation exchange depends strongly on surface properties. Desirable radiation properties on surfaces can be obtained by special coatings and surface treatments. When electronics in sealed boxes are cooled by a liquid flowing through the outer surface of the electronics box, it is important to run a fan in the box to circulate the air, since there are no natural convection currents in space because of the absence of a gravity field.

Electronic equipment in *ships* and *submarines* is usually housed in rugged cabinets to protect it from vibrations and shock during stormy weather. Because of easy access to water, water-cooled heat exchangers are commonly used to cool shipboard electronics. This is usually done by cooling air in a closed- or open-loop air-to-water heat exchanger and forcing the cool air to the electronic cabinet by a fan. When forced-air cooling is used, it is important to establish a flow path for air such that no trapped hot-air pockets will be formed in the cabinets.

*Communication systems* located at remote locations offer challenges to thermal designers because of the extreme conditions under which they operate. These electronic systems operate for long periods of time under adverse conditions such as rain, snow, high winds, solar radiation, high altitude, high humidity, and extremely high or low temperatures. Large communication systems are housed in specially built shelters. Sometimes it is necessary to air-condition these shelters to safely dissipate the large quantities of heat dissipated by the electronics of communication systems.

Electronic components used in high-power *microwave equipment* such as radars generate enormous amounts of heat because of the low conversion efficiency of electrical energy to microwave energy. Klystron tubes of high-power radar systems where radio-frequency energy is generated can yield local heat fluxes as high as 2000 W/cm<sup>2</sup>, which is close to one-third of the heat flux on the sun's surface. The safe and reliable dissipation of these high heat fluxes usually requires the immersion of such equipment in a suitable dielectric fluid that can remove large quantities of heat by boiling.

The manufacturers of electronic devices usually specify the *rate of heat dissipation* and the *maximum allowable component temperature* for reliable operation. These two numbers help us determine the cooling techniques that are suitable for the device under consideration.

The heat fluxes attainable at specified temperature differences are plotted in Fig. 15-17 for some common heat transfer mechanisms. When the power

**FIGURE 15-17**

Heat fluxes that can be attained at specified temperature differences with various heat transfer mechanisms and fluids.

(From Kraus and Bar-Cohen, 1983, p. 22; reproduced with permission.)

rating of a device or component is given, the heat flux is determined by dividing the power rating by the exposed surface area of the device or component. Then suitable heat transfer mechanisms can be determined from Fig. 15-17 from the requirement that the temperature difference between the surface of the device and the surrounding medium not exceed the allowable maximum value. For example, a heat flux of  $0.5 \text{ W/cm}^2$  for an electronic component would result in a temperature difference of about  $500^\circ\text{C}$  between the component surface and the surrounding air if natural convection in air is used. Considering that the maximum allowable temperature difference is typically under  $80^\circ\text{C}$ , the natural convection cooling of this component is out of the question. But forced convection with air is a viable option if using a fan is acceptable. Note that at heat fluxes greater than  $1 \text{ W/cm}^2$ , even forced convection with air will be inadequate, and we must use a sufficiently large heat sink or switch to a different cooling fluid such as water. Forced convection with water can be used effectively for cooling electronic components with high heat fluxes. Also note that dielectric liquids such as fluorochemicals can remove high heat fluxes by immersing the component directly in them.

## 15-6 • CONDUCTION COOLING

Heat is *generated* in electronic components whenever electric current flows through them. The generated heat causes the temperature of the components to rise, and the resulting temperature difference drives the heat away from the components through a path of *least thermal resistance*. The temperature of the components stabilizes when the heat dissipated equals the heat generated. In order to minimize the temperature rise of the components, *effective heat transfer*

**FIGURE 15-18**

The thermal resistance of a medium is proportional to its length in the direction of heat transfer, and inversely proportional to its heat transfer surface area and thermal conductivity.

*paths* must be established between the components and the ultimate heat sink, which is usually the atmospheric air.

The selection of a cooling mechanism for electronic equipment depends on the *magnitude* of the heat generated, *reliability* requirements, *environmental* conditions, and *cost*. For low-cost electronic equipment, inexpensive cooling mechanisms such as natural or forced convection with air as the cooling medium are commonly used. For high-cost, high-performance electronic equipment, however, it is often necessary to resort to expensive and complicated cooling techniques.

Conduction cooling is based on the *diffusion* of heat through a solid, liquid, or gas as a result of molecular interactions in the absence of any bulk fluid motion. Steady *one-dimensional* heat conduction through a plane medium of thickness  $L$ , heat transfer surface area  $A$ , and thermal conductivity  $k$  is given by (Fig. 15-18).

$$\dot{Q} = kA \frac{\Delta T}{L} = \frac{\Delta T}{R} \quad (\text{W}) \quad (15-3)$$

where

$$R = \frac{L}{kA} = \frac{\text{Length}}{\text{Thermal conductivity} \times \text{Heat transfer area}} \quad (15-4)$$

is the *thermal resistance* of the medium and  $\Delta T$  is the temperature difference across the medium. Note that this is analogous to the *electric current* being equal to the potential difference divided by the electrical resistance.

The thermal resistance concept enables us to solve heat transfer problems in an analogous manner to electric circuit problems using the thermal resistance network, as discussed in Chapter 3. When the rate of heat conduction  $\dot{Q}$  is known, the temperature drop along a medium whose thermal resistance is  $R$  is simply determined from

$$\Delta T = \dot{Q}R \quad (\text{°C}) \quad (15-5)$$

Therefore, the greatest temperature drops along the path of heat conduction will occur across portions of the heat flow path with the largest thermal resistances.

## Conduction in Chip Carriers

The conduction analysis of an electronic device starts with the *circuitry* or *junction* of a chip, which is the site of *heat generation*. In order to understand the heat transfer mechanisms at the chip level, consider the DIP (dual in-line package) type chip carrier shown in Fig. 15-19.

The heat generated at the junction spreads throughout the chip and is conducted across the *thickness* of the chip. The spread of heat from the junction to the body of the chip is three-dimensional in nature, but can be approximated as one-dimensional by adding a *constriction thermal resistance* to the thermal resistance network. For a small heat generation area of diameter  $d$  on a considerably larger body, the constriction resistance is given by

$$R_{\text{constriction}} = \frac{1}{\sqrt{\pi dk}} \quad (\text{°C/W}) \quad (15-6)$$

where  $k$  is the thermal conductivity of the larger body.

**FIGURE 15-19**

The schematic for the internal geometry and the cross-sectional view of a DIP (dual in-line package) type electronic device with 14 leads.

The chip is attached to the lead frame with a highly conductive *bonding material* that provides a low-resistance path for heat flow from the chip to the lead frame. There is no metal connection between the *lead frame* and the *leads*, since this would short-circuit the entire chip. Therefore, heat flow from the lead frame to the leads is through the dielectric case material such as *plastic* or *ceramic*. Heat is then transported outside the electronic device through the leads.

When solving a heat transfer problem, it is often necessary to make some simplifying assumptions regarding the *primary* heat flow path and the magnitudes of heat transfer in other directions (Fig. 15-20). In the chip carrier discussed above, for example, heat transfer through the top is disregarded since it is very small because of the large thermal resistance of the stagnant air space between the chip and the lid. Heat transfer from the base of the electronic device is also considered to be negligible because of the low thermal conductivity of the case material and the lack of effective convection on the base surface.

**FIGURE 15-20**

Heat generated at the junction of an electronic device flows through the path of least resistance.

### EXAMPLE 15-3 Analysis of Heat Conduction in a Chip

A chip is dissipating 0.6 W of power in a DIP with 12 pin leads. The materials and the dimensions of various sections of this electronic device are as given in the table below. If the temperature of the leads is 40°C, estimate the temperature at the junction of the chip.

| Section and Material  | Thermal Conductivity, W/m · °C | Thickness, mm | Heat Transfer Surface Area |
|-----------------------|--------------------------------|---------------|----------------------------|
| Junction constriction | —                              | —             | diameter 0.4 mm            |
| Silicon chip          | 120 <sup>†</sup>               | 0.4           | 3 mm × 3 mm                |
| Eutectic bond         | 296                            | 0.03          | 3 mm × 3 mm                |
| Copper lead frame     | 386                            | 0.25          | 3 mm × 3 mm                |
| Plastic separator     | 1                              | 0.2           | 12 × 1 mm × 0.25 mm        |
| Copper leads          | 386                            | 5             | 12 × 1 mm × 0.25 mm        |

<sup>†</sup>The thermal conductivity of silicon varies greatly with temperature from 153.5 W/m · °C at 27°C to 113.7 W/m · °C at 100°C, and the value 120 W/m · °C reflects the anticipation that the temperature of the silicon chip will be close to 100°C.

FIGURE 15-21

Thermal resistance network for the electronic device considered in Example 15-3.

**SOLUTION** The dimensions and power dissipation of a chip are given. The junction temperature of the chip is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through various components is one-dimensional. 3 Heat transfer through the air gap and the lid on top of the chip is negligible because of the very large thermal resistance involved along this path.

**Analysis** The geometry of the device is as shown in Fig. 15-20. We take the primary heat flow path to be the chip, the eutectic bond, the lead frame, the plastic insulator, and the 12 leads. When the constriction resistance between the junction and the chip is considered, the thermal resistance network for this problem becomes as shown in Fig. 15-21.

The various thermal resistances on the path of primary heat flow are determined as follows.

$$R_{\text{constriction}} = \frac{1}{\sqrt{\pi dk}} = \frac{1}{\sqrt{\pi}(0.4 \times 10^{-3} \text{ m})(120 \text{ W/m} \cdot ^\circ\text{C})} = 11.75^\circ\text{C/W}$$

$$R_{\text{chip}} = \left( \frac{L}{kA} \right)_{\text{chip}} = \frac{0.4 \times 10^{-3} \text{ m}}{(120 \text{ W/m} \cdot ^\circ\text{C})(9 \times 10^{-6} \text{ m}^2)} = 0.37^\circ\text{C/W}$$

$$R_{\text{bond}} = \left( \frac{L}{kA} \right)_{\text{bond}} = \frac{0.03 \times 10^{-3} \text{ m}}{(296 \text{ W/m} \cdot ^\circ\text{C})(9 \times 10^{-6} \text{ m}^2)} = 0.01^\circ\text{C/W}$$

$$R_{\text{lead frame}} = \left( \frac{L}{kA} \right)_{\text{lead frame}} = \frac{0.25 \times 10^{-3} \text{ m}}{(386 \text{ W/m} \cdot ^\circ\text{C})(9 \times 10^{-6} \text{ m}^2)} = 0.07^\circ\text{C/W}$$

$$R_{\text{plastic}} = \left( \frac{L}{kA} \right)_{\text{plastic}} = \frac{0.2 \times 10^{-3} \text{ m}}{(1 \text{ W/m} \cdot ^\circ\text{C})(12 \times 0.25 \times 10^{-6} \text{ m}^2)} = 66.67^\circ\text{C/W}$$

$$R_{\text{leads}} = \left( \frac{L}{kA} \right)_{\text{leads}} = \frac{5 \times 10^{-3} \text{ m}}{(386 \text{ W/m} \cdot ^\circ\text{C})(12 \times 0.25 \times 10^{-6} \text{ m}^2)} = 4.32^\circ\text{C/W}$$

Note that for heat transfer purposes, all 12 leads can be considered as a single lead whose cross-sectional area is 12 times as large. The alternative is to find the resistance of a single lead and to calculate the equivalent resistance for 12 such resistances connected in parallel. Both approaches give the same result.

All the resistances determined here are in series. Thus the total thermal resistance between the junction and the leads is determined by simply adding them up:

$$\begin{aligned} R_{\text{total}} &= R_{\text{junction-lead}} = R_{\text{constriction}} + R_{\text{chip}} + R_{\text{bond}} + R_{\text{lead frame}} + R_{\text{plastic}} + R_{\text{leads}} \\ &= (11.75 + 0.37 + 0.01 + 0.07 + 66.67 + 4.32)^\circ\text{C/W} \\ &= 83.19^\circ\text{C/W} \end{aligned}$$

Heat transfer through the chip can be expressed as

$$\dot{Q} = \left( \frac{\Delta T}{R} \right)_{\text{junction-leads}} = \frac{T_{\text{junction}} - T_{\text{leads}}}{R_{\text{junction-leads}}}$$

Solving for  $T_{\text{junction}}$  and substituting the given values, the junction temperature is determined to be

$$T_{\text{junction}} = T_{\text{leads}} + \dot{Q}R_{\text{junction-leads}} = 40^\circ\text{C} + (0.6 \text{ W})(83.19^\circ\text{C/W}) = 89.9^\circ\text{C}$$

Note that the plastic layer between the lead frame and the leads accounts for  $66.67/83.19 = 80$  percent of the total thermal resistance and thus the

80 percent of the temperature drop ( $0.6 \times 66.67 = 40^\circ\text{C}$ ) between the junction and the leads. In other words, the temperature of the junction would be just  $89.9 - 40 = 49.9^\circ\text{C}$  if the thermal resistance of the plastic was eliminated.

**Discussion** The simplified analysis given here points out that any attempt to reduce the thermal resistance in the chip carrier and thus improve the heat flow path should start with the plastic layer. We also notice from the magnitudes of individual resistances that some sections, such as the eutectic bond and the lead frame, have negligible thermal resistances, and any attempt to improve them further will have practically no effect on the junction temperature of the chip.

The analytical determination of the junction-to-case thermal resistance of an electronic device can be rather complicated and can involve considerable uncertainty, as already shown. Therefore, the manufacturers of electronic devices usually determine this value *experimentally* and list it as part of their product description. When the thermal resistance is known, the *temperature difference* between the junction and the outer surface of the device can be determined from

$$\Delta T_{\text{junction-case}} = T_{\text{junction}} - T_{\text{case}} = \dot{Q}R_{\text{junction-case}} \quad (\text{°C}) \quad (15-7)$$

where  $\dot{Q}$  is the power consumed by the device.

The determination of the *actual junction temperature* depends on the ambient temperature  $T_{\text{ambient}}$  as well as the thermal resistance  $R_{\text{case-ambient}}$  between the case and the ambient (Fig. 15-22). The magnitude of this resistance depends on the type of ambient (such as air or water) and the fluid velocity. The two thermal resistances discussed above are in series, and the total resistance between the junction and the ambient is determined by simply adding them up:

$$R_{\text{total}} = R_{\text{junction-ambient}} = R_{\text{junction-case}} + R_{\text{case-ambient}} \quad (\text{°C/W}) \quad (15-8)$$

Many manufacturers of electronic devices go the extra step and list the *total resistance* between the junction and the ambient for various chip configurations and ambient conditions likely to be encountered. Once the total thermal resistance is available, the *junction temperature* corresponding to the specified power consumption (or heat dissipation rate) of  $\dot{Q}$  is determined from

$$T_{\text{junction}} = T_{\text{ambient}} + \dot{Q}R_{\text{junction-ambient}} \quad (\text{°C}) \quad (15-9)$$

A typical chart for the total junction-to-ambient thermal resistance for a single DIP-type electronic device mounted on a circuit board is given in Fig. 15-23 for various air velocities and lead numbers. The values at the intersections of the curves and the vertical axis represent the thermal resistances corresponding to *natural convection* conditions (zero air velocity). Note that the thermal resistance and thus the junction temperature decrease with increasing air velocity and the number of leads extending from the electronic device, as expected.

$$R_{\text{total}} = R_{\text{junction-case}} + R_{\text{case-ambient}}$$

$$T_{\text{junction}} = T_{\text{ambient}} + \dot{Q}R_{\text{total}}$$

**FIGURE 15-22**

The junction temperature of a chip depends on the external case-to-ambient thermal resistance as well as the internal junction-to-case resistance.

**FIGURE 15-23**

Total thermal resistance between the junction of a plastic DIP device mounted on a circuit board and the ambient air as a function of the air velocity and the number of leads  
(Courtesy of Motorola Semiconductor Products, Inc.)

**FIGURE 15-24**

Schematic for Example 15-4.

### **EXAMPLE 15-4 Predicting the Junction Temperature of a Device**

A fan blows air at 30°C at a velocity of 200 m/min over a 1.2-W plastic DIP with 16 leads mounted on a PCB, as shown in Fig. 15-24. Using data from Fig. 15-23, determine the junction temperature of the electronic device. What would the junction temperature be if the fan were to fail?

**SOLUTION** A plastic DIP with 16 leads is cooled by forced air. Using data supplied by the manufacturer, the junction temperature is to be determined.

**Assumptions** Steady operating conditions exist.

**Analysis** The junction-to-ambient thermal resistance of the device with 16 leads corresponding to an air velocity of 200 m/min is determined from Fig. 15-23 to be

$$R_{\text{junction-ambient}} = 55^{\circ}\text{C}/\text{W}$$

Then the junction temperature can be determined from Eq. 15-9 to be

$$T_{\text{junction}} = T_{\text{ambient}} + \dot{Q}R_{\text{junction-ambient}} = 30^{\circ}\text{C} + (1.2 \text{ W})(55^{\circ}\text{C}/\text{W}) = 96^{\circ}\text{C}$$

When the fan fails, the airflow velocity over the device will be zero. The total thermal resistance in this case is determined from the same chart by reading the value at the intersection of the curve and the vertical axis to be

$$R_{\text{junction-ambient}} = 70^{\circ}\text{C}/\text{W}$$

which gives

$$T_{\text{junction}} = T_{\text{ambient}} + \dot{Q}R_{\text{junction-ambient}} = 30^{\circ}\text{C} + (1.2 \text{ W})(70^{\circ}\text{C}/\text{W}) = 114^{\circ}\text{C}$$

**Discussion** Note that the temperature of the junction will rise by 18°C when the fan fails. Of course, this analysis assumes the temperature of the surrounding air still to be 30°C, which may no longer be the case. Any increase in the ambient temperature as a result of inadequate airflow will reflect on the junction temperature, which will seriously jeopardize the safety of the electronic device.

## Conduction in Printed Circuit Boards

Heat-generating electronic devices are commonly mounted on thin rectangular *boards*, usually 10 cm × 15 cm in size, made of electrically insulating materials such as *glass-epoxy laminates*, which are also poor conductors of heat. The resulting printed circuit boards are usually cooled by blowing air or passing a dielectric liquid through them. In such cases, the components on the PCBs are cooled directly, and we are not concerned about heat conduction along the PCBs. But in some critical applications such as those encountered in the military, the PCBs are contained in *sealed enclosures*, and the boards provide the only effective heat path between the components and the heat sink attached to the sealed enclosure. In such cases, heat transfer from the side faces of the PCBs is negligible, and the heat generated in the components must be conducted along the PCB toward its edges, which are clamped to cold plates for removing the heat externally.

Heat transfer along a PCB is complicated in nature because of the multidimensional effects and nonuniform heat generation on the surfaces. We can still obtain sufficiently accurate results by using the thermal resistance network in one or more dimensions.

Copper or aluminum *cladding*, *heat frames*, or *cores* are commonly used to enhance heat conduction along the PCBs. The thickness of the copper cladding on the PCB is usually expressed in terms of *ounces of copper*, which is the thickness of 1-ft<sup>2</sup> copper sheet made of one ounce of copper. An ounce of copper is equivalent to 0.03556-mm (1.4-mil) thickness of a copper layer.

When analyzing heat conduction along a PCB with *copper* (or aluminum) *cladding* on one or both sides, often the question arises whether heat transfer along the epoxy laminate can be ignored relative to that along the copper layer, since the thermal conductivity of copper is about 1500 times that of epoxy. The answer depends on the relative cross-sectional areas of each layer, since heat conduction is proportional to the cross-sectional area as well as the thermal conductivity.

Consider a copper-clad PCB of width  $w$  and length  $L$ , across which the temperature difference is  $\Delta T$ , as shown in Fig. 15–25. Assuming heat conduction is along the length  $L$  only and heat conduction in other dimensions is negligible, the rate of heat conduction along this PCB is the sum of the heat conduction along the *epoxy board* and the *copper* layer and is expressed as

$$\begin{aligned}\dot{Q}_{\text{PCB}} &= \dot{Q}_{\text{epoxy}} + \dot{Q}_{\text{copper}} = \left( kA \frac{\Delta T}{L} \right)_{\text{epoxy}} + \left( kA \frac{\Delta T}{L} \right)_{\text{copper}} \\ &= [(kA)_{\text{epoxy}} + (kA)_{\text{copper}}] \frac{\Delta T}{L} \\ &= [(kt)_{\text{epoxy}} + (kt)_{\text{copper}}] \frac{w\Delta T}{L}\end{aligned}\quad (15-10)$$

where  $t$  denotes the thickness. Therefore, the relative magnitudes of heat conduction along the two layers depend on the relative magnitudes of the thermal conductivity–thickness product  $kt$  of the layer. Therefore, if the  $kt$  product of the copper is 100 times that of epoxy, then neglecting heat conduction along the epoxy board will involve an error of just 1 percent, which is negligible.

**FIGURE 15–25**  
Schematic of a copper-clad epoxy board and heat conduction along it.

We can also define an **effective thermal conductivity** for metal-clad PCBs as

$$k_{\text{eff}} = \frac{(kt)_{\text{epoxy}} + (kt)_{\text{copper}}}{t_{\text{epoxy}} + t_{\text{copper}}} \quad (\text{W/m} \cdot ^{\circ}\text{C}) \quad (15-11)$$

so that the rate of heat conduction along the PCB can be expressed as

$$\dot{Q}_{\text{PCB}} = k_{\text{eff}}(t_{\text{epoxy}} + t_{\text{copper}}) \frac{w\Delta T}{L} = k_{\text{eff}} A_{\text{PCB}} \frac{\Delta T}{L} \quad (\text{W}) \quad (15-12)$$

where  $A_{\text{PCB}} = w(t_{\text{epoxy}} + t_{\text{copper}})$  is the area normal to the direction of heat transfer. When there are holes or discontinuities along the copper cladding, the above analysis needs to be modified to account for their effect.

**FIGURE 15-26**

Schematic for Example 15-5.

### EXAMPLE 15-5 Heat Conduction along a PCB with Copper Cladding

Heat is to be conducted along a PCB with copper cladding on one side. The PCB is 10 cm long and 10 cm wide, and the thickness of the copper and epoxy layers are 0.04 mm and 0.16 mm, respectively, as shown in Fig. 15-26. Disregarding heat transfer from side surfaces, determine the percentages of heat conduction along the copper ( $k = 386 \text{ W/m} \cdot ^{\circ}\text{C}$ ) and epoxy ( $k = 0.26 \text{ W/m} \cdot ^{\circ}\text{C}$ ) layers. Also, determine the effective thermal conductivity of the PCB.

**SOLUTION** A PCB with copper cladding is given. The percentages of heat conduction along the copper and epoxy layers as well as the effective thermal conductivity of the PCB are to be determined.

**Assumptions** 1 Heat conduction along the PCB is one-dimensional since heat transfer from side surfaces is negligible. 2 The thermal properties of epoxy and copper layers are constant.

**Analysis** The length and width of both layers are the same, and so is the temperature difference across each layer. Heat conduction along a layer is proportional to the thermal conductivity–thickness product  $kt$ , which is determined for each layer and the entire PCB to be

$$(kt)_{\text{copper}} = (386 \text{ W/m} \cdot ^{\circ}\text{C})(0.04 \times 10^{-3} \text{ m}) = 15.44 \times 10^{-3} \text{ W}/^{\circ}\text{C}$$

$$(kt)_{\text{epoxy}} = (0.26 \text{ W/m} \cdot ^{\circ}\text{C})(0.16 \times 10^{-3} \text{ m}) = 0.04 \times 10^{-3} \text{ W}/^{\circ}\text{C}$$

$$(kt)_{\text{PCB}} = (kt)_{\text{copper}} + (kt)_{\text{epoxy}} = (15.44 + 0.04) \times 10^{-3} \text{ m} = 15.48 \times 10^{-3} \text{ W}/^{\circ}\text{C}$$

Therefore, heat conduction along the epoxy board will constitute

$$f = \frac{(kt)_{\text{epoxy}}}{(kt)_{\text{PCB}}} = \frac{0.04 \times 10^{-3} \text{ W}/^{\circ}\text{C}}{15.48 \times 10^{-3} \text{ W}/^{\circ}\text{C}} = 0.0026$$

or 0.26 percent of the thermal conduction along the PCB, which is negligible. Therefore, heat conduction along the epoxy layer in this case can be disregarded without any reservations.

The effective thermal conductivity of the board is determined from Eq. 15-11 to be

$$k_{\text{eff}} = \frac{(kt)_{\text{epoxy}} + (kt)_{\text{copper}}}{t_{\text{epoxy}} + t_{\text{copper}}} = \frac{(15.44 + 0.04) \times 10^{-3} \text{ W}/^{\circ}\text{C}}{(0.16 + 0.04) \times 10^{-3} \text{ m}} = 77.4 \text{ W/m} \cdot ^{\circ}\text{C}$$

That is, the entire PCB can be treated as a 0.20-mm-thick single homogeneous layer whose thermal conductivity is 77.4 W/m · °C for heat transfer along its length.

**Discussion** Note that a very thin layer of copper cladding on a PCB improves heat conduction along the PCB drastically, and thus it is commonly used in conduction-cooled electronic devices.

## Heat Frames

In applications where direct cooling of circuit boards by passing air or a dielectric liquid over the electronic components is not allowed, and the junction temperatures are to be maintained relatively low to meet strict safety requirements, a thick *heat frame* is used instead of a thin layer of copper cladding. This is especially the case for multilayer PCBs that are packed with high-power output chips.

The schematic of a PCB that is conduction-cooled via a heat frame is shown in Fig. 15–27. Heat generated in the chips is conducted through the circuit board, through the epoxy adhesive, to the center of the heat frame, along the heat frame, and to a heat sink or cold plate, where heat is externally removed.

The heat frame provides a low-resistance path for the flow of heat from the circuit board to the heat sink. The thicker the heat frame, the lower the thermal resistance, and thus the smaller the temperature difference between the center and the ends of the heat frame. When the heat load is evenly distributed on the PCB, there will be thermal symmetry about the centerline, and the temperature distribution along the heat frame and the PCB will be *parabolic* in nature, with the chips in the middle of the PCB (farthest away from the edges) operating at the highest temperatures and the chips near the edges operating at the lowest temperatures. Also, when the PCB is cooled from two edges, heat generated in the left half of the PCB will flow toward the left edge and heat generated in the right half will flow toward the right edge of the heat frame. But when the PCB is cooled from all four edges, the heat transfer along the heat frame as well as the resistance network will be two-dimensional.

When a heat frame is used, heat conduction in the epoxy layer of the PCB is through its *thickness* instead of along its length. The epoxy layer in this case offers a much smaller resistance to heat flow because of the short distance involved. This resistance can be made even smaller by drilling holes in the epoxy and filling them with copper, as shown in Fig. 15–28. These copper fillings are usually 1 mm in diameter and their centers are a few millimeters apart. Such highly conductive fillings provide easy passageways for heat from one side of the PCB to the other and result in considerable reduction in the thermal resistance of the board along its thickness, as shown in Examples 15–6, 15–7, and 15–8.

### EXAMPLE 15–6 Thermal Resistance of an Epoxy Glass Board

Consider a 10-cm × 15-cm glass–epoxy laminate ( $k = 0.26 \text{ W/m} \cdot \text{°C}$ ) whose thickness is 0.8 mm, as shown in Fig. 15–29. Determine the thermal resistance of this epoxy layer for heat flow (a) along the 15-cm-long side and (b) across its thickness.

FIGURE 15–27

Conduction cooling of a printed circuit board with a heat frame, and the typical temperature distribution along the frame.

FIGURE 15–28

Planting the epoxy board with copper fillings decreases the thermal resistance across its thickness considerably.

FIGURE 15–29

Schematic for Example 15–6.

**SOLUTION** The dimensions of an epoxy–glass laminate are given. The thermal resistances for heat flow along the layers and across the thickness are to be determined.

**Assumptions** 1 Heat conduction in the laminate is one-dimensional in either case. 2 Thermal properties of the laminate are constant.

**Analysis** The thermal resistance of a plane parallel medium in the direction of heat conduction is given by

$$R = \frac{L}{kA}$$

where  $L$  is the length in the direction of heat flow,  $k$  is the thermal conductivity, and  $A$  is the area normal to the direction of heat conduction. Substituting the given values, the thermal resistances of the board for both cases are determined to be

$$(a) R_{\text{along length}} = \left( \frac{L}{kA} \right)_{\text{along length}} = \frac{0.15 \text{ m}}{(0.26 \text{ W/m} \cdot ^\circ\text{C})(0.1 \text{ m})(0.8 \times 10^{-3} \text{ m})} = 7212^\circ\text{C/W}$$

$$(b) R_{\text{across thickness}} = \left( \frac{L}{kA} \right)_{\text{across thickness}} = \frac{0.8 \times 10^{-3} \text{ m}}{(0.26 \text{ W/m} \cdot ^\circ\text{C})(0.1 \text{ m})(0.15 \text{ m})} = 0.21^\circ\text{C/W}$$

**Discussion** Note that heat conduction at a rate of 1 W along this PCB would cause a temperature difference of  $7212^\circ\text{C}$  across a length of 15 cm. But the same rate of heat conduction would cause a temperature difference of only  $0.21^\circ\text{C}$  across the thickness of the epoxy board.

FIGURE 15-30

Schematic for Example 15-7.

### EXAMPLE 15-7 Planting Cylindrical Copper Fillings in an Epoxy Board

Reconsider the  $10\text{-cm} \times 15\text{-cm}$  glass–epoxy laminate ( $k = 0.26 \text{ W/m} \cdot ^\circ\text{C}$ ) of thickness 0.8 mm discussed in Example 15-6. In order to reduce the thermal resistance across its thickness from the current value of  $0.21^\circ\text{C/W}$ , cylindrical copper fillings ( $k = 386 \text{ W/m} \cdot ^\circ\text{C}$ ) of 1-mm diameter are to be planted throughout the board with a center-to-center distance of 2.5 mm, as shown in Fig. 15-30. Determine the new value of the thermal resistance of the epoxy board for heat conduction across its thickness as a result of this modification.

**SOLUTION** Cylindrical copper fillings are planted throughout an epoxy glass board. The thermal resistance of the board across its thickness is to be determined.

**Assumptions** 1 Heat conduction along the board is one-dimensional. 2 Thermal properties of the board are constant.

**Analysis** Heat flow through the thickness of the board in this case will take place partly through the copper fillings and partly through the epoxy in parallel paths. The thickness of both materials is the same and is given to be 0.8 mm.

But we also need to know the surface area of each material before we can determine the thermal resistances.

It is stated that the distance between the centers of the copper fillings is 2.5 mm. That is, there is only one 1-mm-diameter copper filling in every 2.5-mm  $\times$  2.5-mm square section of the board. The number of such squares and thus the number of copper fillings on the board are

$$n = \frac{\text{Area of the board}}{\text{Area of one square}} = \frac{(100 \text{ mm})(150 \text{ mm})}{(2.5 \text{ mm})(2.5 \text{ mm})} = 2400$$

Then the surface areas of the copper fillings and the remaining epoxy layer become

$$A_{\text{copper}} = n \frac{\pi D^2}{4} = (2400) \frac{\pi (1 \times 10^{-3} \text{ m})^2}{4} = 0.001885 \text{ m}^2$$

$$A_{\text{total}} = (\text{Length})(\text{Width}) = (0.1 \text{ m})(0.15 \text{ m}) = 0.015 \text{ m}^2$$

$$A_{\text{epoxy}} = A_{\text{total}} - A_{\text{copper}} = (0.015 - 0.001885) \text{ m}^2 = 0.013115 \text{ m}^2$$

The thermal resistance of each material is

$$R_{\text{copper}} = \left( \frac{L}{kA} \right)_{\text{copper}} = \frac{0.8 \times 10^{-3} \text{ m}}{(386 \text{ W/m} \cdot ^\circ\text{C})(0.001885 \text{ m}^2)} = 0.0011^\circ\text{C/W}$$

$$R_{\text{epoxy}} = \left( \frac{L}{kA} \right)_{\text{epoxy}} = \frac{0.8 \times 10^{-3} \text{ m}}{(0.26 \text{ W/m} \cdot ^\circ\text{C})(0.013115 \text{ m}^2)} = 0.2346^\circ\text{C/W}$$

Noting that these two resistances are in parallel, the equivalent thermal resistance of the entire board is determined from

$$\frac{1}{R_{\text{board}}} = \frac{1}{R_{\text{copper}}} + \frac{1}{R_{\text{epoxy}}} = \frac{1}{0.0011^\circ\text{C/W}} + \frac{1}{0.2346^\circ\text{C/W}}$$

which gives

$$R_{\text{board}} = 0.00109^\circ\text{C/W}$$

**Discussion** Note that the thermal resistance of the epoxy board has dropped from 0.21°C/W by a factor of almost 200 to just 0.00109°C/W as a result of implanting 1-mm-diameter copper fillings into it. Therefore, implanting copper pins into the epoxy laminate has virtually eliminated the thermal resistance of the epoxy across its thickness.

### EXAMPLE 15-8 Conduction Cooling of PCBs by a Heat Frame

A 10-cm  $\times$  12-cm circuit board dissipating 24 W of heat is to be conduction-cooled by a 1.2-mm-thick copper heat frame ( $k = 386 \text{ W/m} \cdot ^\circ\text{C}$ ) 10 cm  $\times$  14 cm in size. The epoxy laminate ( $k = 0.26 \text{ W/m} \cdot ^\circ\text{C}$ ) has a thickness of 0.8 mm and is attached to the heat frame with conductive epoxy adhesive ( $k = 1.8 \text{ W/m} \cdot ^\circ\text{C}$ ) of 0.13-mm thickness, as shown in Fig. 15-31. The PCB is attached to a heat sink by clamping a 5-mm-wide portion of the edge to the heat sink from both ends. The temperature of the heat frame at this point is 20°C. Heat is uniformly generated on the PCB at a rate of 2 W per 1-cm  $\times$  10-cm strip. Considering only one-half of the PCB board because of symmetry, determine the

FIGURE 15-31

The schematic and thermal resistance network for Example 15-8.

maximum temperature on the PCB and the temperature distribution along the heat frame.

**SOLUTION** A circuit board with uniform heat generation is to be conduction-cooled by a copper heat frame. Temperature distribution along the heat frame and the maximum temperature in the PCB are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Thermal properties are constant. 3 There is no direct heat dissipation from the surface of the PCB, and thus all the heat generated is conducted by the heat frame to the heat sink.

**Analysis** The PCB under consideration possesses thermal symmetry about the centerline. Therefore, the heat generated on the left half of the PCB is conducted to the left heat sink, and the heat generated on the right half is conducted to the right heat sink. Thus we need to consider only half of the board in the analysis.

The maximum temperature will occur at a location furthest away from the heat sinks, which is the symmetry line. Therefore, the temperature of the electronic components located at the center of the PCB will be the highest, and their reliability will be the lowest.

Heat generated in the components on each strip is conducted through the epoxy layer underneath. Heat is then conducted across the epoxy adhesive and to the middle of the copper heat frame. Finally, heat is conducted along the heat frame to the heat sink.

The thermal resistance network associated with heat flow in the right half of the PCB is also shown in Fig. 15-31. Note that all vertical resistances are identical and are equal to the sum of the three resistances in series. Also note that heat conduction toward the heat sink is assumed to be predominantly along the heat frame, and conduction along the epoxy adhesive is considered to be negligible. This assumption is quite reasonable, since the conductivity-thickness product of the heat frame is much larger than those of the other two layers.

The properties and dimensions of various sections of the PCB are summarized in this table.

| Section and Material                                | Thermal Conductivity, W/m · °C | Thickness, mm | Heat Transfer Surface Area |
|---|--------------------------------|---------------|----------------------------|
| Epoxy board   | 0.26                           | 0.8           | 10 mm × 100 mm             |
| Epoxy adhesive                                      | 1.8                            | 0.13          | 10 mm × 100 mm             |
| Copper heat frame, $\perp$<br>(normal to frame)     | 386                            | 0.6           | 10 mm × 100 mm             |
| Copper heat frame, $\parallel$<br>(along the frame) | 386                            | 10            | 1.2 mm × 100 mm            |

Using the values in the table, the various thermal resistances are determined to be

$$R_{\text{epoxy}} = \left( \frac{L}{kA} \right)_{\text{epoxy}} = \frac{0.8 \times 10^{-3} \text{ m}}{(0.26 \text{ W/m} \cdot \text{°C})(0.01 \text{ m} \times 0.1 \text{ m})} = 3.077 \text{ °C/W}$$

$$R_{\text{adhesive}} = \left( \frac{L}{kA} \right)_{\text{adhesive}} = \frac{0.13 \times 10^{-3} \text{ m}}{(1.8 \text{ W/m} \cdot \text{°C})(0.01 \text{ m} \times 0.1 \text{ m})} = 0.072 \text{ °C/W}$$

$$R_{\text{copper}, \perp} = \left( \frac{L}{kA} \right)_{\text{copper}, \perp} = \frac{0.6 \times 10^{-3} \text{ m}}{(386 \text{ W/m} \cdot \text{°C})(0.01 \text{ m} \times 0.1 \text{ m})} = 0.002 \text{ °C/W}$$

$$\begin{aligned} R_{\text{frame}} &= R_{\text{copper}, \parallel} = \left( \frac{L}{kA} \right)_{\text{copper}, \parallel} = \frac{0.01 \text{ m}}{(386 \text{ W/m} \cdot \text{°C})(0.0012 \text{ m} \times 0.1 \text{ m})} \\ &= 0.216 \text{ °C/W} \end{aligned}$$

The combined resistance between the electronic components on each strip and the heat frame can be determined, by adding the three resistances in series, to be

$$\begin{aligned} R_{\text{vertical}} &= R_{\text{epoxy}} + R_{\text{adhesive}} + R_{\text{copper}, \perp} \\ &= (3.077 + 0.072 + 0.002) \text{ °C/W} \\ &= 3.151 \text{ °C/W} \end{aligned}$$

The various temperatures along the heat frame can be determined from the relation

$$\Delta T = T_{\text{high}} - T_{\text{low}} = \dot{Q}R$$

where  $R$  is the thermal resistance between two specified points,  $\dot{Q}$  is the heat transfer rate through that resistance, and  $\Delta T$  is the temperature difference across that resistance.

The temperature at the location where the heat frame is clamped to the heat sink is given as  $T_0 = 20^\circ\text{C}$ . Noting that the entire 12 W of heat generated on the right half of the PCB must pass through the last thermal resistance adjacent to the heat sink, the temperature  $T_1$  can be determined from

$$T_1 = T_0 + \dot{Q}_{1-0} R_{1-0} = 20^\circ\text{C} + (12 \text{ W})(0.216 \text{ °C/W}) = \mathbf{22.59^\circ\text{C}}$$

Following the same line of reasoning, the temperatures at specified locations along the heat frame are determined to be

$$T_2 = T_1 + \dot{Q}_{2-1} R_{2-1} = 22.59^\circ\text{C} + (10 \text{ W})(0.216 \text{ °C/W}) = \mathbf{24.75^\circ\text{C}}$$

$$T_3 = T_2 + \dot{Q}_{3-2} R_{3-2} = 24.75^\circ\text{C} + (8 \text{ W})(0.216 \text{ °C/W}) = \mathbf{26.48^\circ\text{C}}$$

$$T_4 = T_3 + \dot{Q}_{4-3} R_{4-3} = 26.48^\circ\text{C} + (6 \text{ W})(0.216 \text{ °C/W}) = \mathbf{27.78^\circ\text{C}}$$

$$T_5 = T_4 + \dot{Q}_{5-4} R_{5-4} = 27.78^\circ\text{C} + (4 \text{ W})(0.216 \text{ °C/W}) = \mathbf{28.64^\circ\text{C}}$$

$$T_6 = T_5 + \dot{Q}_{6-5} R_{6-5} = 28.64^\circ\text{C} + (2 \text{ W})(0.216 \text{ °C/W}) = \mathbf{29.07^\circ\text{C}}$$

Finally,  $T_7$ , which is the maximum temperature on the PCB, is determined from

$$T_7 = T_6 + \dot{Q}_{\text{vertical}} R_{\text{vertical}} = 29.07^\circ\text{C} + (2 \text{ W})(3.151^\circ\text{C}/\text{W}) = \mathbf{35.37^\circ\text{C}}$$

**Discussion** The maximum temperature difference between the PCB and the heat sink is only  $15.37^\circ\text{C}$ , which is very impressive considering that the PCB has no direct contact with the cooling medium. The junction temperatures in this case can be determined by calculating the temperature difference between the junction and the leads of the chip carrier at the point of contact to the PCB and adding  $35.37^\circ\text{C}$  to it. The maximum temperature rise of  $15.37^\circ\text{C}$  can be reduced, if necessary, by using a thicker heat frame.

**FIGURE 15-32**

A two-sided printed circuit board with a metal core for conduction cooling.

Conduction cooling can also be used when electronic components are mounted on *both sides* of the PCB by using a copper or aluminum core plate in the middle of the PCB, as shown in Fig. 15–32. The heat load in this case will be twice that of a PCB that has components on one side only. Again, heat generated in the components will be conducted through the thickness of the epoxy layer to the *metal core*, which serves as a *channel* for effective heat removal. The thickness of the core is selected such that the maximum component temperatures remain below specified values to meet a prescribed reliability criterion.

The thermal expansion coefficients of aluminum and copper are about twice as large as that of the glass–epoxy. This large difference in *thermal expansion coefficients* can cause *warping* on the PCBs if the epoxy and the metal are not bonded properly. One way of avoiding warping is to use PCBs with components on both sides, as discussed. Extreme care should be exercised during the bonding and curing process when components are mounted on only one side of the PCB.

## The Thermal Conduction Module (TCM)

The heat flux for logic chips has been increasing steadily as a result of the increasing circuit density in the chips. For example, the peak flux at the chip level has increased from  $2 \text{ W/cm}^2$  on IBM System 370 to  $20 \text{ W/cm}^2$  on IBM System 3081, which was introduced in the early 1980s. The conventional forced-air cooling technique used in earlier machines was inadequate for removing such high heat fluxes, and it was necessary to develop a new and more effective cooling technique. The result was the **thermal conduction** module, shown in Fig. 15–33. The TCM was different from previous chip packaging designs in that it incorporated both electrical and thermal considerations in early stages of chip design. Previously, a chip would be designed primarily by electrical designers, and the thermal designer would be told to come up with a cooling scheme for the chip. That approach resulted in unnecessarily high junction temperatures, and reduced reliability, since the thermal designer had no direct access to the chip. The TCM reflects a new philosophy in electronic packaging in that the thermal and electrical aspects are given equal treatment in the design process, and a successful thermal design starts at the chip level.

**FIGURE 15-33**  
Cutaway view of the thermal conduction module (TCM), and the thermal resistance network between a single chip and the cooling fluid.  
(Courtesy of IBM Corporation.)

In the TCM, one side of the chip is reserved for electrical connections and the other side for heat rejection. The chip is cooled by direct contact to the cooling system to minimize the junction-to-case thermal resistance.

The TCM houses 100 to 118 logic chips, which are bonded to a multilayer ceramic substrate 90 mm × 90 mm in size with solder balls, which also provide the electrical connections between the chips and the substrate. Each chip dissipates about 4 W of power. The heat flow path from the chip to the metal casing is provided by a *piston*, which is pressed against the back surface of the chip by a spring. The tip of the piston is slightly curved to ensure good thermal contact even when the chip is tilted or misaligned.

Heat conduction between the chip and the piston occurs primarily through the gas space between the chip and the piston because of the limited contact area between them. To maximize heat conduction through the gas, the air in the TCM cavity is evacuated and is replaced by helium gas, whose thermal conductivity is about six times that of air. Heat is then conducted through the piston, across the surrounding helium gas layer, through the module housing, and finally to the cooling water circulating through the cold plate attached to the top surface of the TCM.

The total *internal thermal resistance*  $R_{int}$  of the TCM is about 8°C/W, which is rather impressive. This means that the temperature difference between the chip surface and the outer surface of the housing of the module will be only 24°C for a 3-W chip. The *external thermal resistance*  $R_{ext}$  between the housing of the module and the cooling fluid is usually comparable in magnitude to  $R_{int}$ . Also, the thermal resistance between the junction and the surface of the chip can be taken to be 1°C/W.

The compact design of the TCM significantly reduces the *distance* between the chips, and thus the signal transmission time between the chips. This, in turn, increases the *operating speed* of the electronic device.

### EXAMPLE 15-9 Cooling of Chips by the Thermal Conduction Module

Consider a thermal conduction module with 100 chips, each dissipating 3 W of power. The module is cooled by water at 25°C flowing through the cold plate on top of the module. The thermal resistances in the path of heat flow are  $R_{\text{chip}} = 1^{\circ}\text{C}/\text{W}$  between the junction and the surface of the chip,  $R_{\text{int}} = 8^{\circ}\text{C}/\text{W}$  between the surface of the chip and the outer surface of the thermal conduction module, and  $R_{\text{ext}} = 6^{\circ}\text{C}/\text{W}$  between the outer surface of the module and the cooling water. Determine the junction temperature of the chip.

**SOLUTION** A thermal conduction module TCM with 100 chips is cooled by water. The junction temperature of the chip is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through various components is one-dimensional.

**Analysis** Because of symmetry, we will consider only one of the chips in our analysis. The thermal resistance network for heat flow is given in Fig. 15-34. Noting that all resistances are in series, the total thermal resistance between the junction and the cooling water is

$$R_{\text{total}} = R_{\text{junction-water}} = R_{\text{chip}} + R_{\text{int}} + R_{\text{ext}} = (1 + 8 + 6)^{\circ}\text{C}/\text{W} = 15^{\circ}\text{C}/\text{W}$$

Noting that the total power dissipated by the chip is 3 W and the water temperature is 25°C, the junction temperature of the chip in steady operation can be determined from

$$\dot{Q} = \left( \frac{\Delta T}{R} \right)_{\text{junction-water}} = \frac{T_{\text{junction}} - T_{\text{water}}}{R_{\text{junction-water}}}$$

Solving for  $T_{\text{junction}}$  and substituting the specified values gives

$$T_{\text{junction}} = T_{\text{water}} + \dot{Q}R_{\text{junction-water}} = 25^{\circ}\text{C} + (3 \text{ W})(15^{\circ}\text{C}/\text{W}) = 70^{\circ}\text{C}$$

Therefore, the circuits of the chip will operate at about 70°C, which is considered to be a safe operating temperature for silicon chips.

FIGURE 15-34

Thermal resistance network for Example 15-9.

Cold plates are usually made of metal plates with fluid channels running through them, or copper tubes attached to them by brazing. Heat transferred to the cold plate is conducted to the tubes, and from the tubes to the fluid flowing through them. The heat carried away by the fluid is finally dissipated to the ambient in a heat exchanger.

## 15-7 • AIR COOLING: NATURAL CONVECTION AND RADIATION

Low-power electronic systems are conveniently cooled by *natural convection* and *radiation*. Natural convection cooling is very desirable, since it does not involve any fans that may break down.

Natural convection is based on the *fluid motion* caused by the density differences in a fluid due to a temperature difference. A fluid expands when heated and becomes less dense. In a gravitational field, this lighter fluid rises and initiates a motion in the fluid called *natural convection currents* (Fig. 15–35). Natural convection cooling is most effective when the path of the fluid is relatively free of obstacles, which tend to slow down the fluid, and is least effective when the fluid has to pass through narrow flow passages and over many obstacles.

The magnitude of the natural convection heat transfer between a surface and a fluid is directly related to the *flow rate* of the fluid. The higher the flow rate, the higher the heat transfer rate. In natural convection, no blowers are used and therefore the flow rate cannot be controlled externally. The flow rate in this case is established by the dynamic balance of *buoyancy* and *friction*. The *larger* the temperature difference between the fluid adjacent to a hot surface and the fluid away from it, the *larger* the buoyancy force, and the *stronger* the natural convection currents, and thus the *higher* the heat transfer rate. Also, whenever two bodies in contact move relative to each other, a *friction force* develops at the contact surface in the direction opposite to that of the motion. This opposing force slows down the fluid, and thus reduces the flow rate of the fluid. Under steady conditions, the airflow rate driven by buoyancy is established at the point where these two effects *balance* each other. The friction force increases as more and more solid surfaces are introduced, seriously disrupting the fluid flow and heat transfer.

Electronic components or PCBs placed in *enclosures* such as a TV or DVD player are cooled by natural convection by providing a sufficient number of *vents* on the case to enable the cool air to enter and the heated air to leave the case freely, as shown in Fig. 15–36. From the heat transfer point of view, the vents should be as large as possible to minimize the flow resistance and should be located at the bottom of the case for air entering and at the top for air leaving. But equipment and human safety requirements dictate that the vents should be quite narrow to discourage unintended entry into the box. Also, concern about human habits such as putting a cup of coffee on the closest flat surface make it very risky to place vents on the top surface. The narrow clearance allowed under the case also offers resistance to airflow. Therefore, vents on the enclosures of natural convection-cooled electronic equipment are usually placed at the *lower section* of the side or back surfaces for air inlet and at the *upper section* of those surfaces for air exit.

The heat transfer from a surface at temperature  $T_s$  to a fluid at temperature  $T_{\text{fluid}}$  by convection is expressed as

$$\dot{Q}_{\text{conv}} = h_{\text{conv}} A_s \Delta T = h_{\text{conv}} A_s (T_s - T_{\text{fluid}}) \quad (\text{W}) \quad (15-13)$$

where  $h_{\text{conv}}$  is the convection heat transfer coefficient and  $A_s$  is the heat transfer surface area. The value of  $h_{\text{conv}}$  depends on the geometry of the surface and the type of fluid flow, among other things.

Natural convection currents start out as *laminar* (smooth and orderly) and turn *turbulent* when the dimension of the body and the temperature difference between the hot surface and the fluid are large. For air, the flow remains laminar when the temperature differences involved are less than 100°C and the characteristic length of the body is less than 0.5 m, which is almost always the

FIGURE 15–35

Natural convection currents around a hot object in air.

FIGURE 15–36

Natural convection cooling of electronic components in an enclosure with air vents.

case in electronic equipment. Therefore, the airflow in the analysis of electronic equipment can be assumed to be laminar.

The natural convection heat transfer coefficient for laminar flow of *air* at atmospheric pressure is given by a simplified relation of the form

$$h_{\text{conv}} = K \left( \frac{\Delta T}{L_c} \right)^{0.25} \quad (\text{W/m}^2 \cdot ^\circ\text{C}) \quad (15-14)$$

where  $\Delta T = T_s - T_{\text{fluid}}$  is the temperature difference between the surface and the fluid,  $L_c$  is the characteristic length (the length of the body along the heat flow path), and  $K$  is a constant whose value depends on the *geometry* and *orientation* of the body.

The heat transfer coefficient relations are given in Table 15-1 for some common geometries encountered in electronic equipment in both SI and English unit systems. Once  $h_{\text{conv}}$  has been determined from one of these relations, the rate of heat transfer can be determined from Eq. 15-13. The relations in Table 15-1 can also be used at pressures other than 1 atm by multiplying them by  $\sqrt{P}$ , where  $P$  is the *air pressure* in *atm* (1 atm = 101.325 kPa = 14.696 psia). That is,

$$h_{\text{conv}, P \text{ atm}} = h_{\text{conv}, 1 \text{ atm}} \sqrt{P} \quad (\text{W/m}^2 \cdot ^\circ\text{C}) \quad (15-15)$$

When hot surfaces are surrounded by cooler surfaces such as the walls and ceilings of a room or just the sky, the surfaces are also cooled by *radiation*, as shown in Fig. 15-37. The magnitude of radiation heat transfer, in general, is comparable to the magnitude of natural convection heat transfer. This is especially the case for surfaces whose emissivity is close to *unity*, such as plastics and painted surfaces (regardless of color). Radiation heat transfer is negligible for *polished metals* because of their very low emissivity and for bodies surrounded by surfaces at about the same temperature.

Radiation heat transfer between a surface at temperature  $T_s$  completely surrounded by a much larger surface at temperature  $T_{\text{surr}}$  can be expressed as

$$\dot{Q}_{\text{rad}} = \varepsilon A_s \sigma (T_s^4 - T_{\text{surr}}^4) \quad (\text{W}) \quad (15-16)$$

where  $\varepsilon$  is the emissivity of the surface,  $A_s$  is the heat transfer surface area, and  $\sigma$  is the Stefan–Boltzmann constant, whose value is  $\sigma = 5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4 = 0.1714 \times 10^{-8} \text{ Btu/h} \cdot \text{ft}^2 \cdot \text{R}^4$ . Here, both temperatures must be expressed in K or R. Also, if the hot surface analyzed has only a partial view of the surrounding cooler surface at  $T_{\text{surr}}$ , the result obtained from Eq. 15-16 must be multiplied by a *view factor*, which is the fraction of the view of the hot surface blocked by the cooler surface. The value of the view factor ranges from 0 (the hot surface has no direct view of the cooler surface) to 1 (the hot surface is completely surrounded by the cooler surface). In preliminary analysis, the surface is usually assumed to be completely surrounded by a single hypothetical surface whose temperature is the equivalent average temperature of the surrounding surfaces.

Arrays of low-power PCBs are often cooled by natural convection by mounting them within a chassis with adequate openings at the top and at the bottom to facilitate airflow, as shown in Fig. 15-38. The air between the PCBs rises when heated by the electronic components and is replaced by the cooler air entering from below. This initiates the natural convection flow through the

**FIGURE 15-37**

Simultaneous natural convection heat transfer to air and radiation heat transfer to the surrounding surfaces from a hot electronic component mounted on the wall of an enclosure.

**FIGURE 15-38**

A chassis with an array of vertically oriented PCBs cooled by natural convection.

FIGURE 15-39

The PCBs in a chassis must be oriented vertically and spaced adequately to maximize heat transfer by natural convection.

parallel flow passages formed by the PCBs. The PCBs must be placed *vertically* to take advantage of natural convection currents and to minimize trapped air pockets (Fig. 15-39). Placing the PCBs too far from each other wastes valuable cabinet space, and placing them too close tends to “choke” the flow because of the increased resistance. Therefore, there should be an optimum spacing between the PCBs. It turns out that a distance of about 2 cm between the PCBs provides adequate air flow for effective natural convection cooling.

In the heat transfer analysis of PCBs, *radiation* heat transfer is *disregarded*, since the view of the components is largely *blocked* by other heat-generating components. As a result, hot components face other hot surfaces instead of a cooler surface. The exceptions are the two PCBs at the ends of the chassis that view the cooler side surfaces. Therefore, it is wise to mount any high-power components on the PCBs facing the walls of the chassis to take advantage of the additional cooling provided by radiation.

Circuit boards that dissipate up to about 5 W of power (or that have a power density of about  $0.02 \text{ W/cm}^2$ ) can be cooled effectively by natural convection. Heat transfer from PCBs can be analyzed by treating them as rectangular plates with uniformly distributed heat sources on one side, and insulated on the other side, since heat transfer from the back surfaces of the PCBs is usually small. For PCBs with electronic components mounted on both sides, the rate of heat transfer and the heat transfer surface area will be twice as large.

It should be remembered that natural convection currents occur only in *gravitational fields*. Therefore, there can be no heat transfer in space by natural convection. This will also be the case when the air passageways are blocked and hot air cannot rise. In such cases, there will be no air motion, and heat transfer through the air will be by convection.

The heat transfer from hot surfaces by natural convection and radiation can be enhanced by attaching fins to the surfaces. The heat transfer in this case can best be determined by using the data supplied by the manufacturers, as discussed in Chapter 3, especially for complex geometries.

Schematic for Example 15-10.

### EXAMPLE 15-10 Cooling of a Sealed Electronic Box

Consider a sealed electronic box whose dimensions are  $15 \text{ cm} \times 30 \text{ cm} \times 40 \text{ cm}$  placed on top of a stand in a room at  $35^\circ\text{C}$ , as shown in Fig. 15-40. The box is painted, and the emissivity of its outer surface is 0.85. If the electronic components in the box dissipate 75 W of power and the outer surface temperature of the box is not to exceed  $65^\circ\text{C}$ , determine if this box can be cooled by natural convection and radiation alone. Assume the heat transfer from the bottom surface of the box to the stand to be negligible.

**SOLUTION** The surface temperature of a sealed electronic box placed on top of a stand is not to exceed  $65^\circ\text{C}$ . It is to be determined if this box can be cooled by natural convection and radiation alone.

**Assumptions** 1 The box is located at sea level so that the local atmospheric pressure is 1 atm. 2 The temperature of the surrounding surfaces is the same as the air temperature in the room.

**Analysis** The sealed electronic box will lose heat from the top and the side surfaces by natural convection and radiation. All four side surfaces of the box

can be treated as 0.15-m-high vertical surfaces. Then the natural convection heat transfer from these surfaces is determined to be

$$\begin{aligned}L &= 0.15 \text{ m} \\A_{\text{side}} &= (2 \times 0.4 \text{ m} + 2 \times 0.3 \text{ m})(0.15 \text{ m}) = 0.21 \text{ m}^2 \\h_{\text{conv, side}} &= \left(\frac{\Delta T}{L}\right)^{0.25} = 1.42 \left(\frac{65 - 35}{0.15}\right)^{0.25} = 5.34 \text{ W/m}^2 \cdot ^\circ\text{C} \\\dot{Q}_{\text{conv, side}} &= h_{\text{conv, side}} A_{\text{side}} (T_s - T_{\text{fluid}}) \\&= (5.34 \text{ W/m}^2 \cdot ^\circ\text{C})(0.21 \text{ m}^2)(65 - 35)^\circ\text{C} \\&= 33.6 \text{ W}\end{aligned}$$

Similarly, heat transfer from the horizontal top surface by natural convection is determined to be

$$\begin{aligned}L_c &= \frac{4A_{\text{top}}}{p} = \frac{4(0.3 \text{ m})(0.4 \text{ m})}{2(0.3 + 0.4) \text{ m}} = 0.34 \text{ m} \\A_{\text{top}} &= (0.3 \text{ m})(0.4 \text{ m}) = 0.12 \text{ m}^2 \\h_{\text{conv, top}} &= 1.32 \left(\frac{\Delta T}{L_c}\right)^{0.25} = 1.32 \left(\frac{65 - 35}{0.34}\right)^{0.25} = 4.05 \text{ W/m}^2 \cdot ^\circ\text{C} \\\dot{Q}_{\text{conv, top}} &= h_{\text{conv, top}} A_{\text{top}} (T_s - T_{\text{fluid}}) \\&= (4.05 \text{ W/m}^2 \cdot ^\circ\text{C})(0.12 \text{ m}^2)(65 - 35)^\circ\text{C} \\&= 14.6 \text{ W}\end{aligned}$$

Therefore, the natural convection heat transfer from the entire box is

$$\dot{Q}_{\text{conv}} = \dot{Q}_{\text{conv, side}} + \dot{Q}_{\text{conv, top}} = 33.6 + 14.6 = 48.2 \text{ W}$$

The box is completely surrounded by the surfaces of the room, and it is stated that the temperature of the surfaces facing the box is equal to the air temperature in the room. Then the rate of heat transfer from the box by radiation can be determined from

$$\begin{aligned}\dot{Q}_{\text{rad}} &= \varepsilon A_s \sigma (T_s^4 - T_{\text{surr}}^4) \\&= 0.85[(0.21 + 0.12) \text{ m}^2](5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4) \\&\quad \times [(65 + 273)^4 - (35 + 273)^4] \text{ K}^4 \\&= 64.5 \text{ W}\end{aligned}$$

Note that we must use absolute temperatures in radiation calculations. Then the total heat transfer from the box is simply

$$\dot{Q}_{\text{total}} = \dot{Q}_{\text{conv}} + \dot{Q}_{\text{rad}} = 48.2 + 64.5 = 112.7 \text{ W}$$

which is greater than 75 W. Therefore, this box can be cooled by combined natural convection and radiation, and there is no need to install any fans. There is even some safety margin left for occasions when the air temperature rises above 35°C.

### EXAMPLE 15-11 Cooling of a Component by Natural Convection

A 0.2-W small cylindrical resistor mounted on a PCB is 1 cm long and has a diameter of 0.3 cm, as shown in Fig. 15-41. The view of the resistor is largely

**FIGURE 15-41**  
Schematic for Example 15-11.

blocked by the PCB facing it, and the heat transfer from the connecting wires is negligible. The air is free to flow through the parallel flow passages between the PCBs. If the air temperature at the vicinity of the resistor is 50°C, determine the surface temperature of the resistor.

**SOLUTION** A small cylindrical resistor mounted on a PCB is being cooled by natural convection and radiation. The surface temperature of the resistor is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The device is located at sea level so that the local atmospheric pressure is 1 atm. 3 Radiation is negligible in this case since the resistor is surrounded by surfaces that are at about the same temperature, and the net radiation heat transfer between two surfaces at the same temperature is zero. This leaves natural convection as the only mechanism of heat transfer from the resistor.

**Analysis** Using the relation for components on a circuit board from Table 15-1, the natural convection heat transfer coefficient for this cylindrical component can be determined from

$$h_{\text{conv}} = 2.44 \left( \frac{T_s - T_{\text{fluid}}}{D} \right)^{0.25}$$

where the diameter  $D = 0.003$  m, which is the length in the heat flow path, is the characteristic length. We cannot determine  $h_{\text{conv}}$  yet since we do not know the surface temperature of the component and thus  $\Delta T$ . But we can substitute this relation into the heat transfer relation to get

$$\begin{aligned} \dot{Q}_{\text{conv}} &= h_{\text{conv}} A_s (T_s - T_{\text{fluid}}) = 2.44 \left( \frac{T_s - T_{\text{fluid}}}{D} \right)^{0.25} A_s (T_s - T_{\text{fluid}}) \\ &= 2.44 A_s \left( \frac{T_s - T_{\text{fluid}}}{D} \right)^{1.25} \end{aligned}$$

The heat transfer surface area of the component is

$$A_s = 2 \times \frac{1}{4}\pi D^2 + \pi D L = 2 \times \frac{1}{4}\pi(0.3 \text{ cm})^2 + \pi(0.3 \text{ cm})(1 \text{ cm}) = 1.084 \text{ cm}^2$$

Substituting this and other known quantities in proper units (W for  $\dot{Q}$ , °C for  $T$ ,  $\text{m}^2$  for  $A$ , and m for  $D$ ) into this equation and solving for  $T_s$  yields

$$0.2 = 2.44(1.084 \times 10^{-4}) \frac{(T_s - 50)^{1.25}}{0.003^{0.25}} \longrightarrow T_s = 113^\circ\text{C}$$

Therefore, the surface temperature of the resistor on the PCB will be 113°C, which is considered to be a safe operating temperature for the resistors. Note that blowing air to the circuit board will lower this temperature considerably as a result of increasing the convection heat transfer coefficient and decreasing the air temperature at the vicinity of the components due to the larger flow rate of air.

FIGURE 15-42

Schematic for Example 15-12.

### EXAMPLE 15-12 Cooling of a PCB in a Box by Natural Convection

A 15-cm × 20-cm PCB has electronic components on one side, dissipating a total of 7 W, as shown in Fig. 15-42. The PCB is mounted in a rack vertically together with other PCBs. If the surface temperature of the components is not

to exceed 100°C, determine the maximum temperature of the environment in which this PCB can operate safely at sea level. What would your answer be if this rack is located at a location at 4000 m altitude where the atmospheric pressure is 61.66 kPa?

**SOLUTION** The surface temperature of a PCB is not to exceed 100°C. The maximum environment temperatures for safe operation at sea level and at 4000 m altitude are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Radiation heat transfer is negligible since the PCB is surrounded by other PCBs at about the same temperature. 3 Heat transfer from the back surface of the PCB will be very small and thus negligible.

**Analysis** The entire heat load of the PCB is dissipated to the ambient air by natural convection from its front surface, which can be treated as a vertical flat plate.

Using the simplified relation for a vertical surface from Table 15–1, the natural convection heat transfer coefficient for this PCB can be determined from

$$h_{\text{conv}} = 1.42 \left( \frac{\Delta T}{L} \right)^{0.25} = 1.42 \left( \frac{T_s - T_{\text{fluid}}}{L} \right)^{0.25}$$

The characteristic length in this case is the height ( $L = 0.15$  m) of the PCB, which is the length in the path of heat flow. We cannot determine  $h_{\text{conv}}$  yet, since we do not know the ambient temperature and thus  $\Delta T$ . But we can substitute this relation into the heat transfer relation to get

$$\begin{aligned} \dot{Q}_{\text{conv}} &= h_{\text{conv}} A_s (T_s - T_{\text{fluid}}) = 1.42 \left( \frac{T_s - T_{\text{fluid}}}{L} \right)^{0.25} A_s (T_s - T_{\text{fluid}}) \\ &= 1.42 A_s \frac{(T_s - T_{\text{fluid}})^{1.25}}{L^{0.25}} \end{aligned}$$

The heat transfer surface area of the PCB is

$$A_s = (\text{Width})(\text{Height}) = (0.2 \text{ m})(0.15 \text{ m}) = 0.03 \text{ m}^2$$

Substituting this and other known quantities in proper units (W for  $\dot{Q}$ , °C for  $T$ , m<sup>2</sup> for  $A_s$ , and m for  $L$ ) into this equation and solving for  $T_{\text{fluid}}$  yields

$$7 = 1.42(0.03) \frac{(100 - T_{\text{fluid}})^{1.25}}{0.15^{0.25}} \longrightarrow T_{\text{fluid}} = 59.5^\circ\text{C}$$

Therefore, the PCB will operate safely in environments with temperatures up to 59.5°C by relying solely on natural convection.

At an altitude of 4000 m, the atmospheric pressure is 61.66 kPa, which is equivalent to

$$P = (61.66 \text{ kPa}) \frac{1 \text{ atm}}{101.325 \text{ kPa}} = 0.609 \text{ atm}$$

The heat transfer coefficient in this case is obtained by multiplying the value at sea level by  $\sqrt{P}$ , where  $P$  is in atm. Substituting

$$7 = 1.42(0.03) \frac{(100 - T_{\text{fluid}})^{1.25}}{0.15^{0.25}} \sqrt{0.609} \longrightarrow T_{\text{fluid}} = 50.6^\circ\text{C}$$

which is about 10°C lower than the value obtained at 1 atm pressure. Therefore, the effect of altitude on convection should be considered in high-altitude applications.

## 15-8 • AIR COOLING: FORCED CONVECTION

We mentioned earlier that convection heat transfer between a solid surface and a fluid is proportional to the velocity of the fluid. The *higher* the velocity, the *larger* the flow rate and the *higher* the heat transfer rate. The fluid velocities associated with natural convection currents are naturally low, and thus natural convection cooling is limited to low-power electronic systems.

When natural convection cooling is not adequate, we simply add a *fan* and blow air through the enclosure that houses the electronic components. In other words, we resort to *forced convection* in order to enhance the velocity and thus the flow rate of the fluid as well as the heat transfer. By doing so, we can increase the heat transfer coefficient by a factor of up to about 10, depending on the size of the fan. This means we can remove heat at much higher rates for a specified temperature difference between the components and the air, or we can reduce the surface temperature of the components considerably for a specified power dissipation.

The *radiation* heat transfer in forced-convection-cooled electronic systems is usually disregarded for two reasons. First, forced convection heat transfer is usually much larger than that due to radiation, and the consideration of radiation causes no significant change in the results. Second, the electronic components and circuit boards in convection-cooled systems are mounted so close to each other that a component is almost entirely surrounded by other components at about the same high temperature. That is, the components have hardly any direct view of a cooler surface. This results in little or no radiation heat transfer from the components. The components near the edges of circuit boards with a large view of a cooler surface may benefit somewhat from the additional cooling by radiation, and it is a good design practice to reserve those spots for high-power components to have a thermally balanced system.

When heat transfer from the outer surface of the enclosure of the electronic equipment is negligible, the amount of heat absorbed by the air becomes equal to the amount of heat rejected (or power dissipated) by the electronic components in the enclosure, and can be expressed as (Fig. 15-43)

$$\dot{Q} = \dot{m}c_p(T_{\text{out}} - T_{\text{in}}) \quad (\text{W}) \quad (15-17)$$

where  $\dot{Q}$  is the rate of heat transfer to the air;  $c_p$  is the specific heat of air;  $T_{\text{in}}$  and  $T_{\text{out}}$  are the average temperatures of air at the inlet and exit of the enclosure, respectively; and  $\dot{m}$  is the mass flow rate of air.

Note that for a specified mass flow rate and power dissipation, the *temperature rise* of air,  $T_{\text{out}} - T_{\text{in}}$ , remains constant as it flows through the enclosure. Therefore, the higher the inlet temperature of the air, the higher the exit temperature, and thus the higher the surface temperature of the components. It is considered a good design practice to limit the temperature rise of air to 10°C and the maximum exit temperature of air to 70°C. In a properly designed forced-air-cooled system, this results in a maximum component surface temperature of under 100°C.

The mass flow rate of air required for cooling an electronic box depends on the temperature of air available for cooling. In cool environments, such as an air-conditioned room, a smaller flow rate will be adequate. However, in hot environments, we may need to use a larger flow rate to avoid overheating the components and the potential problems associated with it.

**FIGURE 15-43**

In steady operation, the heat absorbed by air per unit time as it flows through an electronic box is equal to the power consumed by the electronic components in the box.

Forced convection is covered in detail in a separate chapter. For those who skipped that chapter because of time limitations, here we present a brief review of basic concepts and relations.

The fluid flow over a body such as a transistor is called **external flow**, and flow through a confined space such as inside a tube or through the parallel passage area between two circuit boards in an enclosure is called **internal flow** (Fig. 15-44). Both types of flow are encountered in a typical electronic system.

Fluid flow is also categorized as being **laminar** (smooth and streamlined) or **turbulent** (intense eddy currents and random motion of chunks of fluid). Turbulent flow is desirable in heat transfer applications since it results in a much larger heat transfer coefficient. But it also comes with a much larger friction coefficient, which requires a much larger fan (or pump for liquids).

Numerous experimental studies have shown that turbulence tends to occur at larger velocities, during flow over larger bodies or flow through larger channels, and with fluids having smaller viscosities. These effects are combined into the dimensionless **Reynolds number**, defined as

$$\text{Re} = \frac{VL_c}{\nu} \quad (15-18)$$

where

$V$  = velocity of the fluid (*free-stream* velocity for external flow and *average* velocity for internal flow), m/s

$L_c$  = characteristic length of the geometry (the length the fluid flows over in external flow, and the equivalent diameter in internal flow), m

$\nu = \mu/\rho$  = kinematic viscosity of the fluid,  $\text{m}^2/\text{s}$

The Reynolds number at which the flow changes from laminar to turbulent is called the *critical Reynolds number*, whose value is 2300 for internal flow, 500,000 for flow over a flat plate, and 200,000 for flow over a cylinder or sphere.

The *equivalent* (or *hydraulic*) diameter for internal flow is defined as

$$D_h = \frac{4A_c}{p} \quad (\text{m}) \quad (15-19)$$

where  $A_c$  is the cross-sectional area of the flow passage and  $p$  is the perimeter. Note that for a circular pipe, the hydraulic diameter is equivalent to the ordinary diameter.

The convection heat transfer is expressed by *Newton's law of cooling* as

$$\dot{Q}_{\text{conv}} = hA_s(T_s - T_{\text{fluid}}) \quad (\text{W}) \quad (15-20)$$

where

$h$  = average convection heat transfer coefficient,  $\text{W}/\text{m}^2 \cdot ^\circ\text{C}$

$A_s$  = heat transfer surface area,  $\text{m}^2$

$T_s$  = temperature of the surface,  $^\circ\text{C}$

$T_{\text{fluid}}$  = temperature of the fluid sufficiently far from the surface for *external* flow, and average temperature of the fluid at a specified location in *internal* flow,  $^\circ\text{C}$

When the heat load is distributed uniformly on the surfaces with a constant heat flux  $\dot{q}$ , the total rate of heat transfer can also be expressed as  $\dot{Q} = \dot{q}A_s$ .

**FIGURE 15-44**

Internal flow through a circular tube and external flow over it.

FIGURE 15-45

Under constant heat flux conditions, the surface and fluid temperatures increase linearly, but their difference remains constant in the fully developed region.

In *fully developed flow* through a pipe or duct (i.e., when the entrance effects are negligible) subjected to constant heat flux on the surfaces, the convection heat transfer coefficient  $h$  remains *constant*. In this case, both the surface temperature  $T_s$  and the fluid temperature  $T_{\text{fluid}}$  increase *linearly*, as shown in Fig. 15-45, but the difference between them,  $T_s - T_{\text{fluid}}$ , remains *constant*. Then the *temperature rise* of the surface above the fluid temperature can be determined from Eq. 15-20 to be

$$\Delta T_{\text{rise, surface}} = T_s - T_{\text{fluid}} = \frac{\dot{Q}_{\text{conv}}}{hA_s} \quad (\text{°C}) \quad (15-21)$$

Note that the temperature rise of the surface is inversely proportional to the convection heat transfer coefficient. Therefore, the greater the convection coefficient, the lower the surface temperature of the electronic components.

When the exit temperature of the fluid,  $T_{\text{out}}$ , is known, the highest surface temperature that will occur at the end of the flow channel can be determined from Eq. 15-21 to be

$$T_{s, \text{max}} = T_{\text{fluid, max}} + \frac{\dot{Q}}{hA_s} = T_{\text{out}} + \frac{\dot{Q}}{hA_s} \quad (\text{°C}) \quad (15-22)$$

If this temperature is within the safe range, then we don't need to worry about temperatures at other locations. But if it is not, it may be necessary to use a larger fan to increase the flow rate of the fluid.

In convection analysis, the convection heat transfer coefficient  $h$  is usually expressed in terms of the dimensionless **Nusselt number**  $\text{Nu}$  as

$$h = \frac{k}{D} \text{Nu} \quad (\text{W/m}^2 \cdot \text{°C}) \quad (15-23)$$

where  $k$  is the thermal conductivity of the fluid and  $D$  is the characteristic length of the geometry. Relations for the average Nusselt number based on experimental data are given in Table 15-2 for external flow and in Table 15-3 for laminar ( $\text{Re} < 2300$ ) internal flow under a uniform heat flux condition, which is closely approximated by electronic equipment. For *turbulent flow* ( $\text{Re} > 10,000$ ) through smooth tubes and channels, the Nusselt number can be determined from the Dittus–Boelter correlation,

$$\text{Nu} = 0.023 \text{ Re}^{0.8} \text{Pr}^{0.4} \quad (15-24)$$

for any geometry. Here  $\text{Pr}$  is the dimensionless **Prandtl number**, and its value is about 0.7 for air at room temperature.

The fluid properties in the above relations are to be evaluated at the *bulk mean fluid temperature*  $T_{\text{avg}} = \frac{1}{2}(T_{\text{in}} + T_{\text{out}})$  for internal flow, which is the arithmetic average of the mean fluid temperatures at the inlet and the exit of the tube, and at the *film temperature*  $T_{\text{film}} = \frac{1}{2}(T_s + T_{\text{fluid}})$  for external flow, which is the arithmetic average of the surface temperature and free-stream temperature of the fluid.

The relations in Table 15-3 for internal flow assume fully developed flow over the entire flow section, and disregard the heat transfer enhancement effects of the development region at the entrance. Therefore, the results obtained from these relations are on the conservative side. We don't mind this much, however, since it is common practice in engineering design to have some safety margin to fall back to "just in case," as long as it does not result in a grossly overdesigned system. Also, it may sometimes be necessary to do

[From Jakob (1949) and Zukauskas (1972)]

some local analysis for critical components with small surface areas to assure reliability and to incorporate solutions to local problems such as attaching heat sinks to high power components.

## Fan Selection

Air can be supplied to electronic equipment by one or several fans. Although the air is free and abundant, the fans are not. Therefore, a few words about the fan selection are in order.

A fan at a fixed speed (or fixed rpm) will deliver a fixed volume of air regardless of the altitude and pressure. But the mass flow rate of air will be less at *high altitude* as a result of the lower density of air. For example, the atmospheric

**TABLE 15-3**

pressure of air drops by more than 50 percent at an altitude of 6000 m from its value at sea level. This means that the fan will deliver *half* as much air mass at this altitude at the same rpm and temperature, and thus the temperature rise of air cooling will double. This may create serious reliability problems and catastrophic failures of electronic equipment if proper precautions are not taken. *Variable-speed fans* that automatically increase speed when the air density decreases are available to avoid such problems. Expensive electronic systems are usually equipped with thermal cutoff switches to prevent overheating due to inadequate airflow rate or the failure of the cooling fan.

Fans draw in not only cooling air but also all kinds of *contaminants* that are present in the air, such as lint, dust, moisture, and even oil. If unattended, these contaminants can pile up on the components and plug up narrow passageways, causing overheating. It should be remembered that the dust that settles on the electronic components acts as an insulation layer that makes it very difficult for the heat generated in the component to escape. To minimize the contamination problem, air filters are commonly used. It is good practice to use the largest air filter practical to minimize the pressure drop of air and to maximize the dust capacity.

Often the question arises about whether to place the fan at the inlet or the exit of an electronic box. The generally preferred location is the *inlet*. A fan placed at the inlet draws air in and pressurizes the electronic box and prevents air infiltration into the box from cracks or other openings. Having only one location for air inlet makes it practical to install a filter at the inlet to clean the air from all the dust and dirt before they enter the box. This allows the electronic system to operate in a *clean* environment. Also, a fan placed at the inlet handles cooler and thus *denser* air, which results in a higher mass flow rate for the same volume flow rate or rpm. Since the fan is always subjected to cool air, this has the added benefit that it increased the reliability and extends the life of the fan. The major disadvantage associated with having a fan mounted at the inlet is that the *heat* generated by the fan and its motor is picked up by air on its way into the box, which adds to the heat load of the system.

When the fan is placed at the *exit*, the heat generated by the fan and its motor is immediately discarded to the atmosphere without getting blown first into the electronic box. However, a fan at the exit creates a *vacuum* inside the box, which draws air into the box through inlet vents as well as any cracks and openings (Fig. 15-46). Therefore, the air is difficult to filter, and the dirt and dust that collect on the components undermine the reliability of the system.

There are several types of fans available on the market for cooling electronic equipment, and the right choice depends on the situation on hand. There are two primary considerations in the selection of the fan: the *static pressure head* of the system, which is the total resistance an electronic system offers to air as it passes through, and the *volume flow rate* of the air. *Axial fans* are simple, small, light, and inexpensive, and they can deliver a large flow rate. However, they are suitable for systems with relatively small pressure heads. Also, axial fans usually run at very high speeds, and thus they are noisy. The *radial* or *centrifugal fans*, on the other hand, can deliver moderate flow rates to systems with high-static pressure heads at relatively low speeds. But they are larger, heavier, more complex, and more expensive than axial fans.

The performance of a fan is represented by a set of curves called the *characteristic curves*, which are provided by fan manufacturers to help engineers

**FIGURE 15-46**

A fan placed at the exit of an electronic box draws in air as well as contaminants in the air through cracks.

with the selection of fans. A typical static pressure head curve for a fan is given in Fig. 15-47 together with a typical system flow resistance curve plotted against the flow rate of air. Note that a fan creates the *highest* pressure head at *zero* flow rate. This corresponds to the limiting case of blocked exit vents of the enclosure. The flow rate increases with decreasing static head and reaches its maximum value when the fan meets no flow resistance.

Any electronic enclosure will offer some resistance to flow. The system resistance curve is *parabolic* in shape, and the pressure or head loss due to this resistance is nearly proportional to the *square* of the flow rate. The fan must overcome this resistance to maintain flow through the enclosure. The design of a forced convection cooling system requires the determination of the total system resistance characteristic curve. This curve can be generated accurately by measuring the static pressure drop at different flow rates. It can also be determined approximately by evaluating the pressure drops.

A fan will operate at the *point* where the fan static head curve and the system resistance curve *intersect*. Note that a fan will deliver a higher flow rate to a system with a low flow resistance. The required airflow rate for a system can be determined from heat transfer requirements alone, using the *design heat load* of the system and the *allowable temperature rise* of air. Then the flow resistance of the system at this flow rate can be determined analytically or experimentally. Knowing the flow rate and the needed pressure head, it is easy to select a fan from manufacturers' catalogs that will meet both of these requirements.

Below we present some general guidelines associated with the forced-air cooling of electronic systems.

1. Before deciding on forced-air cooling, check to see if *natural convection* cooling is adequate. If it is, which may be the case for low-power systems, incorporate it and avoid all the problems associated with fans such as cost, power consumption, noise, complexity, maintenance, and possible failure.
2. Select a fan that is neither too small nor too large. An *undersized* fan may cause the electronic system to overheat and fail. An *oversized* fan will definitely provide adequate cooling, but it will needlessly be larger and more expensive and will consume more power.
3. If the temperature rise of air due to the power consumed by the motor of the fan is acceptable, mount the fan at the *inlet* of the box to pressurize the box and filter the air to keep dirt and dust out (Fig. 15-48).
4. Position and size the air exit vents so that there is *adequate airflow* throughout the entire box. More air can be directed to a certain area by enlarging the size of the vent at that area. The total exit areas should be at least as large as the inlet flow area to avoid the choking of the airflow, which may result in a reduced airflow rate.
5. Place the most critical electronic components near the *entrance*, where the air is coolest. Place the non-critical components that consume a lot of power near the exit (Fig. 15-49).
6. Arrange the circuit boards and the electronic components in the box such that the *resistance* of the box to airflow is *minimized* and thus the flow rate of air through the box is maximized for the same fan speed. Make sure that no hot air pockets are formed during operation.

FIGURE 15-47

The airflow rate a fan delivers into an electronic enclosure depends on the flow resistance of that system as well as the variation of the static head of the fan with flow rate.

FIGURE 15-48

Installing the fan at the inlet keeps the dirt and dust out, but the heat generated by the fan motor in.

**FIGURE 15-49**

Sensitive components should be located near the inlet and high-power components near the exit.

**FIGURE 15-50**

A desktop personal computer with monitor and keyboard.

7. Consider the effect of *altitude* in high-altitude applications.
8. Try to avoid any flow sections that increase the flow resistance of the systems, such as unnecessary corners, sharp turns, sudden expansions and contractions, and very high velocities (greater than 7 m/s), since the flow resistance is nearly proportional to the flow rate. Also, avoid very low velocities since these result in a poor heat transfer performance and allow the dirt and the dust in the air to settle on the components.
9. Arrange the system such that *natural convection* helps forced convection instead of hurting it. For example, mount the PCBs vertically, and blow the air from the bottom toward the top instead of the other way around.
10. When the design calls for the use of two or more fans, a decision needs to be made about mounting the fans in parallel or in series. Fans mounted in *series* will boost the pressure head available and are best suited for systems with a high flow resistance. Fans connected in *parallel* will increase the flow rate of air and are best suited for systems with small flow resistance.

## Cooling Personal Computers

The introduction of the 4004 chip, the first general-purpose microprocessor, by the Intel Corporation in the early 1970s marked the beginning of the electronics era in consumer goods, from calculators and washing machines to personal computers. The microprocessor, which is the “brain” of the personal computer, is basically a DIP-type LSE package that incorporates a central processing unit (CPU), memory, and some input/output capabilities.

A typical desktop personal computer consists of a few circuit boards plugged into a mother board, which houses the microprocessor and the memory chips, as well as the network of interconnections enclosed in a formed sheet metal chassis, which also houses the disk and CD-ROM and DVD drives. Connected to this “magic” box are the monitor, a keyboard, a printer, and other auxiliary equipment (Fig. 15–50). The PCBs are normally mounted vertically on a mother board, since this facilitates better cooling.

A small and quiet fan is usually mounted to the rear or side of the chassis to cool the electronic components. There are also louvers and openings on the side surfaces to facilitate air circulation. Such openings are not placed on the top surface, since many users would block them by putting books or other things there, which will jeopardize safety, and a coffee or soda spill can cause major damage to the system.

### **EXAMPLE 15-13      Forced-Air Cooling of a Hollow-Core PCB**

Some strict specifications of electronic equipment require that the cooling air not come into direct contact with the electronic components, in order to protect them from exposure to the contaminants in the air. In such cases, heat generated in the components on a PCB must be conducted a long way to the walls of the enclosure through a metal core strip or a heat frame attached to the PCB. An alternative solution is the *hollow-core PCB*, which is basically a narrow duct of rectangular cross section made of thin glass-epoxy board with electronic components mounted on both sides, as shown in Fig. 15–51. Heat generated in the

components is conducted to the hollow core through a thin layer of epoxy board and is then removed by the cooling air flowing through the core. Effective sealing is provided to prevent air leakage into the component chamber.

Consider a hollow-core PCB 12 cm high and 18 cm long, dissipating a total of 40 W. The width of the air gap between the two sides of the PCB is 0.3 cm. The cooling air enters the core at 20°C at a rate of 0.72 L/s. Assuming the heat generated to be uniformly distributed over the two side surfaces of the PCB, determine (a) the temperature at which the air leaves the hollow core and (b) the highest temperature on the inner surface of the core.

**SOLUTION** A hollow-core PCB is cooled by forced air. The outlet temperature of air and the highest surface temperature are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 The inner surfaces of the duct are smooth. 3 Air is an ideal gas. 4 Operation is at sea level and thus the atmospheric pressure is 1 atm. 5 The entire heat generated in electronic components is removed by the air flowing through the hollow core.

**Properties** The temperature of air varies as it flows through the core, and so do its properties. We will perform the calculations using property values at 40°C from Table A-15 since the air enters at 20°C and its temperature will increase.

$$\begin{aligned}\rho &= 1.127 \text{ kg/m}^3 & k &= 0.02662 \text{ W/m} \cdot ^\circ\text{C} \\ c_p &= 1007 \text{ J/kg} \cdot ^\circ\text{C} & \nu &= 1.702 \times 10^{-5} \text{ m}^2/\text{s} \\ \text{Pr} &= 0.7255\end{aligned}$$

After we calculate the exit temperature of air, we can repeat the calculations, if necessary, using properties at the average temperature.

**Analysis** The cross-sectional area of the channel and its hydraulic diameter are

$$\begin{aligned}A_c &= (\text{Height})(\text{Width}) = (0.12 \text{ m})(0.003 \text{ m}) = 3.6 \times 10^{-4} \text{ m}^2 \\ D_h &= \frac{4A_c}{p} = \frac{4 \times (3.6 \times 10^{-4} \text{ m}^2)}{2 \times (0.12 + 0.003) \text{ m}} = 0.005854 \text{ m}\end{aligned}$$

The average velocity and the mass flow rate of air are

$$\begin{aligned}V &= \frac{\dot{V}}{A_c} = \frac{0.72 \times 10^{-3} \text{ m}^3/\text{s}}{3.6 \times 10^{-4} \text{ m}^2} = 2.0 \text{ m/s} \\ \dot{m} &= \rho \dot{V} = (1.127 \text{ kg/m}^3)(0.72 \times 10^{-3} \text{ m}^3/\text{s}) = 0.8114 \times 10^{-3} \text{ kg/s}\end{aligned}$$

(a) The temperature of air at the exit of the hollow core can be determined from

$$\dot{Q} = \dot{m}c_p(T_{\text{out}} - T_{\text{in}})$$

Solving for  $T_{\text{out}}$  and substituting the given values, we obtain

$$T_{\text{out}} = T_{\text{in}} + \frac{\dot{Q}}{\dot{m}c_p} = 20^\circ\text{C} + \frac{40 \text{ J/s}}{(0.8114 \times 10^{-3} \text{ kg/s})(1007 \text{ J/kg} \cdot ^\circ\text{C})} = 69.0^\circ\text{C}$$

The average air temperature is  $(20 + 69)/2 = 44.5^\circ\text{C}$ , which is sufficiently close to the assumed value of 40°C. Therefore, there is no need to repeat the calculations.

(b) The surface temperature of the channel at any location can be determined from

$$\dot{Q}_{\text{conv}} = hA_s(T_s - T_{\text{fluid}})$$

**FIGURE 15-51**

The hollow-core PCB discussed in Example 15-13.

where the heat transfer surface area is

$$A_s = 2A_{\text{side}} = 2(\text{Height})(\text{Length}) = 2(0.12 \text{ m})(0.18 \text{ m}) = 0.0432 \text{ m}^2$$

To determine the convection heat transfer coefficient, we first need to calculate the Reynolds number:

$$\text{Re} = \frac{VD_h}{\nu} = \frac{(2 \text{ m/s})(0.005854 \text{ m})}{1.702 \times 10^{-5} \text{ m}^2/\text{s}} = 688 < 2300$$

Therefore, the flow is laminar, and, assuming fully developed flow, the Nusselt number for the airflow in this rectangular cross section corresponding to the aspect ratio  $a/b = (12 \text{ cm})/(0.3 \text{ cm}) = 40 \approx \infty$  is determined from Table 15-3 to be

$$\text{Nu} = 8.24$$

and thus

$$h = \frac{k}{D_h} \text{ Nu} = \frac{0.02662 \text{ W/m} \cdot ^\circ\text{C}}{0.005854 \text{ m}} (8.24) = 37.5 \text{ W/m}^2 \cdot ^\circ\text{C}$$

Then the surface temperature of the hollow core near the exit becomes

$$T_{s,\max} = T_{\text{out}} + \frac{\dot{Q}}{hA_s} = 69.0^\circ\text{C} + \frac{40 \text{ W}}{(37.5 \text{ W/m}^2 \cdot ^\circ\text{C})(0.0432 \text{ m}^2)} = 93.7^\circ\text{C}$$

**Discussion** Note that the temperature difference between the surface and the air at the exit of the hollow core is  $24.7^\circ\text{C}$ . This temperature difference between the air and the surface remains at that value throughout the core, since the heat generated on the side surfaces is uniform and the convection heat transfer coefficient is constant. Therefore, the surface temperature of the core at the inlet will be  $20^\circ\text{C} + 24.7^\circ\text{C} = 44.7^\circ\text{C}$ . In reality, however, this temperature will be somewhat lower because of the entrance effects, which affect heat transfer favorably. The fully developed flow assumption gives somewhat conservative results but is commonly used in practice because it provides considerable simplification in calculations.

FIGURE 15-52

Schematic for Example 15-14.

### EXAMPLE 15-14 Forced-Air Cooling of a Transistor Mounted on a PCB

A TO 71 transistor with a height of 0.53 cm and a diameter of 0.44 cm is mounted on a circuit board, as shown in Fig. 15-52. The transistor is cooled by air flowing over it at a velocity of 90 m/min. If the air temperature is  $65^\circ\text{C}$  and the transistor case temperature is not to exceed  $95^\circ\text{C}$ , determine the amount of power this transistor can dissipate safely.

**SOLUTION** A transistor mounted on a circuit board is cooled by air flowing over it. The power dissipated when its case temperature is  $90^\circ\text{C}$  is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Air is an ideal gas. 3 Operation is at sea level and thus the atmospheric pressure is 1 atm.

**Properties** The properties of air at 1 atm pressure and the film temperature of  $T_f = (T_s + T_{\text{fluid}})/2 = (95 + 65)/2 = 80^\circ\text{C}$  are

$$\begin{aligned}\rho &= 0.9994 \text{ kg/m}^3 & k &= 0.02953 \text{ W/m} \cdot ^\circ\text{C} \\ c_p &= 1008 \text{ J/kg} \cdot ^\circ\text{C} & \nu &= 2.097 \times 10^{-5} \text{ m}^2/\text{s} \\ \text{Pr} &= 0.7154\end{aligned}$$

**Analysis** The transistor is cooled by forced convection through its cylindrical surface as well as its flat top and bottom surfaces. The characteristic length for flow over a cylinder is the diameter  $D = 0.0044 \text{ m}$ . Then the Reynolds number becomes

$$\text{Re} = \frac{VD}{\nu} = \frac{(90/60 \text{ m/s})(0.0044 \text{ m})}{2.097 \times 10^{-5} \text{ m}^2/\text{s}} = 315$$

which falls into the range 40 to 4000. Using the corresponding relation from Table 15–2 for the Nusselt number, we obtain

$$\text{Nu} = 0.683 \text{ Re}^{0.466} \text{ Pr}^{1/3} = 0.683(315)^{0.466}(0.7154)^{1/3} = 8.91$$

and

$$h = \frac{k}{D} \text{ Nu} = \frac{0.02953 \text{ W/m} \cdot ^\circ\text{C}}{0.0044 \text{ m}} (8.91) = 59.8 \text{ W/m}^2 \cdot ^\circ\text{C}$$

Also,

$$A_{\text{cyl}} = \pi D L = \pi(0.0044 \text{ m})(0.0053 \text{ m}) = 0.7326 \times 10^{-4} \text{ m}^2$$

Then the rate of heat transfer from the cylindrical surface becomes

$$\begin{aligned}\dot{Q}_{\text{cyl}} &= h A_{\text{cyl}} (T_s - T_{\text{fluid}}) \\ &= (59.8 \text{ W/m}^2 \cdot ^\circ\text{C})(0.7326 \times 10^{-4} \text{ m}^2)(95 - 65)^\circ\text{C} = 0.131 \text{ W}\end{aligned}$$

We now repeat the calculations for the top and bottom surfaces of the transistor, which can be treated as flat plates of length  $L = 0.0044 \text{ m}$  in the flow direction (which is the diameter), and, using the proper relation from Table 15–2,

$$\begin{aligned}\text{Re} &= \frac{VL}{\nu} = \frac{(90/60 \text{ m/s})(0.0044 \text{ m})}{2.097 \times 10^{-5} \text{ m}^2/\text{s}} = 315 \\ \text{Nu} &= 0.664 \text{ Re}^{1/2} \text{ Pr}^{1/3} = 0.664(315)^{1/2}(0.7154)^{1/3} = 10.5\end{aligned}$$

and

$$h = \frac{k}{D} \text{ Nu} = \frac{0.02953 \text{ W/m} \cdot ^\circ\text{C}}{0.0044 \text{ m}} (10.5) = 70.7 \text{ W/m}^2 \cdot ^\circ\text{C}$$

Also,

$$\begin{aligned}A_{\text{flat}} &= A_{\text{top}} + A_{\text{bottom}} = 2 \times \frac{1}{4}\pi D^2 = 2 \times \frac{1}{4}\pi(0.0044 \text{ m})^2 = 0.3041 \times 10^{-4} \text{ m}^2 \\ \dot{Q}_{\text{flat}} &= h A_{\text{flat}} (T_s - T_{\text{fluid}}) = (70.7 \text{ W/m}^2 \cdot ^\circ\text{C})(0.3041 \times 10^{-4} \text{ m}^2)(95 - 65)^\circ\text{C} \\ &= 0.065 \text{ W}\end{aligned}$$

Therefore, the total rate of heat that can be dissipated from all surfaces of the transistor is

$$\dot{Q}_{\text{total}} = \dot{Q}_{\text{cyl}} + \dot{Q}_{\text{flat}} = (0.131 + 0.065) \text{ W} = \mathbf{0.196 \text{ W}}$$

which seems to be low. This value can be increased considerably by attaching a heat sink to the transistor to enhance the heat transfer surface area and thus heat transfer, or by increasing the air velocity, which will increase the heat transfer coefficient.

**FIGURE 15-53**

Schematic for Example 15-15.

**EXAMPLE 15-15 Choosing a Fan to Cool a Computer**

The desktop computer shown in Fig. 15-53 is to be cooled by a fan. The electronics of the computer consume 75 W of power under full-load conditions. The computer is to operate in environments at temperatures up to 40°C and at elevations up to 2000 m, where the atmospheric pressure is 79.50 kPa. The exit temperature of air is not to exceed 70°C to meet reliability requirements. Also, the average velocity of air is not to exceed 75 m/min at the exit of the computer case, where the fan is installed, to keep the noise level down. Determine the flow rate of the fan that needs to be installed and the diameter of the casing of the fan.

**SOLUTION** A desktop computer is to be cooled by a fan safely in hot environments and high elevations. The airflow rate of the fan and the diameter of the casing are to be determined.

**Assumptions** 1 Steady operation under worst conditions is considered. 2 Air is an ideal gas.

**Properties** The specific heat of air at the average temperature of  $(40 + 70)/2 = 55^\circ\text{C}$  is 1007 J/kg · °C.

**Analysis** We need to determine the flow rate of air for the worst-case scenario. Therefore, we assume the inlet temperature of air to be 40°C and the atmospheric pressure to be 79.50 kPa and disregard any heat transfer from the outer surfaces of the computer case. Note that any direct heat loss from the computer case will provide a safety margin in the design.

Noting that all the heat dissipated by the electronic components is absorbed by air, the required mass flow rate of air to absorb heat at a rate of 75 W can be determined from

$$\dot{Q} = \dot{m}c_p(T_{\text{out}} - T_{\text{in}})$$

Solving for  $\dot{m}$  and substituting the given values, we obtain

$$\begin{aligned}\dot{m} &= \frac{\dot{Q}}{c_p(T_{\text{out}} - T_{\text{in}})} = \frac{75 \text{ J/s}}{(1007 \text{ J/kg} \cdot ^\circ\text{C})(70 - 40)^\circ\text{C}} \\ &= 0.00248 \text{ kg/s} = 0.148 \text{ kg/min}\end{aligned}$$

In the worst case, the exhaust fan will handle air at 70°C. Then the density of air entering the fan and the volume flow rate become

$$\begin{aligned}\rho &= \frac{P}{RT} = \frac{79.50 \text{ kPa}}{(0.287 \text{ kPa} \cdot \text{m}^3/\text{kg} \cdot \text{K})(70 + 273) \text{ K}} = 0.8076 \text{ kg/m}^3 \\ \dot{V} &= \frac{\dot{m}}{\rho} = \frac{0.148 \text{ kg/min}}{0.8076 \text{ kg/m}^3} = 0.183 \text{ m}^3/\text{min}\end{aligned}$$

Therefore, the fan must be able to provide a flow rate of 0.183 m<sup>3</sup>/min or 6.5 cfm (cubic feet per minute). Note that if the fan were installed at the inlet instead of the exit, then we would need to determine the flow rate using the density of air at the inlet temperature of 40°C, and we would need to add the power consumed by the motor of the fan to the heat load of 75 W. The result may be a slightly smaller or larger fan, depending on which effect dominates.

For an average velocity of 75 m/min, the diameter of the duct in which the fan is installed can be determined from

$$\dot{V} = A_c V = \frac{1}{4} \pi D^2 V$$

Solving for  $D$  and substituting the known values, we obtain

$$D = \sqrt{\frac{4\dot{V}}{\pi V}} = \sqrt{\frac{4 \times 0.183 \text{ m}^3/\text{min}}{\pi(7.5 \text{ m}/\text{min})}} = 0.176 \text{ m} = 17.6 \text{ cm}$$

Therefore, a fan with a casing diameter of 17.6 cm and a flow rate of 0.183 m<sup>3</sup>/min will meet the design requirements.

### EXAMPLE 15–16 Cooling of a Computer by a Fan

A computer cooled by a fan contains six PCBs, each dissipating 15 W of power, as shown in Fig. 15–54. The height of the PCBs is 15 cm and the length is 20 cm. The clearance between the tips of the components on the PCB and the back surface of the adjacent PCB is 0.4 cm. The cooling air is supplied by a 20-W fan mounted at the inlet. If the temperature rise of air as it flows through the case of the computer is not to exceed 10°C, determine (a) the flow rate of the air the fan needs to deliver, (b) the fraction of the temperature rise of air due to the heat generated by the fan and its motor, and (c) the highest allowable inlet air temperature if the surface temperature of the components is not to exceed 90°C anywhere in the system.

**SOLUTION** A computer cooled by a fan, and the temperature rise of air is limited to 10°C. The flow rate of the air, the fraction of the temperature rise of air caused by the fan and its motor, and maximum allowable air inlet temperature are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Air is an ideal gas. 3 The computer is located at sea level so that the local atmospheric pressure is 1 atm. 4 The entire heat generated by the electronic components is removed by air flowing through the opening between the PCBs. 5 The entire power consumed by the fan motor is transferred as heat to the cooling air. This is a conservative approach since the fan and its motor are usually mounted to the chassis of the electronic system, and some of the heat generated in the motor may be conducted to the chassis through the mounting brackets.

**Properties** We use properties of air at 30°C since the air enters at room temperature, and the temperature rise of air is limited to just 10°C.(Table A–15)

$$\begin{aligned}\rho &= 1.164 \text{ kg/m}^3 & k &= 0.02588 \text{ W/m} \cdot ^\circ\text{C} \\ c_p &= 1007 \text{ J/kg} \cdot ^\circ\text{C} & \nu &= 1.608 \times 10^{-5} \text{ m}^2/\text{s} \\ \text{Pr} &= 0.7282\end{aligned}$$

**Analysis** Because of symmetry, we consider the flow area between the two adjacent PCBs only. We assume the flow rate of air through all six channels to be identical, and to be equal to one-sixth of the total flow rate.

(a) Noting that the temperature rise of air is limited to 10°C and that the power consumed by the fan is also absorbed by the air, the total mass flow rate of air through the computer can be determined from

$$\dot{Q} = \dot{m}c_p(T_{\text{out}} - T_{\text{in}})$$

Solving for  $\dot{m}$  and substituting the given values, we obtain

$$\dot{m} = \frac{\dot{Q}}{c_p(T_{\text{out}} - T_{\text{in}})} = \frac{(6 \times 15 + 20) \text{ J/s}}{(1007 \text{ J/kg} \cdot ^\circ\text{C})(10^\circ\text{C})} = 0.01092 \text{ kg/s}$$

FIGURE 15–54

Schematic of the computer discussed in Example 15–16.

Then the volume flow rate of air and the air velocity become

$$\dot{V} = \frac{\dot{m}}{\rho} = \frac{0.01092 \text{ kg/s}}{1.164 \text{ kg/m}^3} = 0.009381 \text{ m}^3/\text{s} = \mathbf{0.563 \text{ m}^3/\text{min}}$$

$$V = \frac{\dot{V}}{A_c} = \frac{0.009381 \text{ m}^3/\text{s}}{(0.15 \times 0.004) \text{ m}^2} = 2.606 \text{ m/s}$$

Therefore, the fan needs to supply air at a rate of 0.563 m<sup>3</sup>/min, or about 20 cfm.

(b) The temperature rise of air due to the power consumed by the fan motor can be determined by assuming the entire 20 W of power consumed by the motor to be transferred to air as heat:

$$\Delta T_{\text{air, rise}} = \frac{\dot{Q}_{\text{fan}}}{\dot{m}c_p} = \frac{20 \text{ J/s}}{(0.01092 \text{ kg/s})(1007 \text{ J/kg} \cdot ^\circ\text{C})} = \mathbf{1.8^\circ\text{C}}$$

Therefore, 18 percent of the temperature rise of air is due to the heat generated by the fan motor. Note that the fraction of the power consumed by the fan is also 18 percent of the total, as expected.

(c) The surface temperature of the channel at any location can be determined from

$$\dot{q}_{\text{conv}} = \dot{Q}_{\text{conv}}/A_s = h(T_s - T_{\text{fluid}})$$

where the heat transfer surface area is

$$A_s = A_{\text{side}} = (\text{Height})(\text{Length}) = (0.15 \text{ m})(0.20 \text{ m}) = 0.03 \text{ m}^2$$

To determine the convection heat transfer coefficient, we first need to calculate the Reynolds number. The cross-sectional area of the channel and its hydraulic diameter are

$$A_c = (\text{Height})(\text{Width}) = (0.15 \text{ m})(0.004 \text{ m}) = 6 \times 10^{-4} \text{ m}^2$$

$$D_h = \frac{4A_c}{P} = \frac{4 \times (6 \times 10^{-4} \text{ m}^2)}{2 \times (0.15 + 0.004) \text{ m}} = 0.007792 \text{ m}$$

Then the Reynolds number becomes

$$\text{Re} = \frac{VD_h}{\nu} = \frac{(2.606 \text{ m/s})(0.007792 \text{ m})}{1.608 \times 10^{-5} \text{ m}^2/\text{s}} = 1263 < 2300$$

Therefore, the flow is laminar, and, assuming fully developed flow, the Nusselt number for the airflow in this rectangular cross-section corresponding to the aspect ratio  $a/b = (15 \text{ cm})/(0.4 \text{ cm}) = 37.5 \approx \infty$  is determined from Table 15-3 to be

$$\text{Nu} = 8.24$$

and thus

$$h = \frac{k}{D_h} \text{ Nu} = \frac{0.02588 \text{ W/m} \cdot ^\circ\text{C}}{0.007792 \text{ m}} (8.24) = 27.4 \text{ W/m}^2 \cdot ^\circ\text{C}$$

Disregarding the entrance effects, the temperature difference between the surface of the PCB and the air anywhere along the channel is determined to be

$$T_s - T_{\text{fluid}} = \left( \frac{\dot{q}}{h} \right)_{\text{PCB}} = \frac{(15 \text{ W})/(0.03 \text{ m}^2)}{27.4 \text{ W/m}^2 \cdot ^\circ\text{C}} = 18.3^\circ\text{C}$$

That is, the surface temperature of the components on the PCB will be  $18.3^\circ\text{C}$  higher than the temperature of air passing by.

The highest air and component temperatures will occur at the exit. Therefore, in the limiting case, the component surface temperature at the exit will be  $90^\circ\text{C}$ . The air temperature at the exit in this case will be

$$T_{\text{out, max}} = T_{s, \text{max}} - \Delta T_{\text{rise}} = 90^\circ\text{C} - 18.3^\circ\text{C} = 71.7^\circ\text{C}$$

Noting that the air experiences a temperature rise of  $10^\circ\text{C}$  between the inlet and the exit, the inlet temperature of air is

$$T_{\text{in, max}} = T_{\text{out, max}} - 10^\circ\text{C} = (71.7 - 10)^\circ\text{C} = 61.7^\circ\text{C}$$

This is the highest allowable air inlet temperature if the surface temperature of the components is not to exceed  $90^\circ\text{C}$  anywhere in the system.

It should be noted that the analysis presented above is approximate since we have made some simplifying assumptions. However, the accuracy of the results obtained is usually adequate for engineering purposes.

## 15–9 • LIQUID COOLING

Liquids normally have much higher thermal conductivities than gases, and thus much higher heat transfer coefficients associated with them. Therefore, liquid cooling is far more effective than gas cooling. However, liquid cooling comes with its own risks and potential problems, such as leakage, corrosion, extra weight, and condensation. Therefore, liquid cooling is reserved for applications involving power densities that are too high for safe dissipation by air cooling.

Liquid cooling systems can be classified as **direct cooling** and **indirect cooling** systems. In *direct cooling* systems, the electronic components are in direct contact with the liquid, and thus the heat generated in the components is transferred directly to the liquid. In *indirect cooling* systems, however, there is no direct contact with the components. The heat generated in this case is first transferred to a medium such as a *cold plate* before it is carried away by the liquid. Liquid cooling systems are also classified as *closed-loop* and *open-loop* systems, depending on whether the liquid is discarded or recirculated after it is heated. In open-loop systems, tap water flows through the cooling system and is discarded into a drain after it is heated. The heated liquid in closed-loop systems is cooled in a heat exchanger and recirculated through the system. Closed-loop systems facilitate better temperature control while conserving water.

The electronic components in direct cooling systems are usually completely immersed in the liquid. The heat transfer from the components to the liquid can be by natural or forced convection or *boiling*, depending on the temperature levels involved and the properties of the fluids. Immersion cooling of electronic devices usually involves boiling and thus very high heat transfer coefficients, as discussed in the next section. Note that only *dielectric fluids* can be used in immersion or direct liquid cooling. This limitation immediately excludes water from consideration as a prospective fluid in immersion cooling.

Fluorocarbon fluids such as FC75 are well suited for direct cooling and are commonly used in such applications.

Indirect liquid cooling systems of electronic devices operate just like the cooling system of a *car engine*, where the water (actually a mixture of water and ethylene glycol) circulates through the passages around the cylinders of the engine block, absorbing heat generated in the cylinders by combustion. The heated water is then routed by the water pump to the radiator, where it is cooled by air blown through the radiator coils by the cooling fan. The cooled water is then rerouted to the engine to transfer more heat. To appreciate the effectiveness of the cooling system of a car engine, it will suffice to say that the temperatures encountered in the engine cylinders are typically much higher than the melting temperatures of the engine blocks.

In an electronic system, the heat is generated in the *components* instead of the combustion chambers. The components in this case are mounted on a metal plate made of a highly conducting material such as copper or aluminum. The metal plate is cooled by circulating a cooling fluid through tubes attached to it, as shown in Fig. 15-55. The heated liquid is then cooled in a heat exchanger, usually by air (or sea water in marine applications), and is recirculated by a pump through the tubes. The expansion and storage tank accommodates any expansions and contractions of the cooling liquid due to temperature variations while acting as a liquid reservoir.

The liquids used in the cooling of electronic equipment must meet several requirements, depending on the specific application. Desirable characteristics of cooling liquids include *high thermal conductivity* (yields high heat transfer coefficients), *high specific heat* (requires smaller mass flow rate), *low viscosity* (causes a smaller pressure drop, and thus requires a smaller pump), *high surface tension* (less likely to cause leakage problems), *high dielectric strength* (a must in direct liquid cooling), *chemical inertness* (does not react with surfaces with which it comes into contact), *chemical stability* (does not decompose under prolonged use), *nontoxic* (safe for personnel to handle), *low freezing and high boiling points* (extends the useful temperature range), and *low cost*. Different fluids may be selected in different applications because of the different priorities set in the selection process.

The heat sinks or cold plates of an electronic enclosure are usually cooled by *water* by passing it through channels made for this purpose or through tubes attached to the cold plate. High heat removal rates can be achieved by circulating water through these channels or tubes. In high-performance systems, a *refrigerant* can be used in place of water to keep the temperature of the heat sink at subzero temperatures and thus reduce the junction temperatures of the electronic components proportionately. The heat transfer and pressure drop calculations in liquid cooling systems can be performed using appropriate relations.

Liquid cooling can be used effectively to cool clusters of electronic devices attached to a tubed metal plate (or heat sink), as shown in Fig. 15-56. Here 12 TO-3 cases, each dissipating up to 150 W of power, are mounted on a heat sink equipped with tubes on the back side through which a liquid flows. The thermal resistance between the case of the devices and the liquid is minimized in this case, since the electronic devices are mounted directly over the cooling lines. The case-to-liquid thermal resistance depends on the spacing between the devices, the quality of the thermal contact between the devices and the plate, the thickness of the plate, and the flow rate of the liquid, among other

**FIGURE 15-55**

Schematic of an indirect liquid cooling system.

**FIGURE 15-56**

Liquid cooling of TO-3 packages placed on top of the coolant line.  
(Courtesy of Wakefield Engineering.)

things. The tubed metal plate shown is 15.2 cm × 18 cm × 2.5 cm in size and is capable of dissipating up to 2 kW of power.

The thermal resistance network of a liquid cooling system is shown in Fig. 15-57. The junction temperatures of silicon-based electronic devices are usually limited to 125°C. The *junction-to-case* thermal resistance of a device is provided by the manufacturer. The *case-to-liquid* thermal resistance can be determined experimentally by measuring the temperatures of the case and the liquid, and dividing the difference by the total power dissipated. The *liquid-to-air* thermal resistance at the heat exchanger can be determined in a similar manner. That is,

$$R_{\text{case-liquid}} = \frac{T_{\text{case}} - T_{\text{liquid, device}}}{\dot{Q}} \quad (\text{°C/W}) \quad (15-25)$$

$$R_{\text{liquid-air}} = \frac{T_{\text{liquid, hx}} - T_{\text{air, in}}}{\dot{Q}}$$

where  $T_{\text{liquid, device}}$  and  $T_{\text{liquid, hx}}$  are the inlet temperatures of the liquid to the electronic device and the heat exchanger, respectively. The required mass flow rate of the liquid corresponding to a specified temperature rise of the liquid as it flows through the electronic systems can be determined from Eq. 15-17.

Electronic components mounted on liquid-cooled metal plates should be provided with good thermal contact in order to minimize the thermal resistance between the components and the plate. The thermal resistance can be minimized by applying silicone grease or beryllium oxide to the contact surfaces and fastening the components tightly to the metal plate. The liquid cooling of a cold plate with a large number of high-power components attached to it is illustrated in Example 15-17.

### EXAMPLE 15-17 Cooling of Power Transistors on a Cold Plate by Water

A cold plate that supports 20 power transistors, each dissipating 40 W, is to be cooled with water, as shown in Fig. 15-58. Half of the transistors are attached to the back side of the cold plate. It is specified that the temperature rise of the water is not to exceed 3°C and the velocity of water is to remain under 1 m/s. Assuming that 20 percent of the heat generated is dissipated from the

**FIGURE 15-57**

Thermal resistance network for a liquid-cooled electronic device.

**FIGURE 15-58**

Schematic for Example 15-17.

components to the surroundings by convection and radiation, and the remaining 80 percent is removed by the cooling water, determine the mass flow rate of water needed and the diameter of the pipe to satisfy the restriction imposed on the flow velocity. Also, determine the case temperature of the devices if the total case-to-liquid thermal resistance is  $0.030^{\circ}\text{C}/\text{W}$  and the water enters the cold plate at  $35^{\circ}\text{C}$ .

**SOLUTION** A cold plate is to be cooled by water. The mass flow rate of water, the diameter of the pipe, and the case temperature of the transistors are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 About 20 percent of the heat generated is dissipated from the components to the surroundings by convection and radiation.

**Properties** The properties of water at room temperature are  $\rho = 1000 \text{ kg/m}^3$  and  $c_p = 4180 \text{ J/kg} \cdot ^{\circ}\text{C}$ .

**Analysis** Noting that each of the 20 transistors dissipates 40 W of power and 80 percent of this power must be removed by the water, the amount of heat that must be removed by the water is

$$\dot{Q} = (20 \text{ transistors})(40 \text{ W/transistor})(0.80) = 640 \text{ W}$$

In order to limit the temperature rise of the water to  $3^{\circ}\text{C}$ , the mass flow rate of water must be no less than

$$\dot{m} = \frac{\dot{Q}}{c_p \Delta T_{\text{rise}}} = \frac{640 \text{ J/s}}{(4180 \text{ J/kg} \cdot ^{\circ}\text{C})(3^{\circ}\text{C})} = 0.051 \text{ kg/s} = \mathbf{3.06 \text{ kg/min}}$$

The mass flow rate of a fluid through a circular pipe can be expressed as

$$\dot{m} = \rho A_c V = \rho \frac{\pi D^2}{4} V$$

Then the diameter of the pipe to maintain the velocity of water under 1 m/s is determined to be

$$D = \sqrt{\frac{4\dot{m}}{\pi \rho V}} = \sqrt{\frac{4(0.051 \text{ kg/s})}{\pi(1000 \text{ kg/m}^3)(1 \text{ m/s})}} = 0.0081 \text{ m} = \mathbf{0.81 \text{ cm}}$$

Noting that the total case-to-liquid thermal resistance is  $0.030^{\circ}\text{C}/\text{W}$  and the water enters the cold plate at  $35^{\circ}\text{C}$ , the case temperature of the devices is determined from Eq. 15-25 to be

$$T_{\text{case}} = T_{\text{liquid, device}} + \dot{Q} R_{\text{case-liquid}} = 35^{\circ}\text{C} + (640 \text{ W})(0.03^{\circ}\text{C}/\text{W}) = \mathbf{54.2^{\circ}\text{C}}$$

The junction temperature of the device can be determined similarly by using the junction-to-case thermal resistance of the device supplied by the manufacturer.

## 15-10 • IMMERSION COOLING

High-power electronic components can be cooled effectively by immersing them in a *dielectric liquid* and taking advantage of the very high heat transfer coefficients associated with boiling. Immersion cooling has been used since the 1940s in the cooling of electronic equipment, but for many years its

use was largely limited to the electronics of high-power radar systems. The miniaturization of electronic equipment and the resulting high heat fluxes brought about renewed interest in immersion cooling, which had been largely viewed as an exotic cooling technique.

You will recall from thermodynamics that, at a specified pressure, a fluid boils isothermally at the corresponding saturation temperature. A large amount of heat is absorbed during the boiling process, essentially in an isothermal manner. Therefore, immersion cooling also provides a constant-temperature bath for the electronic components and eliminates hot spots effectively.

The simplest type of immersion cooling system involves an *external reservoir* that supplies liquid continually to the electronic enclosure. The vapor generated inside is simply allowed to escape to the atmosphere, as shown in Fig. 15-59. A pressure relief valve on the vapor vent line keeps the pressure and thus the temperature inside at the preset value, just like the petcock of a pressure cooker. Note that without a pressure relief valve, the pressure inside the enclosure would be atmospheric pressure and the temperature would have to be the boiling temperature of the fluid at the atmospheric pressure.

The **open-loop**-type immersion cooling system described here is simple, but there are several impracticalities associated with it. First of all, it is heavy and bulky because of the presence of an external liquid reservoir, and the fluid lost through evaporation needs to be replenished continually, which adds to the cost. Further, the release of the vapor into the atmosphere greatly limits the fluids that can be used in such a system. Therefore, the use of open-loop immersion systems is limited to applications that involve occasional use and thus have a light duty cycle.

More sophisticated immersion cooling systems operate in a **closed loop** in that the vapor is condensed and returned to the electronic enclosure instead of being purged to the atmosphere. Schematics of two such systems are given in Fig. 15-60. The first system involves a condenser *external* to the electronics

**FIGURE 15-59**

A simple open-loop immersion cooling system.

(a) System with external condenser

(b) System with internal condenser

**FIGURE 15-60**

The schematics of two closed-loop immersion cooling systems.

**FIGURE 15-61**

The schematics of two all-liquid immersion cooling systems.

enclosure, and the vapor leaving the enclosure is cooled by a cooling fluid such as air or water outside the enclosure. The condensate is returned to the enclosure for reuse. The condenser in the second system is actually *submerged* in the electronic enclosure and is part of the electronic system. The cooling fluid in this case circulates through the condenser tube, removing heat from the vapor. The vapor that condenses drips on top of the liquid in the enclosure and continues to recirculate.

The performance of closed-loop immersion cooling systems is most susceptible to the presence of *noncondensable gases* such as air in the vapor space. An increase of 0.5 percent of air by mass in the vapor can cause the condensation heat transfer coefficient to drop by a factor of up to 5. Therefore, the fluid used in immersion cooling systems should be degassed as much as practical, and care should be taken during the filling process to avoid introducing any air into the system.

The problems associated with the condensation process and noncondensable gases can be avoided by *submerging* the condenser (actually, heat exchanger tubes in this case) in the *liquid* instead of the vapor in the electronic enclosure, as shown in Fig. 15-61a. The cooling fluid, such as water, circulating through the tubes absorbs heat from the dielectric liquid at the top portion of the enclosure and subcools it. The liquid in contact with the electronic components is heated and may even be vaporized as a result of absorbing heat from the components. But these vapor bubbles collapse as they move up, as a result of transferring heat to the cooler liquid with which they come in contact. This system can still remove heat at high rates from the surfaces of electronic components in an isothermal manner by utilizing the boiling process, but its overall capacity is limited by the rate of heat that can be removed by the external cooling fluid in a *liquid-to-liquid* heat exchanger. Noting that the heat transfer coefficients associated with forced convection are far less than those associated with condensation, this all-liquid immersion cooling system is not suitable for electronic boxes with very high power dissipation rates per unit volume.

A step further in the all-liquid immersion cooling systems is to remove the heat from the dielectric liquid directly from the *outer surface* of the electronics enclosure, as shown in Fig. 15-61b. In this case, the dielectric liquid inside

FIGURE 15-62

Typical heat transfer coefficients for various dielectric fluids.  
(From Hwang and Moran, 1981.)

the sealed enclosure is heated as a result of absorbing the heat dissipated by the electronic components. The heat is then transferred to the walls of the enclosure, where it is removed by external means. This immersion cooling technique is the most reliable of all since it does not involve any penetration into the electronics enclosure and the components reside in a completely sealed liquid environment. However, the use of this system is limited to applications that involve moderate power dissipation rates. The heat dissipation is limited by the ability of the system to reject the heat from the outer surface of the enclosure. To enhance this ability, the outer surfaces of the enclosures are often *finned*, especially when the enclosure is cooled by air.

Typical ranges of heat transfer coefficients for various dielectric fluids suitable for use in the cooling of electronic equipment are given in Fig. 15-62 for natural convection, forced convection, and boiling. Note that extremely high heat transfer coefficients (from about 1500 to 6000 W/m<sup>2</sup> · °C) can be attained with the boiling of *fluorocarbon fluids* such as FC78 and FC86 manufactured by the 3M company. Fluorocarbon fluids, not to be confused with the ozone-destroying fluorochloro fluids, are found to be very suitable for immersion cooling of electronic equipment. They have boiling points ranging from 30°C to 174°C and freezing points below –50°C. They are nonflammable, chemically inert, and highly compatible with materials used in electronic equipment.

Experimental results for the power dissipation of a chip having a heat transfer area of 0.457 cm<sup>2</sup> and its substrate during immersion cooling in an FC86 bath are given in Fig. 15-63. The FC86 liquid is maintained at a bulk temperature of 5°C during the experiments by the use of a heat exchanger. Heat transfer from the chip is by *natural convection* in regime A–B, and *bubble formation* and thus boiling begins in regime B–C. Note that the chip surface temperature suddenly drops with the onset of *boiling* because of the high heat transfer coefficients associated with boiling. Heat transfer is by *nucleate boiling* in regime C–D, and very high heat transfer rates can be achieved in this regime with relatively small temperature differences.

FIGURE 15-63

Heat transfer from a chip immersed in the fluorocarbon fluid FC86.  
(From Hwang and Moran, 1981.)

**FIGURE 15–64**

Schematic for Example 15–18.

### EXAMPLE 15–18 Immersion Cooling of a Logic Chip

A logic chip used in an IBM 3081 computer dissipates 4 W of power and has a heat transfer surface area of  $0.279 \text{ cm}^2$ , as shown in Fig. 15–64. If the surface of the chip is to be maintained at  $80^\circ\text{C}$  while being cooled by immersion in a dielectric fluid at  $20^\circ\text{C}$ , determine the necessary heat transfer coefficient and the type of cooling mechanism that needs to be used to achieve that heat transfer coefficient.

**SOLUTION** A logic chip is to be cooled by immersion in a dielectric fluid. The minimum heat transfer coefficient and the type of cooling mechanism are to be determined.

**Assumptions** Steady operating conditions exist.

**Analysis** The average heat transfer coefficient over the surface of the chip can be determined from Newton's law of cooling,

$$\dot{Q} = hA_s(T_{\text{chip}} - T_{\text{fluid}})$$

Solving for  $h$  and substituting the given values, the convection heat transfer coefficient is determined to be

$$h = \frac{\dot{Q}}{A_s(T_{\text{chip}} - T_{\text{fluid}})} = \frac{4 \text{ W}}{(0.279 \times 10^{-4} \text{ m}^2)(80 - 20)^\circ\text{C}} = 2390 \text{ W/m}^2 \cdot ^\circ\text{C}$$

which is rather high. Examination of Figure 15–62 reveals that we can obtain such high heat transfer coefficients with the boiling of fluorocarbon fluids. Therefore, a suitable cooling technique in this case is immersion cooling in such a fluid. A viable alternative to immersion cooling is the thermal conduction module discussed earlier.

### EXAMPLE 15–19 Cooling of a Chip by Boiling

An 8-W chip having a surface area of  $0.6 \text{ cm}^2$  is cooled by immersing it into FC86 liquid that is maintained at a temperature of  $15^\circ\text{C}$ , as shown in Fig. 15–65. Using the boiling curve in Fig. 15–63, estimate the temperature of the chip surface.

**SOLUTION** A chip is cooled by boiling in a dielectric fluid. The surface temperature of the chip is to be determined.

**Assumptions** The boiling curve in Fig. 15–63 is prepared for a chip having a surface area of  $0.457 \text{ cm}^2$  being cooled in FC86 maintained at  $5^\circ\text{C}$ . The chart can be used for similar cases with reasonable accuracy.

**Analysis** The heat flux is

$$\dot{q} = \frac{\dot{Q}}{A_s} = \frac{8 \text{ W}}{0.6 \text{ cm}^2} = 13.3 \text{ W/cm}^2$$

Corresponding to this value on the chart is  $T_{\text{chip}} - T_{\text{fluid}} = 60^\circ\text{C}$ . Therefore,

$$T_{\text{chip}} = T_{\text{fluid}} + 60 = 15 + 60 = 75^\circ\text{C}$$

That is, the surface of this 8-W chip will be at  $75^\circ\text{C}$  as it is cooled by boiling in the dielectric fluid FC86.

**FIGURE 15–65**

Schematic for Example 15–19.

A liquid-based cooling system brings with it the possibility of leakage and associated reliability concerns. Therefore, the consideration of immersion cooling should be limited to applications that require precise temperature control and those that involve heat dissipation rates that are too high for effective removal by conduction or air cooling.

## SUMMARY

Electric current flow through a resistance is always accompanied by heat generation, and the essence of thermal design is the safe removal of this internally generated heat by providing an effective path for heat flow from electronic components to the surrounding medium. In this chapter, we have discussed several *cooling techniques* commonly used in electronic equipment, such as conduction cooling, natural convection and radiation cooling, forced-air convection cooling, liquid cooling, immersion cooling, and heat pipes.

In a chip carrier, heat generated at the junction is conducted along the thickness of the chip, the bonding material, the lead frame, the case material, and the leads. The *junction-to-case thermal resistance*  $R_{\text{junction-case}}$  represents the total resistance to heat transfer between the junction of a component and its case. This resistance should be as low as possible to minimize the temperature rise of the junction above the case temperature. The epoxy board used in PCBs is a poor heat conductor, and so it is necessary to use copper cladding or to attach the PCB to a heat frame in conduction-cooled systems.

Low-power electronic systems can be cooled effectively with natural convection and radiation. The heat transfer from a surface at temperature  $T_s$  to a fluid at temperature  $T_{\text{fluid}}$  by *convection* is expressed as

$$\dot{Q}_{\text{conv}} = hA_s(T_s - T_{\text{fluid}})$$

where  $h$  is the convection heat transfer coefficient and  $A_s$  is the heat transfer surface area. The natural convection heat transfer coefficient for laminar flow of air at atmospheric pressure is given by a simplified relation of the form

$$h = K \left( \frac{\Delta T}{L_c} \right)^{0.25}$$

where  $\Delta T = T_s - T_{\text{fluid}}$  is the temperature difference between the surface and the fluid,  $L_c$  is the characteristic length (the length of the body along the heat flow path), and  $K$  is a constant, whose value is given in Table 15–1. The relations in Table 15–1 can also be used at pressures other than 1 atm by multiplying them by  $\sqrt{P}$ , where  $P$  is the air pressure in atm.

Radiation heat transfer between a surface at temperature  $T_s$  completely surrounded by a much larger surface at temperature  $T_{\text{surr}}$  can be expressed as

$$\dot{Q}_{\text{rad}} = \epsilon A_s \sigma (T_s^4 - T_{\text{surr}}^4)$$

where  $\epsilon$  is the emissivity of the surface,  $A_s$  is the heat transfer surface area, and  $\sigma$  is the Stefan–Boltzmann constant, whose value is  $\sigma = 5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4 = 0.1714 \times 10^{-8} \text{ Btu/h} \cdot \text{ft}^2 \cdot \text{R}^4$ .

Fluid flow over a body such as a transistor is called *external flow*, and flow through a confined space such as inside a tube or through the parallel passage area between two circuit boards in an enclosure is called *internal flow*. Fluid flow is also categorized as being *laminar* or *turbulent*, depending on the value of the Reynolds number. In convection analysis, the convection heat transfer coefficient is usually expressed in terms of the dimensionless *Nusselt number*  $\text{Nu}$  as

$$h = \frac{k}{D} \text{Nu}$$

where  $k$  is thermal conductivity of the fluid and  $D$  is the characteristic length of the geometry. Relations for the average Nusselt number based on experimental data are given in Table 15–2 for external flow and in Table 15–3 for laminar internal flow under the uniform heat flux condition, which is closely approximated by electronic equipment. In forced-air-cooled systems, the heat transfer can also be expressed as

$$\dot{Q} = \dot{m}c_p(T_{\text{out}} - T_{\text{in}})$$

where  $\dot{Q}$  is the rate of heat transfer to the air;  $c_p$  is the specific heat of air;  $T_{\text{in}}$  and  $T_{\text{out}}$  are the average temperatures of air at the inlet and exit of the enclosure, respectively; and  $\dot{m}$  is the mass flow rate of air.

The heat transfer coefficients associated with liquids are usually an order of magnitude higher than those associated with gases. Liquid cooling systems can be classified as *direct cooling* and *indirect cooling* systems. In direct cooling systems, the electronic components are in direct contact with the liquid, and thus the heat generated in the components is transferred directly to the liquid. In indirect cooling systems, however, there is no direct contact with the components. Liquid cooling systems are also classified as *closed-loop* and *open-loop* systems, depending on whether the liquid is discharged or recirculated after it is heated. Only *dielectric fluids* can be used in immersion or direct liquid cooling.

High-power electronic components can be cooled effectively by immersing them in a *dielectric liquid* and taking advantage of the very high heat transfer coefficients associated with boiling. The simplest type of immersion cooling system involves an

*external reservoir* that supplies liquid continually to the electronic enclosure. This *open-loop-type* immersion cooling system is simple but often impractical. Immersion cooling systems

usually operate in a *closed loop*, in that the vapor is condensed and returned to the electronic enclosure instead of being purged to the atmosphere.

## PROBLEMS\*

### Introduction and History

**15-1C** What invention started the electronic age? Why did the invention of the transistor mark the beginning of a revolution in that age?

**15-2C** What is an integrated circuit? What is its significance in the electronics era? What do the initials MSI, LSI, and VLSI stand for?

**15-3C** When electric current  $I$  passes through an electrical element having a resistance  $R$ , why is heat generated in the element? How is the amount of heat generation determined?

**15-4C** Consider a TV that is wrapped in the blankets from all sides except its screen. Explain what will happen when the TV is turned on and kept on for a long time, and why. What will happen if the TV is kept on for a few minutes only?

**15-5C** Consider an incandescent light bulb that is completely wrapped in a towel. Explain what will happen when the light is turned on and kept on. (P.S. Do not try this at home!)

**15-6C** A businessman ties a large cloth advertisement banner in front of his car such that it completely blocks the airflow to the radiator. What do you think will happen when he starts the car and goes on a trip?

\*Problems designated by a "C" are concept questions, and students are encouraged to answer them all. Problems designated by an "E" are in English units, and the SI users can ignore them.

**15-7C** Which is more likely to break: a car or a TV? Why?

**15-8C** Why do electronic components fail under prolonged use at high temperatures?

**15-9** The temperature of the case of a power transistor that is dissipating 12 W is measured to be 60°C. If the junction-to-case thermal resistance of this transistor is specified by the manufacturer to be 5°C/W, determine the junction temperature of the transistor. *Answer: 120°C*

**15-10** Power is supplied to an electronic component from a 12-V source, and the variation in the electric current, the junction temperature, and the case temperatures with time are observed. When everything is stabilized, the current is observed to be 0.15 A and the temperatures to be 80°C and 55°C at the junction and the case, respectively. Calculate the junction-to-case thermal resistance of this component.

**15-11** A logic chip used in a computer dissipates 6 W of power in an environment at 55°C and has a heat transfer surface area of 0.32 cm<sup>2</sup>. Assuming the heat transfer from the surface to be uniform, determine (a) the amount of heat this chip dissipates during an 8-h work day, in kWh, and (b) the heat flux on the surface of the chip, in W/cm<sup>2</sup>.

**15-12** A 15-cm × 20-cm circuit board houses 90 closely spaced logic chips, each dissipating 0.1 W, on its surface. If the heat transfer from the back surface of the board is negligible, determine (a) the amount of heat this circuit board dissipates during a 10-h period, in kWh, and (b) the heat flux on the surface of the circuit board, in W/cm<sup>2</sup>.

**FIGURE P15-12**

**15-13E** A resistor on a circuit board has a total thermal resistance of 130°F/W. If the temperature of the resistor is not to exceed 360°F, determine the power at which it can operate safely in an ambient at 120°F.

**15-14** Consider a 0.1-kΩ resistor whose surface-to-ambient thermal resistance is 300°C/W. If the voltage drop across the

resistor is 7.5 V and its surface temperature is not to exceed 150°C, determine the power at which it can operate safely in an ambient at 30°C. *Answer: 0.4 W*

**15-15** Reconsider Prob. 15-14. Using EES (or other) software, plot the power at which the resistor can operate safely as a function of the ambient temperature as the temperature varies from 20°C to 40°C, and discuss the results.

### Manufacturing of Electronic Equipment

**15-16C** Why is a chip in a chip carrier bonded to a lead frame instead of the plastic case of the chip carrier?

**15-17C** Draw a schematic of a chip carrier, and explain how heat is transferred from the chip to the medium outside of the chip carrier.

**15-18C** What does the junction-to-case thermal resistance represent? On what does it depend for a chip carrier?

**15-19C** What is a hybrid chip carrier? What are the advantages of hybrid electronic packages?

**15-20C** What is a PCB? Of what is the board of a PCB made? What does the “device-to-PCB edge” thermal resistance in conduction-cooled systems represent? Why is this resistance relatively high?

**15-21C** What are the three types of printed circuit boards? What are the advantages and disadvantages of each type?

**15-22C** What are the desirable characteristics of the materials used in the fabrication of the circuit boards?

**15-23C** What is an electronic enclosure? What is the primary function of the enclosure of an electronic system? Of what materials are the enclosures made?

### Cooling Load of Electronic Equipment and Thermal Environment

**15-24C** Consider an electronics box that consumes 120 W of power when plugged in. How is the heating load of this box determined?

**15-25C** Why is the development of superconducting materials generating so much excitement among designers of electronic equipment?

**15-26C** How is the duty cycle of an electronic system defined? How does the duty cycle affect the design and selection of a cooling technique for a system?

**15-27C** What is temperature cycling? How does it affect the reliability of electronic equipment?

**15-28C** What is the ultimate heat sink for (a) a TV, (b) an airplane, and (c) a ship? For each case, what is the range of temperature variation of the ambient?

**15-29C** What is the ultimate heat sink for (a) a DVD player, (b) a spacecraft, and (c) a communication system on top of a mountain? For each case, what is the range of temperature variation of the ambient?

### Electronics Cooling in Different Applications

**15–30C** How are the electronics of short-range and long-range missiles cooled?

**15–31C** What is dynamic temperature? What causes it? How is it determined? At what velocities is it significant?

**15–32C** How are the electronics of a ship or submarine cooled?

**15–33C** How are the electronics of the communication systems at remote areas cooled?

**15–34C** How are the electronics of high-power microwave equipment such as radars cooled?

**15–35C** How are the electronics of a space vehicle cooled?

**15–36** Consider an airplane cruising in the air at a temperature of  $-25^{\circ}\text{C}$  at a velocity of 850 km/h. Determine the temperature rise of air at the nose of the airplane as a result of the ramming effect of the air.

FIGURE P15–36

**15–37** The temperature of air in high winds is measured by a thermometer to be  $12^{\circ}\text{C}$ . Determine the true temperature of air if the wind velocity is 90 km/h. *Answer:  $11.7^{\circ}\text{C}$*

**15–38** Reconsider Prob. 15–37. Using EES (or other) software, plot the true temperature of air as a function of the wind velocity as the velocity varies from 20 km/h to 120 km/h, and discuss the results.

**15–39** Air at  $25^{\circ}\text{C}$  is flowing in a channel at a velocity of (a) 1, (b) 10, (c) 100, and (d) 1000 m/s. Determine the temperature that a stationary probe inserted into the channel will read for each case.

**15–40** An electronic device dissipates 2 W of power and has a surface area of  $5 \text{ cm}^2$ . If the surface temperature of the device is not to exceed the ambient temperature by more than  $50^{\circ}\text{C}$ , determine a suitable cooling technique for this device. Use Figure 15–17.

**15–41E** A stand-alone circuit board, 6 in  $\times$  8 in in size, dissipates 20 W of power. The surface temperature of the board is not to exceed  $165^{\circ}\text{F}$  in an  $85^{\circ}\text{F}$  environment. Using Fig. 15–17 as a guide, select a suitable cooling mechanism.

### Conduction Cooling

**15–42C** What are the major considerations in the selection of a cooling technique for electronic equipment?

**15–43C** What is thermal resistance? To what is it analogous in electrical circuits? Can thermal resistance networks be analyzed like electrical circuits? Explain.

**15–44C** If the rate of heat conduction through a medium and the thermal resistance of the medium are known, how can the temperature difference between the two sides of the medium be determined?

**15–45C** Consider a wire of electrical resistance  $R$ , length  $L$ , and cross-sectional area  $A$  through which electric current  $I$  is flowing. How is the voltage drop across the wire determined? What happens to the voltage drop when  $L$  is doubled while  $I$  is held constant?

Now consider heat conduction at a rate of  $\dot{Q}$  through the same wire having a thermal resistance of  $R$ . How is the temperature drop across the wire determined? What happens to the temperature drop when  $L$  is doubled while  $\dot{Q}$  is held constant?

FIGURE P15–45C

**15–46C** What is a heat frame? How does it enhance heat transfer along a PCB? Which components on a PCB attached to a heat frame operate at the highest temperatures: those at the middle of the PCB or those near the edge?

**15–47C** What is constriction resistance in heat flow? To what is it analogous in fluid flow through tubes and electric current flow in wires?

**15–48C** What does the junction-to-case thermal resistance of an electronic component represent? In practice, how is this value determined? How can the junction temperature of a component be determined when the case temperature, the power dissipation of the component, and the junction-to-case thermal resistance are known?

**15–49C** What does the case-to-ambient thermal resistance of an electronic component represent? In practice, how is this value determined? How can the case temperature of a component be determined when the ambient temperature, the power dissipation of the component, and the case-to-ambient thermal resistance are known?

**15–50C** Consider an electronic component whose junction-to-case thermal resistance  $R_{\text{junction-case}}$  is provided by the manufacturer and whose case-to-ambient thermal resistance  $R_{\text{case-ambient}}$  is determined by the thermal designer. When the power dissipation of the component and the ambient temperature are known, explain how the junction temperature can be determined. When  $R_{\text{junction-case}}$  is greater than  $R_{\text{case-ambient}}$ , will the case temperature be closer to the junction or ambient temperature?

**15–51C** Why is the rate of heat conduction along a PCB very low? How can heat conduction from the mid-parts of a PCB to

its outer edges be improved? How can heat conduction across the thickness of the PCB be improved?

**15-52C** Why is the warping of epoxy boards that are copper cladded on one side a major concern? What is the cause of this warping? How can the warping of PCBs be avoided?

**15-53C** Why did the thermal conduction module receive so much attention from thermal designers of electronic equipment? How does the design of TCM differ from traditional chip carrier design? Why is the cavity in the TCM filled with helium instead of air?

**15-54** Consider a chip dissipating 0.8 W of power in a DIP with 18 pin leads. The materials and the dimensions of various sections of this electronic device are given in the table. If the temperature of the leads is 50°C, estimate the temperature at the junction of the chip.

| Section and Material  | Thermal Conductivity, Thickness, Heat Transfer Surface Area |      |                     |
|-----------------------|---|------|---------------------|
|                       | W/m · °C  | mm   |                     |
| Junction constriction | —   | —    | Diameter 0.5 mm     |
| Silicon chip          | 120   | 0.5  | 4 mm × 4 mm         |
| Eutectic bond         | 296   | 0.05 | 4 mm × 4 mm         |
| Copper lead frame     | 386   | 0.25 | 4 mm × 4 mm         |
| Plastic separator     | 1   | 0.3  | 18 × 1 mm × 0.25 mm |
| Copper leads          | 386   | 6    | 18 × 1 mm × 0.25 mm |

FIGURE P15-54

**15-55** A fan blows air at 25°C over a 2-W plastic DIP with 16 leads mounted on a PCB at a velocity of 300 m/min. Using data from Fig. 15-23, determine the junction temperature of the electronic device. What would the junction temperature be if the fan were to fail?

**15-56** Heat is to be conducted along a PCB with copper cladding on one side. The PCB is 12 cm long and 12 cm wide,

FIGURE P15-56

and the thicknesses of the copper and epoxy layers are 0.06 mm and 0.5 mm, respectively. Disregarding heat transfer from the side surfaces, determine the percentages of heat conduction along the copper ( $k = 386 \text{ W/m} \cdot \text{°C}$ ) and epoxy ( $k = 0.26 \text{ W/m} \cdot \text{°C}$ ) layers. Also, determine the effective thermal conductivity of the PCB.

*Answers:* 0.6 percent, 99.4 percent, 41.6  $\text{W/m} \cdot \text{°C}$

**15-57** Reconsider Prob. 15-56. Using EES (or other) software, investigate the effect of the thickness of the copper layer on the percentage of heat conducted along the copper layer and the effective thermal conductivity of the PCB. Let the thickness vary from 0.02 mm to 0.10 mm. Plot the percentage of heat conducted along the copper layer and the effective thermal conductivity as a function of the thickness of the copper layer, and discuss the results.

**15-58** The heat generated in the circuitry on the surface of a silicon chip ( $k = 130 \text{ W/m} \cdot \text{°C}$ ) is conducted to the ceramic substrate to which it is attached. The chip is 6 mm × 6 mm in size and 0.5-mm thick and dissipates 3 W of power. Determine the temperature difference between the front and back surfaces of the chip in steady operation.

**15-59E** Consider a 6-in × 7-in glass–epoxy laminate ( $k = 0.15 \text{ Btu/h} \cdot \text{ft} \cdot \text{°F}$ ) whose thickness is 0.05 in. Determine the thermal resistance of this epoxy layer for heat flow (a) along the 7-in-long side and (b) across its thickness.

**15-60** Consider a 15-cm × 18-cm glass–epoxy laminate ( $k = 0.26 \text{ W/m} \cdot \text{°C}$ ) whose thickness is 1.4 mm. In order to reduce the thermal resistance across its thickness, cylindrical copper fillings ( $k = 386 \text{ W/m} \cdot \text{°C}$ ) of diameter 1 mm are to be planted throughout the board with a center-to-center distance of 3 mm. Determine the new value of the thermal resistance of the epoxy board for heat conduction across its thickness as a result of this modification.

**15-61** Reconsider Prob. 15-60. Using EES (or other) software, investigate the effects of the thermal conductivity and the diameter of the filling material on the thermal resistance of the epoxy board. Let the thermal conductivity vary from 10  $\text{W/m} \cdot \text{°C}$  to 400  $\text{W/m} \cdot \text{°C}$  and the diameter from 0.5 mm to 2.0 mm. Plot the thermal resistance as

functions of the thermal conductivity and the diameter, and discuss the results.

**15-62** A 12-cm  $\times$  15-cm circuit board dissipating 45 W of heat is to be conduction-cooled by a 1.5-mm-thick copper heat frame ( $k = 386 \text{ W/m} \cdot ^\circ\text{C}$ ) 12 cm  $\times$  17 cm in size. The epoxy laminate ( $k = 0.26 \text{ W/m} \cdot ^\circ\text{C}$ ) has a thickness of 2 mm and is attached to the heat frame with conductive epoxy adhesive ( $k = 1.8 \text{ W/m} \cdot ^\circ\text{C}$ ) of thickness 0.12 mm. The PCB is attached to a heat sink by clamping a 5-mm-wide portion of the edge to the heat sink from both ends. The temperature of the heat frame at this point is 30°C. Heat is uniformly generated on the PCB at a rate of 3 W per 1-cm  $\times$  12-cm strip. Considering only one-half of the PCB board because of symmetry, determine the maximum surface temperature on the PCB and the temperature distribution along the heat frame.

FIGURE P15-62

**15-63** Consider a 15-cm  $\times$  20-cm double-sided circuit board dissipating a total of 30 W of heat. The board consists of a 3-mm-thick epoxy layer ( $k = 0.26 \text{ W/m} \cdot ^\circ\text{C}$ ) with 1-mm-diameter aluminum wires ( $k = 237 \text{ W/m} \cdot ^\circ\text{C}$ ) inserted along the 20-cm-long direction, as shown in Fig. P15-63. The distance between the centers of the aluminum wires is 2 mm. The circuit board is attached to a heat sink from both ends, and the temperature of the board at both ends is 30°C. Heat is considered to be uniformly generated on both sides of the epoxy layer

FIGURE P15-63

of the PCB. Considering only a portion of the PCB because of symmetry, determine the magnitude and location of the maximum temperature that occurs in the PCB. *Answer: 88.7°C*

**15-64** Repeat Prob. 15-63, replacing the aluminum wires by copper wires ( $k = 386 \text{ W/m} \cdot ^\circ\text{C}$ ).

**15-65** Repeat Prob. 15-63 for a center-to-center distance of 4 mm instead of 2 mm between the wires.

**15-66** Consider a thermal conduction module with 80 chips, each dissipating 4 W of power. The module is cooled by water at 18°C flowing through the cold plate on top of the module. The thermal resistances in the path of heat flow are  $R_{\text{chip}} = 12^\circ\text{C/W}$  between the junction and the surface of the chip,  $R_{\text{int}} = 9^\circ\text{C/W}$  between the surface of the chip and the outer surface of the thermal conduction module, and  $R_{\text{ext}} = 7^\circ\text{C/W}$  between the outer surface of the module and the cooling water. Determine the junction temperature of the chip.

**15-67** Consider a 0.3-mm-thick epoxy board ( $k = 0.26 \text{ W/m} \cdot ^\circ\text{C}$ ) that is 15 cm  $\times$  20 cm in size. Now a 0.1-mm-thick layer of copper ( $k = 386 \text{ W/m} \cdot ^\circ\text{C}$ ) is attached to the back surface of the PCB. Determine the effective thermal conductivity of the PCB along its 20-cm-long side. What fraction of the heat conducted along that side is conducted through copper?

**15-68** A 0.5-mm-thick copper plate ( $k = 386 \text{ W/m} \cdot ^\circ\text{C}$ ) is sandwiched between two 3-mm-thick epoxy boards ( $k = 0.26 \text{ W/m} \cdot ^\circ\text{C}$ ) that are 12 cm  $\times$  18 cm in size. Determine the effective thermal conductivity of the PCB along its 18-cm-long side. What fraction of the heat conducted along that side is conducted through copper?

FIGURE P15-68

**15-69E** A 6-in  $\times$  8-in  $\times$  0.06-in copper heat frame is used to conduct 20 W of heat generated in a PCB along the

8-in-long side toward the ends. Determine the temperature difference between the midsection and either end of the heat frame. *Answer: 12.8°F*

**15-70** A 12-W power transistor is cooled by mounting it on an aluminum bracket ( $k = 237 \text{ W/m} \cdot \text{°C}$ ) that is attached to a liquid-cooled plate by 0.2-mm-thick epoxy adhesive ( $k = 1.8 \text{ W/m} \cdot \text{°C}$ ), as shown in Fig. P15-70. The thermal resistance of the plastic washer is given as  $2.5^\circ\text{C/W}$ . Preliminary calculations show that about 20 percent of the heat is dissipated by convection and radiation, and the rest is conducted to the liquid-cooled plate. If the temperature of the cold plate is  $50^\circ\text{C}$ , determine the temperature of the transistor case.

FIGURE P15-70

### Air Cooling: Natural Convection and Radiation

**15-71C** A student puts his books on top of a DVD player, completely blocking the air vents on the top surface. What do you think will happen as the student watches a rented movie played by that DVD player?

**15-72C** Can a low-power electronic system in space be cooled by natural convection? Can it be cooled by radiation? Explain.

**15-73C** Why are there several openings on the various surfaces of a TV, DVD player, and other electronic enclosures? What happens if a TV or DVD player is enclosed in a cabinet with no free air space around?

**15-74C** Why should radiation heat transfer always be considered in the analysis of natural convection-cooled electronic equipment?

**15-75C** How does atmospheric pressure affect natural convection heat transfer? What are the best and worst orientations for heat transfer from a square surface?

**15-76C** What is view factor? How does it affect radiation heat transfer between two surfaces?

**15-77C** What is emissivity? How does it affect radiation heat transfer between two surfaces?

**15-78C** For most effective natural convection cooling of a PCB array, should the PCBs be placed horizontally or vertically? Should they be placed close to each other or far from each other?

**15-79C** Why is radiation heat transfer from the components on the PCBs in an enclosure negligible?

**15-80** Consider a sealed 20-cm-high electronic box whose base dimensions are  $35 \text{ cm} \times 50 \text{ cm}$  that is placed on top of a stand in a room at  $30^\circ\text{C}$ . The emissivity of the outer surface of the box is 0.85. If the electronic components in the box dissipate a total of 100 W of power and the outer surface temperature of the box is not to exceed  $65^\circ\text{C}$ , determine if this box can be cooled by natural convection and radiation alone. Assume the heat transfer from the bottom surface of the box to the stand to be negligible, and the temperature of the surrounding surfaces to be the same as the air temperature of the room.

FIGURE P15-80

**15-81** Repeat Prob. 15-80, assuming the box is mounted on a wall instead of a stand such that it is 0.5 m high. Again, assume heat transfer from the bottom surface to the wall to be negligible.

**15-82E** A 0.15-W small cylindrical resistor mounted on a circuit board is 0.5 in long and has a diameter of 0.15 in. The view of the resistor is largely blocked by the circuit board facing it, and the heat transfer from the connecting wires is negligible. The air is free to flow through the parallel flow passages between the PCBs as a result of natural convection currents. If the air temperature in the vicinity of the resistor is  $130^\circ\text{F}$ , determine the surface temperature of the resistor.

*Answer: 194°F*

**15-83** A 14-cm  $\times$  20-cm PCB has electronic components on one side, dissipating a total of 7 W. The PCB is mounted in a rack vertically (height 14 cm) together with other PCBs (Fig. P15-83 on the next page). If the surface temperature of the components is not to exceed  $90^\circ\text{C}$ , determine the maximum temperature of the environment in which this PCB can operate safely at sea level. What would your answer be if this rack is located at a location at 3000 m altitude where the atmospheric pressure is 70.12 kPa?

FIGURE P15-83

**15-84** A cylindrical electronic component whose diameter is 2 cm and length is 4 cm is mounted on a board with its axis in the vertical direction and is dissipating 3 W of power. The emissivity of the surface of the component is 0.8, and the temperature of the ambient air is 30°C. Assuming the temperature of the surrounding surfaces to be 20°C, determine the average surface temperature of the component under combined natural convection and radiation cooling.

**15-85** Repeat Prob. 15-84, assuming the component is oriented horizontally.

**15-86** Reconsider Prob. 15-84. Using EES (or other) software, investigate the effects of surface emissivity and ambient temperature on the average surface temperature of the component. Let the emissivity vary from 0.1 to 1.0 and the ambient temperature from 15°C to 35°C. Take the temperature of the surrounding surfaces to be 10°C smaller than the ambient air temperature. Plot the average surface temperature as functions of the emissivity and the ambient air temperature, and discuss the results.

**15-87** Consider a power transistor that dissipates 0.1 W of power in an environment at 30°C. The transistor is 0.4 cm long and has a diameter of 0.4 cm. Assuming heat to be transferred uniformly from all surfaces, determine (a) the heat flux on the surface of the transistor, in  $\text{W}/\text{cm}^2$ , and (b) the surface temperature of the transistor for a combined convection and radiation heat transfer coefficient of  $18 \text{ W}/\text{m}^2 \cdot ^\circ\text{C}$ .

**15-88** The components of an electronic system dissipating 150 W are located in a 1-m-long horizontal duct whose cross section is 15 cm × 15 cm. The components in the duct are cooled by forced air, which enters at 30°C at a rate of  $0.4 \text{ m}^3/\text{min}$  and leaves at 45°C. The surfaces of the sheet metal duct are not painted, and thus radiation heat transfer from the

outer surfaces is negligible. If the ambient air temperature is 25°C, determine (a) the heat transfer from the outer surfaces of the duct to the ambient air by natural convection and (b) the average temperature of the duct.

*Answers: (a) 31.7 W, (b) 40°C*

FIGURE P15-88

**15-89** Repeat Prob. 15-88 for a circular horizontal duct of diameter 10 cm.

**15-90** Reconsider Prob. 15-88. Using EES (or other) software, investigate the effects of the volume flow rate of air and the side-length of the duct on heat transfer by natural convection and the average temperature of the duct. Let the flow rate vary from  $0.1 \text{ m}^3/\text{min}$  to  $0.5 \text{ m}^3/\text{min}$ , and the side-length from 10 cm to 20 cm. Plot the heat transfer rate by natural convection and the average duct temperature as functions of flow rate and side-length, and discuss the results.

**15-91** Repeat Prob. 15-88, assuming that the fan fails and thus the entire heat generated inside the duct must be rejected to the ambient air by natural convection from the outer surfaces of the duct.

**15-92** A 20-cm × 20-cm circuit board containing 81 square chips on one side is to be cooled by combined natural convection

FIGURE P15-92

and radiation by mounting it on a vertical surface in a room at 25°C. Each chip dissipates 0.08 W of power, and the emissivity of the chip surfaces is 0.65. Assuming the heat transfer from the back side of the circuit board to be negligible and the temperature of the surrounding surfaces to be the same as the air temperature of the room, determine the surface temperature of the chips.

**15-93** Repeat Prob. 15-92, assuming the circuit board to be positioned horizontally with (a) chips facing up and (b) chips facing down.

### Air Cooling: Forced Convection

**15-94C** Why is radiation heat transfer in forced-air-cooled systems disregarded?

**15-95C** If an electronic system can be cooled adequately by either natural convection or forced-air convection, which would you prefer? Why?

**15-96C** Why is forced convection cooling much more effective than natural convection cooling?

**15-97C** Consider a forced-air-cooled electronic system dissipating a fixed amount of power. How will increasing the flow rate of air affect the surface temperature of the components? Explain. How will it affect the exit temperature of the air?

**15-98C** To what do internal and external flow refer in forced convection cooling? Give an example of a forced-air-cooled electronic system that involves both types of flow.

**15-99C** For a specified power dissipation and air inlet temperature, how does the convection heat transfer coefficient affect the surface temperature of the electronic components? Explain.

**15-100C** How does high altitude affect forced convection heat transfer? How would you modify your forced-air cooling system to operate at high altitudes safely?

**15-101C** What are the advantages and disadvantages of placing the cooling fan at the inlet or at the exit of an electronic box?

**15-102C** How is the volume flow rate of air in a forced-air-cooled electronic system that has a constant-speed fan established? If a few more PCBs are added to the box while keeping the fan speed constant, will the flow rate of air through the system change? Explain.

**15-103C** What happens if we attempt to cool an electronic system with an undersized fan? What about if we do that with an oversized fan?

**15-104** Consider a hollow-core PCB that is 15 cm high and 20 cm long, dissipating a total of 30 W. The width of the air gap in the middle of the PCB is 0.25 cm. The cooling air enters the core at 30°C at a rate of 1 L/s. Assuming the heat generated to be uniformly distributed over the two side surfaces of the

PCB, determine (a) the temperature at which the air leaves the hollow core and (b) the highest temperature on the inner surface of the core. *Answers: (a) 56.4°C, (b) 67.6°C*

FIGURE P15-104

**15-105** Repeat Prob. 15-104 for a hollow-core PCB dissipating 45 W.

**15-106** Reconsider Prob. 15-104. Using EES (or other) software, investigate the effects of the power rating of the PCB and the volume flow rate of the air on the exit temperature of the air and the maximum temperature on the inner surface of the core. Let the power vary from 20 W to 60 W and the flow rate from 0.5 L/s to 2.5 L/s. Plot the air exit temperature and the maximum surface temperature of the core as functions of power and flow rate, and discuss the results.

**15-107E** A transistor with a height of 0.25 in and a diameter of 0.2 in is mounted on a circuit board. The transistor is cooled by air flowing over it at a velocity of 400 ft/min. If the air temperature is 140°F and the transistor case temperature is not to exceed 175°F, determine the amount of power this transistor can dissipate safely. *Answer: 0.15 W*

**15-108** A desktop computer is to be cooled by a fan. The electronic components of the computer consume 75 W of power under full-load conditions. The computer is to operate in environments at temperatures up to 45°C and at elevations up to 3400 m where the atmospheric pressure is 66.63 kPa. The exit temperature of air is not to exceed 60°C to meet reliability requirements. Also, the average velocity of air is not to exceed 110 m/min at the exit of the computer case, where the fan is installed to keep the noise level down. Determine the flow rate of the fan that needs to be installed and the diameter of the casing of the fan.

**15-109** Repeat Prob. 15-108 for a computer that consumes 100 W of power.

**15-110** A computer cooled by a fan contains eight PCBs, each dissipating 12 W of power. The height of the PCBs is 12 cm and the length is 18 cm. The clearance between the tips of the components on the PCB and the back surface of the

adjacent PCB is 0.3 cm. The cooling air is supplied by a 15-W fan mounted at the inlet. If the temperature rise of air as it flows through the case of the computer is not to exceed 15°C, determine (a) the flow rate of the air that the fan needs to deliver, (b) the fraction of the temperature rise of air due to the heat generated by the fan and its motor, and (c) the highest allowable inlet air temperature if the surface temperature of the components is not to exceed 90°C anywhere in the system.

**FIGURE P15–110**

**15–111** An array of power transistors, each dissipating 2 W of power, is to be cooled by mounting them on a 20-cm × 20-cm square aluminum plate and blowing air over the plate with a fan at 30°C with a velocity of 3 m/s. The average temperature of the plate is not to exceed 60°C. Assuming the heat transfer from the back side of the plate to be negligible, determine the number of transistors that can be placed on this plate. *Answer: 9*

**FIGURE P15–111**

**15–112** Repeat Prob. 15–111 for a location at an elevation of 1610 m where the atmospheric pressure is 83.4 kPa.

**15–113** Reconsider Prob. 15–111. Using EES (or other) software, investigate the effects of air velocity and the maximum plate temperature on the number of transistors. Let the air velocity vary from 1 m/s to 8 m/s and the maximum plate temperature from 40°C to 80°C. Plot the

number of transistors as functions of air velocity and maximum plate temperature, and discuss the results.

**15–114** An enclosure contains an array of circuit boards, 15 cm high and 20 cm long. The clearance between the tips of the components on the PCB and the back surface of the adjacent PCB is 0.3 cm. Each circuit board contains 75 square chips on one side, each dissipating 0.15 W of power. Air enters the space between the boards through the 0.3-cm × 15-cm cross section at 40°C with a velocity of 300 m/min. Assuming the heat transfer from the back side of the circuit board to be negligible, determine the exit temperature of the air and the highest surface temperature of the chips.

**15–115** The components of an electronic system dissipating 120 W are located in a 1-m-long horizontal duct whose cross section is 20 cm × 20 cm. The components in the duct are cooled by forced air, which enters at 30°C at a rate of 0.5 m<sup>3</sup>/min. Assuming 80 percent of the heat generated inside is transferred to air flowing through the duct and the remaining 20 percent is lost through the outer surfaces of the duct, determine (a) the exit temperature of air and (b) the highest component surface temperature in the duct.

**15–116** Repeat Prob. 15–115 for a circular horizontal duct of diameter 10 cm.

### Liquid Cooling

**15–117C** If an electronic system can be cooled adequately by either forced-air cooling or liquid cooling, which one would you prefer? Why?

**15–118C** Explain how direct and indirect liquid cooling systems differ from each other.

**15–119C** Explain how closed-loop and open-loop liquid cooling systems operate.

**15–120C** What are the properties of a liquid ideally suited for cooling electronic equipment?

**15–121** A cold plate that supports 10 power transistors, each dissipating 40 W, is to be cooled with water. It is specified that the temperature rise of the water not exceed 4°C and the velocity of water remain under 0.5 m/s. Assuming 25 percent of the heat generated is dissipated from the components to the surroundings by convection and radiation, and the remaining 75 percent is removed by the cooling water, determine the mass

**FIGURE P15–121**

flow rate of water needed and the diameter of the pipe to satisfy the restriction imposed on the flow velocity. Also, determine the case temperature of the devices if the total case-to-liquid thermal resistance is  $0.04^{\circ}\text{C}/\text{W}$  and the water enters the cold plate at  $25^{\circ}\text{C}$ .

**15-122**  Reconsider Prob. 15-121. Using EES (or other) software, investigate the effect of the maximum temperature rise of the water on the mass flow rate of water, the diameter of the pipe, and the case temperature. Let the maximum temperature rise vary from  $1^{\circ}\text{C}$  to  $10^{\circ}\text{C}$ . Plot the mass flow rate, the diameter, and the case temperature as a function of the temperature rise, and discuss the results.

**15-123E** Water enters the tubes of a cold plate at  $95^{\circ}\text{F}$  with an average velocity of  $60 \text{ ft}/\text{min}$  and leaves at  $105^{\circ}\text{F}$ . The diameter of the tubes is  $0.25 \text{ in}$ . Assuming 15 percent of the heat generated is dissipated from the components to the surroundings by convection and radiation, and the remaining 85 percent is removed by the cooling water, determine the amount of heat generated by the electronic devices mounted on the cold plate.

*Answer:*  $263 \text{ W}$

**15-124** A sealed electronic box is to be cooled by tap water flowing through channels on two of its sides. It is specified that the temperature rise of the water not exceed  $3^{\circ}\text{C}$ . The power dissipation of the box is  $2 \text{ kW}$ , which is removed entirely by water. If the box operates  $24 \text{ h}$  a day,  $365 \text{ days}$  a year, determine the mass flow rate of water flowing through the box and the amount of cooling water used per year.

**15-125** Repeat Prob. 15-124 for a power dissipation of  $3 \text{ kW}$ .

### Immersion Cooling

**15-126C** What are the desirable characteristics of a liquid used in immersion cooling of electronic devices?

**15-127C** How does an open-loop immersion cooling system operate? How does it differ from closed-loop cooling systems?

**15-128C** How do immersion cooling systems with internal and external cooling differ? Why are externally cooled systems limited to relatively low-power applications?

**15-129C** Why is boiling heat transfer used in the cooling of very high-power electronic devices instead of forced air or liquid cooling?

**15-130** A logic chip used in a computer dissipates  $4 \text{ W}$  of power and has a heat transfer surface area of  $0.3 \text{ cm}^2$ . If the surface of the chip is to be maintained at  $70^{\circ}\text{C}$  while being cooled by immersion in a dielectric fluid at  $20^{\circ}\text{C}$ , determine the necessary heat transfer coefficient and the type of cooling mechanism that needs to be used to achieve that heat transfer coefficient.

**15-131** A  $6\text{-W}$  chip having a surface area of  $0.5 \text{ cm}^2$  is cooled by immersing it into FC86 liquid that is maintained at a

temperature of  $25^{\circ}\text{C}$ . Using the boiling curve in Fig. 15-63, estimate the temperature of the chip surface. *Answer:*  $82^{\circ}\text{C}$

**15-132** A logic chip cooled by immersing it in a dielectric liquid dissipates  $3.5 \text{ W}$  of power in an environment at  $50^{\circ}\text{C}$  and has a heat transfer surface area of  $0.8 \text{ cm}^2$ . The surface temperature of the chip is measured to be  $95^{\circ}\text{C}$ . Assuming the heat transfer from the surface to be uniform, determine (a) the heat flux on the surface of the chip, in  $\text{W}/\text{cm}^2$ , (b) the heat transfer coefficient on the surface of the chip, in  $\text{W}/\text{m}^2 \cdot {^{\circ}\text{C}}$ , and (c) the thermal resistance between the surface of the chip and the cooling medium, in  $^{\circ}\text{C}/\text{W}$ .

FIGURE P15-132

**15-133**  Reconsider Prob. 15-132. Using EES (or other) software, investigate the effect of chip power on the heat flux, the heat transfer coefficient, and the convection resistance on chip surface. Let the power vary from  $2 \text{ W}$  to  $10 \text{ W}$ . Plot the heat flux, the heat transfer coefficient, and the thermal resistance as a function of power dissipated, and discuss the results.

**15-134** A computer chip dissipates  $5 \text{ W}$  of power and has a heat transfer surface area of  $0.4 \text{ cm}^2$ . If the surface of the chip is to be maintained at  $55^{\circ}\text{C}$  while being cooled by immersion in a dielectric fluid at  $10^{\circ}\text{C}$ , determine the necessary heat transfer coefficient and the type of cooling mechanism that needs to be used to achieve that heat transfer coefficient.

**15-135** A  $3\text{-W}$  chip having a surface area of  $0.2 \text{ cm}^2$  is cooled by immersing it into FC86 liquid that is maintained at a temperature of  $45^{\circ}\text{C}$ . Using the boiling curve in Fig. 15-63, estimate the temperature of the chip surface. *Answer:*  $108^{\circ}\text{C}$

**15-136** A logic chip having a surface area of  $0.3 \text{ cm}^2$  is to be cooled by immersing it into FC86 liquid that is maintained at a temperature of  $35^{\circ}\text{C}$ . The surface temperature of the chip is not to exceed  $60^{\circ}\text{C}$ . Using the boiling curve in Fig. 15-63, estimate the maximum power that the chip can dissipate safely.

**15-137** A  $2\text{-kW}$  electronic device that has a surface area of  $120 \text{ cm}^2$  is to be cooled by immersing it in a dielectric fluid with a boiling temperature of  $60^{\circ}\text{C}$  contained in a  $1\text{-m} \times 1\text{-m} \times 1\text{-m}$

cubic enclosure. Noting that the combined natural convection and the radiation heat transfer coefficients in air are typically about  $10 \text{ W/m}^2 \cdot ^\circ\text{C}$ , determine if the heat generated inside can be dissipated to the ambient air at  $20^\circ\text{C}$  by natural convection and radiation. If it cannot, explain what modification you could make to allow natural convection cooling.

Also, determine the heat transfer coefficients at the surface of the electronic device for a surface temperature of  $80^\circ\text{C}$ . Assume the liquid temperature remains constant at  $60^\circ\text{C}$  throughout the enclosure.

FIGURE P15-137

### Review Problems

**15-138C** Several power transistors are to be cooled by mounting them on a water-cooled metal plate. The total power dissipation, the mass flow rate of water through the tube, and the water inlet temperature are fixed. Explain what you would do for the most effective cooling of the transistors.

**15-139C** Consider heat conduction along a vertical copper bar whose sides are insulated. One person claims that the bar should be oriented such that the hot end is at the bottom and the cold end is at the top for better heat transfer, since heat rises. Another person claims that it makes no difference to heat conduction whether heat is conducted downward or upward, and thus the orientation of the bar is irrelevant. With which person do you agree?

**15-140** Consider a  $15\text{-cm} \times 15\text{-cm}$  multilayer circuit board dissipating  $22.5 \text{ W}$  of heat. The board consists of four layers of  $0.1\text{-mm-thick}$  copper ( $k = 386 \text{ W/m} \cdot ^\circ\text{C}$ ) and three layers of  $0.5\text{-mm-thick}$  glass-epoxy ( $k = 0.26 \text{ W/m} \cdot ^\circ\text{C}$ ) sandwiched together, as shown in Fig. P15-140. The circuit board is attached to a heat sink from both ends, and the temperature of the board at those ends is  $35^\circ\text{C}$ . Heat is considered to be uniformly generated in the epoxy layers of the PCB at a rate of  $0.5 \text{ W}$  per  $1\text{-cm} \times 15\text{-cm}$  epoxy laminate strip (or  $1.5 \text{ W}$  per  $1\text{-cm} \times 15\text{-cm}$  strip of the board). Considering only a portion of the PCB because of symmetry, determine the magnitude and location of the maximum temperature that occurs in the PCB. Assume

heat transfer from the top and bottom faces of the PCB to be negligible. *Answer:  $55.5^\circ\text{C}$*

FIGURE P15-140

**15-141** Repeat Prob. 15-140, assuming that the board consists of a single  $1.5\text{-mm-thick}$  layer of glass-epoxy, with no copper layers.

**15-142** The components of an electronic system that is dissipating  $150 \text{ W}$  are located in a  $1\text{-m-long}$  horizontal duct whose cross section is  $10 \text{ cm} \times 10 \text{ cm}$ . The components in the duct are cooled by forced air, which enters at  $30^\circ\text{C}$  and  $50 \text{ m/min}$  and leaves at  $45^\circ\text{C}$ . The surfaces of the sheet metal duct are not painted, and so radiation heat transfer from the outer surfaces is negligible. If the ambient air temperature is  $30^\circ\text{C}$ , determine (a) the heat transfer from the outer surfaces of the duct to the ambient air by natural convection, (b) the average temperature of the duct, and (c) the highest component surface temperature in the duct.

**15-143** Two  $10\text{-W}$  power transistors are cooled by mounting them on the two sides of an aluminum bracket ( $k = 237 \text{ W/m} \cdot ^\circ\text{C}$ ) that is attached to a liquid-cooled plate by  $0.2\text{-mm-thick}$  epoxy adhesive ( $k = 1.8 \text{ W/m} \cdot ^\circ\text{C}$ ), as shown in Fig. P15-143. The thermal resistance of each plastic washer is

FIGURE P15-143

given as  $2^{\circ}\text{C/W}$ , and the temperature of the cold plate is  $40^{\circ}\text{C}$ . The surface of the aluminum plate is untreated, and thus radiation heat transfer from it is negligible because of the low emissivity of aluminum surfaces. Disregarding heat transfer from the 0.3-cm-wide edges of the aluminum plate, determine the surface temperature of the transistor case. Also, determine the fraction of heat dissipation to the ambient air by natural convection and to the cold plate by conduction. Take the ambient temperature to be  $25^{\circ}\text{C}$ .

**15-144E** A fan blows air at  $70^{\circ}\text{F}$  and a velocity of 500 ft/min over a 1.5-W plastic DIP with 24 leads mounted on a PCB. Using data from Fig. 15-23, determine the junction temperature of the electronic device. What would the junction temperature be if the fan were to fail?

**15-145** A 15-cm  $\times$  18-cm double-sided circuit board dissipating a total of 18 W of heat is to be conduction-cooled by a 1.2-mm-thick aluminum core plate ( $k = 237 \text{ W/m} \cdot ^{\circ}\text{C}$ ) sandwiched between two epoxy laminates ( $k = 0.26 \text{ W/m} \cdot ^{\circ}\text{C}$ ). Each epoxy layer has a thickness of 0.5 mm and is attached to the aluminum core plate with conductive epoxy adhesive ( $k = 1.8 \text{ W/m} \cdot ^{\circ}\text{C}$ ) of thickness 0.1 mm. Heat is uniformly generated on each side of the PCB at a rate of 0.5 W per 1-cm  $\times$  15-cm epoxy laminate strip. All of the heat is conducted along the 18-cm side since the PCB is cooled along the two 15-cm-long edges. Considering only part of the PCB board because of symmetry, determine the maximum temperature rise across the 9-cm distance between the center and the sides of the PCB.

*Answer:  $10.1^{\circ}\text{C}$*

**15-146** Ten power transistors, each dissipating 2 W, are attached to a 7-cm  $\times$  7-cm  $\times$  0.2-cm aluminum plate with a square cutout in the middle in a symmetrical arrangement, as shown in Fig. P15-146. The aluminum plate is cooled from two sides by liquid at  $40^{\circ}\text{C}$ . If 70 percent of the heat generated by the transistors is estimated to be conducted through the

FIGURE P15-146

aluminum plate, determine the temperature rise across the 1-cm-wide section of the aluminum plate between the transistors and the heat sink.

**15-147** The components of an electronic system are located in a 1.2-m-long horizontal duct whose cross section is  $10 \text{ cm} \times 20 \text{ cm}$ . The components in the duct are not allowed to come into direct contact with cooling air, and so are cooled by air flowing over the duct at  $30^{\circ}\text{C}$  with a velocity of 250 m/min. The duct is oriented such that air strikes the 10-cm-high side of the duct normally. If the surface temperature of the duct is not to exceed  $60^{\circ}\text{C}$ , determine the total power rating of the electronic devices that can be mounted in the duct. What would your answer be if the duct is oriented such that air strikes the 20-cm-high side normally? *Answers: 481 W, 384 W*

**15-148** Repeat Prob. 15-147 for a location at an altitude of 5000 m, where the atmospheric pressure is 54.05 kPa.

**15-149E** A computer that consumes 65 W of power is cooled by a fan blowing air into the computer enclosure. The dimensions of the computer case are 6 in  $\times$  20 in  $\times$  24 in, and all surfaces of the case are exposed to the ambient, except for the base surface. Temperature measurements indicate that the case is at an average temperature of  $95^{\circ}\text{F}$  when the ambient temperature and the temperature of the surrounding walls are  $80^{\circ}\text{F}$ . If the emissivity of the outer surface of the case is 0.85, determine the fraction of heat lost from the outer surfaces of the computer case.

FIGURE P15-149E

### Computer, Design, and Essay Problems

**15-150** Bring an electronic device that is cooled by heat sinking to class and discuss how the heat sink enhances heat transfer.

**15-151** Obtain a catalog from a heat sink manufacturer and select a heat sink model that can cool a 10-W power transistor safely under (a) natural convection and radiation and (b) forced convection conditions.

**15-152** Take the cover off a PC or another electronic box and identify the individual sections and components. Also, identify the cooling mechanisms involved and discuss how the current design facilitates effective cooling.

# HEATING AND COOLING OF BUILDINGS

The houses in the past were built to keep the rain, snow, and thieves out with hardly any attention given to heat losses and *energy conservation*. Houses had little or no insulation, and the structures had numerous cracks through which air leaked. We have seen dramatic changes in the construction of residential and commercial buildings in the 20th century as a result of increased awareness of limited energy resources together with the escalating energy prices and the demand for a higher level of thermal comfort. Today, most local codes specify the minimum level of insulation to be used in the walls and the roof of new houses, and often require the use of double-pane windows. As a result, today's houses are well insulated, weatherproofed, and nearly air tight, and provide better thermal comfort.

The failures and successes of the past often shed light to the future, and thus we start this chapter with a *brief history* of heating and cooling to put things into historical perspective. Then we discuss the criteria for *thermal comfort*, which is the primary reason for installing heating and cooling systems. In the remainder of the chapter, we present calculation procedures for the *heating and cooling loads* of buildings using the most recent information and design criteria established by the American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc. (ASHRAE), which publishes and periodically revises the most authoritative handbooks in the field. This chapter is intended to introduce the readers to an exciting application area of heat transfer, and to help them develop a deeper understanding of the fundamentals of heat transfer using this familiar setup. The reader is referred to ASHRAE handbooks for more information.

**FIGURE 16-1**

Most animals come into this world with built-in insulation, but human beings come with a delicate skin.

## 16-1 • A BRIEF HISTORY

Unlike animals such as a fox or a bear that are born with built-in furs, human beings come into this world with little protection against the harsh environmental conditions (Fig. 16-1). Therefore, we can claim that the search for thermal comfort dates back to the beginning of human history. It is believed that early human beings lived in caves that provided shelter as well as protection from extreme thermal conditions. Probably the first form of heating system used was *open fire*, followed by fire in dwellings through the use of a *chimney* to vent out the combustion gases. The concept of *central heating* dates back to the times of the Romans, who heated homes by utilizing double-floor construction techniques and passing the fire's fumes through the opening between the two floor layers. The Romans were also the first to use *transparent windows* made of mica or glass to keep the wind and rain out while letting the light in. Wood and coal were the primary energy sources for heating, and oil and candles were used for lighting. The ruins of south-facing houses indicate that the value of *solar heating* was recognized early in the history.

The development of the first *steam heating* system by James Watt dates back to 1770. When the American Society of Heating and Ventilating Engineers was established in New York in 1894, central heating systems using cast iron warm air furnaces and boilers were in common use. *Fans* were added in 1899 to move the air mechanically, and later *automatic firing* replaced the manual firing. The steam heating systems gained widespread acceptance in the early 1900s by the introduction of fluid-operated *thermostatic traps* to improve the fluid circulation. Gravity-driven hot water heating systems were developed in parallel with steam systems. Suspended and floor-type unit heaters, unit ventilators, and panel heaters were developed in the 1920s. *Unit heaters* and *panel heaters* usually used steam, hot water, or electricity as the heat source. It became common practice to conceal the radiators in the 1930s, and the *baseboard radiator* was developed in 1944. Today, air heating systems with a duct distribution network dominate the residential and commercial buildings.

The development of *cooling systems* took the back seat in the history of thermal comfort since there was no quick way of creating "coolness." Therefore, early attempts at cooling were passive measures such as blocking off direct sunlight and using thick stone walls to store coolness at night. A more sophisticated approach was to take advantage of *evaporative cooling* by running water through the structure, as done in the Alhambra castle. Of course, natural *ice* and *snow* served as "cold storage" mediums and provided some cooling.

In 1775, Dr. William Cullen made *ice* in Scotland by evacuating the air in a water tank (Fig. 16-2). It was also known at those times that some chemicals lowered temperatures. For example, the temperature of snow can be dropped to  $-33^{\circ}\text{C}$  ( $-27^{\circ}\text{F}$ ) by mixing it with calcium chloride. This process was commonly used to make ice cream. In 1851, Ferdinand Carre designed the first *ammonia absorption refrigeration system*, while Dr. John Gorrie received a patent for an *open air refrigeration cycle* to produce ice and refrigerated air. In 1853, Alexander Twining of Connecticut produced 1600 pounds (726 kg) of ice a day using sulfuric ether as the refrigerant. In 1872, David Boyle developed an ammonia compression machine that produced ice. Mechanical refrigeration at those times was used primarily to make ice and preserve perishable commodities such as meat and fish (Sauer and Howell, 1994).

**FIGURE 16-2**

In 1775, ice was made by evacuating the air in a water tank.

*Comfort cooling* was obtained by ice or by chillers that used ice. *Air cooling systems* for thermal comfort were built in the 1890s, but they did not find widespread use until the development of mechanical refrigeration in the early 1900s. In 1905, 200 Btu/min (or 12,000 Btu/h) was established as **1 ton of refrigeration**, and in 1902 a 400-ton air-conditioning system was installed in the New York Stock Exchange. The system operated reliably for 20 years. A modern air-conditioning system was installed in the Boston Floating Hospital in 1908, which was a first for a hospital. In a monumental paper presented in 1911, Willis Carrier (1876–1950), known as the “Father of Air Conditioning,” laid out the formulas related to the dry-bulb, wet-bulb, and dew-point temperatures of air and the sensible, latent, and total heat loads. By 1922, the centrifugal refrigeration machine developed by Carrier made water chilling for medium and large commercial and industrial facilities practical and economical. In 1928 the Milan Building in San Antonio, Texas, was the first commercial building designed with and built for comfort air-conditioning specifications (Sauer and Howell, 1994).

Frigidaire introduced the first *room air conditioner* in the late 1920s (Fig. 16–3). The halocarbon refrigerants such as Freon-12 were developed in 1930. The concept of a *heat pump* was described by Sadi Carnot in 1824, and the operation of such a device called the “heat multiplier” was first described by William Thomson (Lord Kelvin) in 1852. T. G. N. Haldane built an experimental heat pump in 1930, and a heat pump was marketed by De La Vargne in 1933. General Electric introduced the heat pump in the mid 1930s, and heat pumps were being mass produced in 1952. *Central air-conditioning systems* were being installed routinely in the 1960s. The oil crises of the 1970s sent shock waves among the consumers and the producers of energy-consuming equipment, which had taken energy for granted, and brought about a renewed interest in the development of energy-efficient systems and more effective insulation materials. Today most residential and commercial buildings are equipped with modern air-conditioning systems that can heat, cool, humidify, dehumidify, clean, and even deodorize the air—in other words, *condition* the air to people’s desires.

**FIGURE 16–3**

The first room air conditioner was introduced by Frigidaire in the late 1920s.

## 16–2 • HUMAN BODY AND THERMAL COMFORT

The term **air-conditioning** is usually used in a restricted sense to imply cooling, but in its broad sense it means *to condition* the air to the desired level by heating, cooling, humidifying, dehumidifying, cleaning, and deodorizing. The purpose of the air-conditioning system of a building is to provide *complete thermal comfort* for its occupants. Therefore, we need to understand the thermal aspects of the *human body* in order to design an effective air-conditioning system.

The building blocks of living organisms are *cells*, which resemble miniature factories performing various functions necessary for the survival of organisms. The human body contains about 100 trillion cells with an average diameter of 0.01 mm. In a typical cell, thousands of chemical reactions occur every second during which some molecules are broken down and energy is released and some new molecules are formed. The high level of chemical activity in the cells that maintain the human body temperature at a temperature of 37.0°C (98.6°F) while performing the necessary bodily functions is called the **metabolism**. In simple terms, metabolism refers to the burning of foods such as carbohydrates, fat, and protein. The metabolizable energy content of foods is

**FIGURE 16–4**

Two fast-dancing people supply more heat to a room than a 1-kW resistance heater.

**TABLE 16-1**

Metabolic rates during various activities (from ASHRAE *Handbook of Fundamentals*, Chap. 8, Table 4)

| Activity                               | Metabolic rate*, W/m <sup>2</sup> |
|--|-----------------------------------|
| Resting:                               |                                   |
| Sleeping                               | 40                                |
| Reclining                              | 45                                |
| Seated, quiet                          | 60                                |
| Standing, relaxed                      | 70                                |
| Walking (on the level):                |                                   |
| 2 mph (0.89 m/s)                       | 115                               |
| 3 mph (1.34 m/s)                       | 150                               |
| 4 mph (1.79 m/s)                       | 220                               |
| Office Activities:                     |                                   |
| Reading, seated                        | 55                                |
| Writing                                | 60                                |
| Typing                                 | 65                                |
| Filing, seated                         | 70                                |
| Filing, standing                       | 80                                |
| Walking about                          | 100                               |
| Lifting/packing                        | 120                               |
| Driving/Flying:                        |                                   |
| Car                                    | 60–115                            |
| Aircraft, routine                      | 70                                |
| Heavy vehicle                          | 185                               |
| Miscellaneous Occupational Activities: |                                   |
| Cooking                                | 95–115                            |
| Cleaning house                         | 115–140                           |
| Machine work:                          |                                   |
| Light                                  | 115–140                           |
| Heavy                                  | 235                               |
| Handling 50-kg bags                    | 235                               |
| Pick and shovel work                   | 235–280                           |
| Miscellaneous Leisure Activities:      |                                   |
| Dancing, social                        | 140–255                           |
| Calisthenics/exercise                  | 175–235                           |
| Tennis, singles                        | 210–270                           |
| Basketball                             | 290–440                           |
| Wrestling, competitive                 | 410–505                           |

\*Multiply by 1.8 m<sup>2</sup> to obtain metabolic rates for an average man. Multiply by 0.3171 to convert to Btu/h · ft<sup>2</sup>.

usually expressed by nutritionists in terms of the capitalized Calorie. One Calorie is equivalent to 1 Cal = 1 kcal = 4.1868 kJ.

The rate of metabolism at the resting state is called the *basal metabolic rate*, which is the rate of metabolism required to keep a body performing the necessary bodily functions such as breathing and blood circulation at zero external activity level. The metabolic rate can also be interpreted as the energy consumption rate for a body. For an *average man* (30 years old, 70 kg, 1.73 m high, 1.8 m<sup>2</sup> surface area), the basal metabolic rate is 84 W. That is, the body is converting chemical energy of the food (or of the body fat if the person had not eaten) into heat at a rate of 84 J/s, which is then dissipated to the surroundings. The metabolic rate increases with the *level of activity*, and it may exceed 10 times the basal metabolic rate when someone is doing strenuous exercise. That is, two people doing heavy exercising in a room may be supplying more energy to the room than a 1-kW resistance heater (Fig. 16-4). An average man generates heat at a rate of 108 W while reading, writing, typing, or listening to a lecture in a classroom in a seated position. The maximum metabolic rate of an average man is 1250 W at age 20 and 730 at age 70. The corresponding rates for women are about 30 percent lower. Maximum metabolic rates of trained athletes can exceed 2000 W.

Metabolic rates during various activities are given in Table 16-1 per unit body surface area. The **surface area** of a nude body was given by D. DuBois in 1916 as

$$A_s = 0.202 m^{0.425} h^{0.725} \quad (\text{m}^2) \quad (16-1)$$

where *m* is the mass of the body in kg and *h* is the height in m. *Clothing* increases the exposed surface area of a person by up to about 50 percent. The metabolic rates given in the table are sufficiently accurate for most purposes, but there is considerable uncertainty at high activity levels. More accurate values can be determined by measuring the rate of respiratory *oxygen consumption*, which ranges from about 0.25 L/min for an average resting man to more than 2 L/min during extremely heavy work. The entire energy released during metabolism can be assumed to be released as *heat* (in sensible or latent forms) since the external mechanical work done by the muscles is very small. Besides, the work done during most activities such as walking or riding an exercise bicycle is eventually converted to heat through friction.

The comfort of the human body depends primarily on three environmental factors: the temperature, relative humidity, and air motion. The temperature of the environment is the single most important index of comfort. Extensive research is done on human subjects to determine the “**thermal comfort zone**” and to identify the conditions under which the body feels comfortable in an environment. It has been observed that most normally clothed people resting or doing light work feel comfortable in the *operative temperature* (roughly, the average temperature of air and surrounding surfaces) range of 23 to 27°C or 73 to 80°F (Fig. 16-5). For unclothed people, this range is 29 to 31°C. Relative humidity also has a considerable effect on comfort since it is a measure of air’s ability to absorb moisture and thus it affects the amount of heat a body can dissipate by evaporation. High relative humidity slows down heat rejection by evaporation, especially at high temperatures, and low relative humidity speeds it up. The desirable level of *relative humidity* is the broad range of 30 to 70 percent, with 50 percent being the most desirable level. Most

people at these conditions feel neither hot nor cold, and the body does not need to activate any of the defense mechanisms to maintain the normal body temperature (Fig. 16–6).

Another factor that has a major effect on thermal comfort is **excessive air motion** or **draft**, which causes undesired local cooling of the human body. Draft is identified by many as a most annoying factor in work places, automobiles, and airplanes. Experiencing discomfort by draft is most common among people wearing indoor clothing and doing light sedentary work, and least common among people with high activity levels. The air velocity should be kept below 9 m/min (30 ft/min) in winter and 15 m/min (50 ft/min) in summer to minimize discomfort by draft, especially when the air is cool. A low level of air motion is desirable as it removes the warm, moist air that builds around the body and replaces it with fresh air. Therefore, air motion should be strong enough to remove heat and moisture from the vicinity of the body, but gentle enough to be unnoticed. High speed air motion causes discomfort outdoors as well. For example, an environment at 10°C (50°F) with 48 km/h winds feels as cold as an environment at –7°C (20°F) with 3 km/h winds because of the chilling effect of the air motion (the wind-chill factor).

A comfort system should provide *uniform conditions* throughout the living space to avoid discomfort caused by nonuniformities such as *drafts*, *asymmetric thermal radiation*, *hot or cold floors*, and *vertical temperature stratification*. **Asymmetric thermal radiation** is caused by the *cold surfaces* of large windows, uninsulated walls, or cold products and the *warm surfaces* of gas or electric radiant heating panels on the walls or ceiling, solar-heated masonry walls or ceilings, and warm machinery. Asymmetric radiation causes discomfort by exposing different sides of the body to surfaces at different temperatures and thus to different heat loss or gain by radiation. A person whose left side is exposed to a cold window, for example, will feel like heat is being drained from that side of his or her body (Fig. 16–7). For thermal comfort, the radiant temperature asymmetry should not exceed 5°C in the vertical direction and 10°C in the horizontal direction. The unpleasant effect of radiation asymmetry can be minimized by properly sizing and installing heating panels, using double-pane windows, and providing generous insulation at the walls and the roof.

Direct contact with **cold** or **hot floor surfaces** also causes localized discomfort in the feet. The temperature of the floor depends on the way it is *constructed* (being directly on the ground or on top of a heated room, being made of wood or concrete, the use of insulation, etc.) as well as the *floor covering used* such as pads, carpets, rugs, and linoleum. A floor temperature of 23 to 25°C is found to be comfortable to most people. The floor asymmetry loses its significance for people with footwear. An effective and economical way of raising the floor temperature is to use radiant heating panels instead of turning the thermostat up. Another nonuniform condition that causes discomfort is **temperature stratification** in a room that exposes the head and the feet to different temperatures. For thermal comfort, the temperature difference between the head and foot levels should not exceed 3°C. This effect can be minimized by using destratification fans.

It should be noted that no thermal environment will please everyone. No matter what we do, some people will express some discomfort. The thermal comfort zone is based on a 90 percent acceptance rate. That is, an environment

FIGURE 16-5

The effect of clothing on the environment temperature that feels comfortable ( $1 \text{ clo} = 0.155 \text{ m}^2 \cdot ^\circ\text{C}/\text{W} = 0.880 \text{ ft}^2 \cdot ^\circ\text{F} \cdot \text{h/Btu}$ ).

(From ASHRAE Standard 55-1981.)

FIGURE 16-6

A thermally comfortable environment.

**FIGURE 16-7**

Cold surfaces cause excessive heat loss from the body by radiation, and thus discomfort on that side of the body.

is deemed comfortable if only 10 percent of the people are dissatisfied with it. Metabolism decreases somewhat with *age*, but it has no effect on the comfort zone. Research indicates that there is no appreciable difference between the environments preferred by old and young people. Experiments also show that *men* and *women* prefer almost the same environment. The metabolism rate of women is somewhat lower, but this is compensated by their slightly lower skin temperature and evaporative loss. Also, there is no significant variation in the comfort zone from one part of the world to another and from winter to summer. Therefore, the same thermal comfort conditions can be used *throughout the world* in any season. Also, people cannot *acclimatize* themselves to prefer different comfort conditions.

In a **cold environment**, the rate of heat loss from the body may exceed the rate of metabolic heat generation. Average specific heat of the human body is  $3.49 \text{ kJ/kg} \cdot ^\circ\text{C}$ , and thus each  $1^\circ\text{C}$  drop in body temperature corresponds to a deficit of 244 kJ in body heat content for an average 70 kg man. A drop of  $0.5^\circ\text{C}$  in mean body temperature causes noticeable but acceptable discomfort. A drop of  $2.6^\circ\text{C}$  causes extreme discomfort. A sleeping person will wake up when his or her mean body temperature drops by  $1.3^\circ\text{C}$  (which normally shows up as a  $0.5^\circ\text{C}$  drop in the deep body and  $3^\circ\text{C}$  in the skin area). The drop of deep body temperature below  $35^\circ\text{C}$  may damage the body temperature regulation mechanism, while a drop below  $28^\circ\text{C}$  may be fatal. Sedentary people reported to feel *comfortable* at a *mean skin temperature* of  $33.3^\circ\text{C}$ , *uncomfortably cold* at  $31^\circ\text{C}$ , *shivering cold* at  $30^\circ\text{C}$ , and *extremely cold* at  $29^\circ\text{C}$ . People doing heavy work reported to feel comfortable at much lower temperatures, which shows that the activity level affects human performance and comfort. The extremities of the body such as hands and feet are most easily affected by cold weather, and their temperature is a better indication of comfort and performance. A hand-skin temperature of  $20^\circ\text{C}$  is perceived to be *uncomfortably cold*,  $15^\circ\text{C}$  to be *extremely cold*, and  $5^\circ\text{C}$  to be *painfully cold*. Useful work can be performed by hands without difficulty as long as the skin temperature of fingers remains above  $16^\circ\text{C}$  (*ASHRAE Handbook of Fundamentals*, Chap. 8).

The first line of defense of the body against excessive heat loss in a cold environment is *to reduce the skin temperature* and thus the rate of heat loss from the skin by constricting the veins and decreasing the blood flow to the skin. This measure decreases the temperature of the tissues subjacent to the skin, but maintains the inner body temperature. The next preventive measure is increasing the rate of *metabolic heat generation* in the body by *shivering*, unless the person does it voluntarily by increasing his or her level of activity or puts on additional clothing. Shivering begins slowly in small muscle groups and may double the rate of metabolic heat production of the body at its initial stages. In the extreme case of total body shivering, the rate of heat production may reach 6 times the resting levels (Fig. 16-8). If this measure also proves inadequate, the deep body temperature starts *falling*. Body parts furthest away from the core such as the hands and feet are at greatest danger for tissue damage.

In **hot environments**, the rate of heat loss from the body may drop below the metabolic heat generation rate. This time the body activates the opposite mechanisms. First the body increases the *blood flow* and thus heat transport to the skin, causing the temperature of the skin and the subjacent tissues to rise and approach the deep body temperature. Under extreme heat conditions, the

**FIGURE 16-8**

The rate of metabolic heat generation may go up by 6 times the resting level during total body shivering in cold weather.

*heart rate* may reach 180 beats per minute in order to maintain adequate blood supply to the brain and the skin. At higher heart rates, the *volumetric efficiency* of the heart drops because of the very short time between the beats to fill the heart with blood, and the blood supply to the skin and more importantly to the brain drops. This causes the person to faint as a result of *heat exhaustion*. Dehydration makes the problem worse. A similar thing happens when a person working very hard for a long time stops suddenly. The blood that has flooded the skin has difficulty returning to the heart in this case since the relaxed muscles no longer force the blood back to the heart, and thus there is less blood available for pumping to the brain.

The next line of defense is releasing water from sweat glands and resorting to *evaporative cooling*, unless the person removes some clothing and reduces the activity level (Fig. 16-9). The body can maintain its core temperature at 37°C in this evaporative cooling mode indefinitely, even in environments at higher temperatures (as high as 200°C during military endurance tests), if the person drinks plenty of liquids to replenish his or her water reserves and the ambient air is sufficiently dry to allow the sweat to evaporate instead of rolling down the skin. If this measure proves inadequate, the body will have to start absorbing the metabolic heat and the deep body temperature will rise. A person can tolerate a temperature rise of 1.4°C without major discomfort but may *collapse* when the temperature rise reaches 2.8°C. People feel sluggish and their efficiency drops considerably when the core body temperature rises above 39°C. A core temperature above 41°C may damage hypothalamic proteins, resulting in cessation of sweating, increased heat production by shivering, and a *heat stroke* with an irreversible and life-threatening damage. Death can occur above 43°C.

A surface temperature of 46°C causes pain on the skin. Therefore, direct contact with a metal block at this temperature or above is painful. However, a person can stay in a room at 100°C for up to 30 min without any damage or pain on the skin because of the convective resistance at the skin surface and evaporative cooling. We can even put our hands into an oven at 200°C for a short time without getting burned.

Another factor that affects thermal comfort, health, and productivity is **ventilation**. Fresh outdoor air can be provided to a building *naturally* by doing nothing, or *forcefully* by a mechanical ventilation system. In the first case, which is the norm in residential buildings, the necessary ventilation is provided by *infiltration through cracks and leaks* in the living space and by the opening of the windows and doors. The additional ventilation needed in the bathrooms and kitchens is provided by *air vents with dampers* or *exhaust fans*. With this kind of uncontrolled ventilation, however, the fresh air supply will be either too high, wasting energy, or too low, causing poor indoor air quality. But the current practice is not likely to change for residential buildings since there is not a public outcry for energy waste or air quality, and thus it is difficult to justify the cost and complexity of mechanical ventilation systems.

Mechanical ventilation systems are part of any heating and air-conditioning system in *commercial buildings*, providing the necessary amount of fresh outdoor air and distributing it uniformly throughout the building. This is not surprising since many rooms in large commercial buildings have no windows and thus rely on mechanical ventilation. Even the rooms with windows are in the same situation since the windows are tightly sealed and cannot be opened in

FIGURE 16-9

In hot environments, a body can dissipate a large amount of metabolic heat by sweating since the sweat absorbs the body heat and evaporates.

**TABLE 16-2**

Minimum fresh air requirements in buildings (from ASHRAE Standard 62-1989)

| Application   | Requirement   |                                    |
|---|---|------------------------------------|
|   | L/s<br>per person   | ft <sup>3</sup> /min<br>per person |
| Classrooms,<br>laundries,<br>libraries,<br>supermarkets | 8   | 15                                 |
| Dining rooms,<br>conference<br>rooms, offices           | 10  | 20                                 |
| Hospital<br>rooms                                       | 13  | 25                                 |
| Hotel rooms   | 15<br>(per room)  | 30<br>(per room)                   |
| Smoking<br>lounges                                      | 30  | 60                                 |
| Retail stores   | 1.0–1.5<br>(per m <sup>2</sup> )  | 0.2–0.3<br>(per ft <sup>2</sup> )  |
| Residential<br>buildings                                | 0.35 air change per<br>hour, but not less<br>than 7.5 L/s<br>(or 15 ft <sup>3</sup> /min)<br>per person |                                    |

**FIGURE 16-10**

Mechanisms of heat loss from the human body and relative magnitudes for a resting person.

most buildings. It is not a good idea to oversize the ventilation system just to be on the “safe side” since exhausting the heated or cooled indoor air wastes energy. On the other hand, reducing the ventilation rates below the required minimum to conserve energy should also be avoided so that the indoor air quality can be maintained at the required levels. The minimum fresh air ventilation requirements are listed in Table 16-2. The values are based on controlling the CO<sub>2</sub> and other contaminants with an adequate margin of safety, which requires each person be supplied with at least 7.5 L/s (15 ft<sup>3</sup>/min) of fresh air.

Another function of the mechanical ventilation system is to **clean** the air by filtering it as it enters the building. Various types of filters are available for this purpose, depending on the cleanliness requirements and the allowable pressure drop.

### 16-3 ■ HEAT TRANSFER FROM THE HUMAN BODY

The metabolic heat generated in the body is dissipated to the environment through the skin and the lungs by convection and radiation as *sensible heat* and by evaporation as *latent heat* (Fig. 16-10). Latent heat represents the heat of vaporization of water as it evaporates in the lungs and on the skin by absorbing body heat, and latent heat is released as the moisture condenses on cold surfaces. The warming of the inhaled air represents sensible heat transfer in the lungs and is proportional to the temperature rise of inhaled air. The total rate of heat loss from the body can be expressed as

$$\begin{aligned}\dot{Q}_{\text{body, total}} &= \dot{Q}_{\text{skin}} + \dot{Q}_{\text{lungs}} \\ &= (\dot{Q}_{\text{sensible}} + \dot{Q}_{\text{latent}})_{\text{skin}} + (\dot{Q}_{\text{sensible}} + \dot{Q}_{\text{latent}})_{\text{lungs}} \\ &= (\dot{Q}_{\text{convection}} + \dot{Q}_{\text{radiation}} + \dot{Q}_{\text{latent}})_{\text{skin}} + (\dot{Q}_{\text{convection}} + \dot{Q}_{\text{latent}})_{\text{lungs}}\end{aligned}\quad (16-2)$$

Therefore, the determination of heat transfer from the body by analysis alone is difficult. Clothing further complicates the heat transfer from the body, and thus we must rely on experimental data. Under steady conditions, the total rate of heat transfer from the body is equal to the rate of metabolic heat generation in the body, which varies from about 100 W for light office work to roughly 1000 W during heavy physical work.

*Sensible heat loss* from the skin depends on the temperatures of the skin, the environment, and the surrounding surfaces as well as the air motion. The *latent heat loss*, on the other hand, depends on the skin wettedness and the relative humidity of the environment as well. *Clothing* serves as insulation and reduces both the sensible and latent forms of heat loss. The heat transfer from the lungs through respiration obviously depends on the frequency of breathing and the volume of the lungs as well as the environmental factors that affect heat transfer from the skin.

Sensible heat from the clothed skin is first transferred to the clothing and then from the clothing to the environment. The convection and radiation heat losses from the outer surface of a clothed body can be expressed as

$$\dot{Q}_{\text{conv}} = h_{\text{conv}} A_{\text{clothing}} (T_{\text{clothing}} - T_{\text{ambient}}) \quad (16-3)$$

$$\dot{Q}_{\text{rad}} = h_{\text{rad}} A_{\text{clothing}} (T_{\text{clothing}} - T_{\text{surr}}) \quad (16-4)$$

where

- $h_{\text{conv}}$  = convection heat transfer coefficient, as given in Table 16–3
- $h_{\text{rad}}$  = radiation heat transfer coefficient,  $4.7 \text{ W/m}^2 \cdot ^\circ\text{C}$  for typical indoor conditions; the emissivity is assumed to be 0.95, which is typical
- $A_{\text{clothing}}$  = outer surface area of a clothed person
- $T_{\text{clothing}}$  = average temperature of exposed skin and clothing
- $T_{\text{ambient}}$  = ambient air temperature
- $T_{\text{surr}}$  = average temperature of the surrounding surfaces

The convection heat transfer coefficients at 1 atm pressure are given in Table 16–3. Convection coefficients at pressures  $P$  other than 1 atm are obtained by multiplying the values at atmospheric pressure by  $P^{0.55}$  where  $P$  is in atm. Also, it is recognized that the temperatures of different surfaces surrounding a person are probably different, and  $T_{\text{surr}}$  represents the *mean radiation temperature*, which is the temperature of an imaginary isothermal enclosure in which radiation heat exchange with the human body equals the radiation heat exchange with the actual enclosure. Noting that most clothing and building materials are very nearly black, the *mean radiation temperature* of an enclosure that consists of  $N$  surfaces at different temperatures can be determined from

$$T_{\text{surr}} \cong F_{\text{person-1}}T_1 + F_{\text{person-2}}T_2 + \dots + F_{\text{person-}N}T_N \quad (16-5)$$

where  $T_i$  is the *temperature of the surface  $i$*  and  $F_{\text{person-}i}$  is the *view factor* between the person and surface  $i$ .

Total sensible heat loss can also be expressed conveniently by combining the convection and radiation heat losses as

$$\dot{Q}_{\text{conv+rad}} = h_{\text{combined}}A_{\text{clothing}}(T_{\text{clothing}} - T_{\text{operative}}) \quad (16-6)$$

$$= (h_{\text{conv}} + h_{\text{rad}})A_{\text{clothing}}(T_{\text{clothing}} - T_{\text{operative}}) \quad (\text{W}) \quad (16-7)$$

where the **operative temperature**  $T_{\text{operative}}$  is the average of the mean radiant and ambient temperatures weighed by their respective convection and radiation heat transfer coefficients and is expressed as (Fig. 16–11)

$$T_{\text{operative}} = \frac{h_{\text{conv}}T_{\text{ambient}} + h_{\text{rad}}T_{\text{surr}}}{h_{\text{conv}} + h_{\text{rad}}} \cong \frac{T_{\text{ambient}} + T_{\text{surr}}}{2} \quad (16-8)$$

Note that the operative temperature will be the arithmetic average of the ambient and surrounding surface temperatures when the convection and radiation heat transfer coefficients are equal to each other. Another environmental index used in thermal comfort analysis is the **effective temperature**, which combines the effects of temperature and humidity. Two environments with the same effective temperature evoke the same thermal response in people even though they are at different temperatures and humidities.

Heat transfer through the *clothing* can be expressed as

$$\dot{Q}_{\text{conv+rad}} = \frac{A_{\text{clothing}}(T_{\text{skin}} + T_{\text{clothing}})}{R_{\text{clothing}}} \quad (16-9)$$

TABLE 16–3

Convection heat transfer coefficients for a clothed body at 1 atm ( $V$  is in m/s) (compiled from various sources)

| Activity   | $\frac{h_{\text{conv}}}{\text{W/m}^2 \cdot ^\circ\text{C}}$ * |
|--|---|
| Seated in air moving at<br>$0 < V < 0.2 \text{ m/s}$                   | 3.1   |
| $0.2 < V < 4 \text{ m/s}$  | $8.3V^{0.6}$  |
| Walking in still air at<br>$0.5 < V < 2 \text{ m/s}$                   | $8.6V^{0.53}$   |
| Walking on treadmill in<br>still air at $0.5 < V <$<br>$2 \text{ m/s}$ | $6.5V^{0.39}$   |
| Standing in moving air at<br>$0 < V < 0.15 \text{ m/s}$                | 4.0   |
| $0.15 < V < 1.5 \text{ m/s}$   | $14.8V^{0.69}$  |

\*At pressures other than 1 atm, multiply by  $P^{0.55}$ , where  $P$  is in atm.

(a) Convection and radiation, separate

(b) Convection and radiation, combined

FIGURE 16–11

Heat loss by convection and radiation from the body can be combined into a single term by defining an equivalent operative temperature.

FIGURE 16-12

Simplified thermal resistance network for heat transfer from a clothed person.

FIGURE 16-13

An average person can lose heat at a rate of up to 730 W by evaporation.

where  $R_{clothing}$  is the **unit thermal resistance of clothing** in  $\text{m}^2 \cdot ^\circ\text{C}/\text{W}$ , which involves the combined effects of conduction, convection, and radiation between the skin and the outer surface of clothing. The thermal resistance of clothing is usually expressed in the unit **clo** where  $1 \text{ clo} = 0.155 \text{ m}^2 \cdot ^\circ\text{C}/\text{W} = 0.880 \text{ ft}^2 \cdot ^\circ\text{F} \cdot \text{h/Btu}$ . The thermal resistance of trousers, long-sleeve shirt, long-sleeve sweater, and T-shirt is 1.0 clo, or  $0.155 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ . Summer clothing such as light slacks and short-sleeved shirt has an insulation value of 0.5 clo, whereas winter clothing such as heavy slacks, long-sleeve shirt, and a sweater or jacket has an insulation value of 0.9 clo.

Then the total sensible heat loss can be expressed in terms of the skin temperature instead of the inconvenient clothing temperature as (Fig. 16-12)

$$\dot{Q}_{\text{conv+rad}} = \frac{A_{\text{clothing}}(T_{\text{skin}} - T_{\text{operative}})}{R_{\text{clothing}} + \frac{1}{h_{\text{combined}}}} \quad (16-10)$$

At a state of thermal comfort, the average skin temperature of the body is observed to be  $33^\circ\text{C}$  ( $91.5^\circ\text{F}$ ). No discomfort is experienced as the skin temperature fluctuates by  $\pm 1.5^\circ\text{C}$  ( $2.5^\circ\text{F}$ ). This is the case whether the body is clothed or unclothed.

**Evaporative or latent heat loss** from the skin is proportional to the difference between the water vapor pressure at the skin and the ambient air, and the skin wettedness, which is a measure of the amount of moisture on the skin. It is due to the combined effects of the *evaporation of sweat* and the *diffusion* of water through the skin, and can be expressed as

$$\dot{Q}_{\text{latent}} = \dot{m}_{\text{vapor}} \eta_{fg} \quad (16-11)$$

where

$\dot{m}_{\text{vapor}}$  = the rate of evaporation from the body,  $\text{kg/s}$

$\eta_{fg}$  = the enthalpy of vaporization of water =  $2430 \text{ kJ/kg}$  at  $30^\circ\text{C}$

Heat loss by evaporation is maximum when the skin is completely wetted. Also, clothing offers resistance to evaporation, and the rate of evaporation in clothed bodies depends on the moisture permeability of the clothes. The maximum evaporation rate for an average man is about  $1 \text{ L/h}$  ( $0.3 \text{ g/s}$ ), which represents an upper limit of  $730 \text{ W}$  for the evaporative cooling rate. A person can lose as much as  $2 \text{ kg}$  of water per hour during a workout on a hot day, but any excess sweat slides off the skin surface without evaporating (Fig. 16-13).

During *respiration*, the inhaled air enters at ambient conditions and exhaled air leaves nearly saturated at a temperature close to the deep body temperature (Fig. 16-14). Therefore, the body loses both sensible heat by convection and latent heat by evaporation from the lungs, and these can be expressed as

$$\dot{Q}_{\text{conv,lungs}} = \dot{m}_{\text{air,lungs}} c_{p,\text{air}} (T_{\text{exhale}} - T_{\text{ambient}}) \quad (16-12)$$

$$\dot{Q}_{\text{latent,lungs}} = \dot{m}_{\text{vapor,lungs}} h_{fg} = \dot{m}_{\text{air,lungs}} (\omega_{\text{exhale}} - \omega_{\text{ambient}}) h_{fg} \quad (16-13)$$

where

$\dot{m}_{\text{air,lungs}}$  = rate of air intake to the lungs,  $\text{kg/s}$

$c_{p,\text{air}}$  = specific heat of air =  $1.0 \text{ kJ/kg} \cdot ^\circ\text{C}$

$T_{\text{exhale}}$  = temperature of exhaled air

$\omega$  = humidity ratio (the mass of moisture per unit mass of dry air)

The rate of air intake to the lungs is directly proportional to the metabolic rate  $\dot{Q}_{\text{met}}$ . The rate of total heat loss from the lungs through respiration can be expressed approximately as

$$\begin{aligned}\dot{Q}_{\text{conv+latent,lungs}} &= 0.0014\dot{Q}_{\text{met}}(34 - T_{\text{ambient}}) \\ &\quad + 0.0173\dot{Q}_{\text{met}}(5.87 - P_{v,\text{ambient}})\end{aligned}\quad (16-14)$$

where  $P_{v,\text{ambient}}$  is the vapor pressure of ambient air in kPa.

The fraction of sensible heat varies from about 40 percent in the case of heavy work to about 70 percent during light work. The rest of the energy is rejected from the body by perspiration in the form of latent heat.

### EXAMPLE 16-1 Effect of Clothing on Thermal Comfort

It is well established that a clothed or unclothed person feels comfortable when the skin temperature is about 33°C. Consider an average man wearing summer clothes whose thermal resistance is 0.6 clo. The man feels very comfortable while standing in a room maintained at 22°C. The air motion in the room is negligible, and the interior surface temperature of the room is about the same as the air temperature. If this man were to stand in that room unclothed, determine the temperature at which the room must be maintained for him to feel thermally comfortable.

**SOLUTION** A man wearing summer clothes feels comfortable in a room at 22°C. The room temperature at which this man would feel thermally comfortable when unclothed is to be determined.

**Assumptions** 1 Steady conditions exist. 2 The latent heat loss from the person remains the same. 3 The heat transfer coefficients remain the same.

**Analysis** The body loses heat in sensible and latent forms, and the sensible heat consists of convection and radiation heat transfer. At low air velocities, the convection heat transfer coefficient for a standing man is given in Table 16-3 to be 4.0 W/m<sup>2</sup> · °C. The radiation heat transfer coefficient at typical indoor conditions is 4.7 W/m<sup>2</sup> · °C. Therefore, the surface heat transfer coefficient for a standing person for combined convection and radiation is

$$h_{\text{combined}} = h_{\text{conv}} + h_{\text{rad}} = 4.0 + 4.7 = 8.7 \text{ W/m}^2 \cdot ^\circ\text{C}$$

The thermal resistance of the clothing is given to be

$$R_{\text{clothing}} = 0.6 \text{ clo} = 0.6 \times 0.155 \text{ m}^2 \cdot ^\circ\text{C/W} = 0.093 \text{ m}^2 \cdot ^\circ\text{C/W}$$

Noting that the surface area of an average man is 1.8 m<sup>2</sup>, the sensible heat loss from this person when clothed is determined to be (Fig. 16-15)

$$\dot{Q}_{\text{sensible,clothed}} = \frac{A_s(T_{\text{skin}} - T_{\text{ambient}})}{\rho_{\text{clothing}} + \frac{1}{\eta_{\text{combined}}}} = \frac{(1.8 \text{ m}^2)(33 - 22)^\circ\text{C}}{0.093 \text{ m}^2 \cdot ^\circ\text{C/W} + \frac{1}{8.7 \text{ W/m}^2 \cdot ^\circ\text{C}}} = 95.2 \text{ W}$$

From a heat transfer point of view, taking the clothes off is equivalent to removing the clothing insulation or setting  $R_{\text{clothing}} = 0$ . The heat transfer in this case can be expressed as

FIGURE 16-14

Part of the metabolic heat generated in the body is rejected to the air from the lungs during respiration.

FIGURE 16-15

Schematic for Example 16-1.

**FIGURE 16-16**

Clothing serves as insulation, and the room temperature needs to be raised when a person is unclothed to maintain the same comfort level.

$$\dot{Q}_{\text{sensible, unclothed}} = \frac{A_s(T_{skin} - T_{\text{ambient}})}{h_{\text{combined}}} = \frac{(1.8 \text{ m}^2)(33 - T_{\text{ambient}})^\circ\text{C}}{8.7 \text{ W/m}^2 \cdot ^\circ\text{C}}$$

To maintain thermal comfort after taking the clothes off, the skin temperature of the person and the rate of heat transfer from him must remain the same. Then setting the equation above equal to 95.2 W gives

$$T_{\text{ambient}} = 26.9^\circ\text{C}$$

Therefore, the air temperature needs to be raised from 22 to 26.9°C to ensure that the person will feel comfortable in the room after he takes his clothes off (Fig. 16-16).

**Discussion** Note that the effect of clothing on latent heat is assumed to be negligible in the solution above. We also assumed the surface area of the clothed and unclothed person to be the same for simplicity, and these two effects should counteract each other.

## 16-4 ■ DESIGN CONDITIONS FOR HEATING AND COOLING

**FIGURE 16-17**

The size of a heating system is determined on the basis of heat loss during indoor and outdoor design conditions.

The size of a heating or cooling system for a building is determined on the basis of the desired indoor conditions that must be maintained based on the outdoor conditions that exist at that location. The desirable ranges of temperatures, humidities, and ventilation rates (the thermal comfort zone) discussed earlier constitute the typical **indoor design conditions**, and they remain fairly constant. For example, the recommended indoor temperature for general comfort heating is 22°C (or 72°F). The outdoor conditions at a location, on the other hand, vary greatly from year to year, month to month, and even hour to hour. The set of extreme outdoor conditions under which a heating or cooling system must be able to maintain a building at the indoor design conditions is called the **outdoor design conditions** (Fig. 16-17).

When designing a heating, ventilating, and air-conditioning (HVAC) system, perhaps the first thought that comes to mind is to select a system that is large enough to keep the indoors at the desired conditions at all times even under the *worst weather conditions*. But sizing an HVAC system on the basis of the most extreme weather on record is not practical since such an oversized system will have a higher initial cost, will occupy more space, and will probably have a higher operating cost because the equipment in this case will run at partial load most of time and thus at a lower efficiency. Most people would not mind experiencing an occasional slight discomfort under extreme weather conditions if it means a significant reduction in the initial and operating costs of the heating or cooling system. The question that arises naturally is *what is a good compromise between economics and comfort?*

To answer this question, we need to know what the weather will be like in the future. But even the best weather forecasters cannot help us with that. Therefore, we turn to the past instead of the future and bet that the past weather data averaged over several years will be representative of a typical year in the future. The weather data in Tables 16-4 and 16-5 are based on the records of numerous weather stations in the United States that recorded

**TABLE 16-4**

\*Based on degrees F; quantities may be converted to degree days based on degrees C by dividing by 1.8. This assumes 18°C corresponds to 65°F.

various weather data in hourly intervals. For ordinary buildings, it turns out that the economics and comfort meet at the 97.5 percent level in winter. That is, the heating system will provide thermal comfort 97.5 percent of the time but may fail to do so during 2.5 percent of the time (Fig. 16-18). For example,

the 97.5 percent winter design temperature for Denver, Colorado, is  $-17^{\circ}\text{C}$ , and thus the temperatures in Denver may fall below  $-17^{\circ}\text{C}$  about 2.5 percent of the time during winter months in a typical year. Critical applications such as health care facilities and certain process industries may require the more stringent 99 percent level.

Table 16–4 lists the outdoor design conditions for both cases as well as summer comfort levels. The winter percentages are based on the weather data for the months of December, January, and February while the summer percentages are based on the four months June through September. The three winter months have a total of  $31 + 31 + 28 = 90$  days and thus 2160 hours. Therefore, the conditions of a house whose heating system is based on the 97.5 percent level may fall below the comfort level for  $2160 \times 2.5\% = 54$  hours during the heating season of a typical year. However, most people will not even notice it because everything in the house will start giving off heat as soon as the temperature drops below the thermostat setting. This is especially the case in buildings with large thermal masses. The minimum temperatures usually occur between 6:00 AM and 8:00 AM solar time, and thus commercial buildings that open late (such as shopping centers) may even use less stringent outdoor design conditions (such as the 95 percent level) for their heating systems. This is also the case with the cooling systems of residences that are unoccupied during the maximum temperatures, which occur between 2:00 PM and 4:00 PM solar time in the summer.

The **heating or cooling loads** of a building represent the heat that must be supplied to or removed from the interior of a building to maintain it at the desired conditions. A distinction should be made between the *design load* and the *actual load* of heating or cooling systems. The *design* (or *peak*) heating load is usually determined with a steady-state analysis using the design conditions for the indoors and the outdoors for the purpose of *sizing* the heating system (Fig. 16–19). This ensures that the system has the required capacity to perform adequately at the anticipated worst conditions. But the energy use of a building during a heating or cooling season is determined on the basis of the *actual* heating or cooling load, which varies throughout the day.

The **internal heat load** (the heat dissipated off by people, lights, and appliances in a building) is usually not considered in the determination of the design heating load but is considered in the determination of the design cooling load. This is to ensure that the heating system selected can heat the building even when there is no contribution from people or appliances, and the cooling system is capable of cooling it even when the heat given off by people and appliances is at its highest level.

Wind increases heat transfer to or from the walls, roof, and windows of a building by increasing the convection heat transfer coefficient and also increasing the infiltration. Therefore, **wind speed** is another consideration when determining the heating and cooling loads. The recommended values of wind speed to be considered are 15 mph (6.7 m/s) for winter and 7.5 mph (3.4 m/s) for summer. The corresponding design values recommended by ASHRAE for heat transfer coefficients for combined convection and radiation on the *outer surface* of a building are

$$h_{o,\text{winter}} = 34.0 \text{ W/m}^2 \cdot ^{\circ}\text{C} = 6.0 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^{\circ}\text{F}$$

$$h_{o,\text{summer}} = 22.7 \text{ W/m}^2 \cdot ^{\circ}\text{C} = 4.0 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^{\circ}\text{F}$$

### SALT LAKE CITY, UTAH

97.5% Winter design temp =  $-13^{\circ}\text{C}$   
No. of hours during winter (Dec., Jan., and Feb.) =  $90 \times 24 = 2160$  hours

Therefore,

$$T_{\text{outdoor}} \begin{cases} > -13^{\circ}\text{C} \text{ for } 2106 \text{ h (97.5\%)} \\ < -13^{\circ}\text{C} \text{ for } 54 \text{ h (2.5\%)} \end{cases}$$

**FIGURE 16–18**

The 97.5 percent winter design temperature represents the outdoor temperature that will be exceeded during 97.5 percent of the time in winter.

**FIGURE 16–19**

The design heat load of a building represents the heat loss of a building during design conditions at the indoors and the outdoors.

**FIGURE 16-20**

Recommended winter design values for heat transfer coefficients for combined convection and radiation on the outer and inner surfaces of a building.

The recommended heat transfer coefficient value for the *interior surfaces* of a building for both summer and winter is (Fig. 16-20)

$$h_i = 8.29 \frac{W}{m^2 \cdot ^\circ C} = 1.46 \frac{\text{Btu}}{h \cdot ft^2 \cdot ^\circ F}$$

For well-insulated buildings, the surface heat transfer coefficients constitute a small part of the overall heat transfer coefficients, and thus the effect of possible deviations from the above values is usually insignificant.

In summer, the **moisture level** of the outdoor air is much higher than that of indoor air. Therefore, the excess moisture that enters a house from the outside with infiltrating air needs to be condensed and removed by the cooling system. But this requires the removal of the latent heat from the moisture, and the cooling system must be large enough to handle this excess cooling load. To size the cooling system properly, we need to know the moisture level of the outdoor air at design conditions. This is usually done by specifying the wet-bulb temperature, which is a good indicator of the amount of moisture in the air. The moisture level of the cold outside air is very low in winter, and thus normally it does not affect the heating load of a building.

**Solar radiation** plays a major role on the heating and cooling of buildings, and you may think that it should be an important consideration in the evaluation of the design heating and cooling loads. Well, it turns out that peak heating loads usually occur early in the mornings just before sunrise. Therefore, solar radiation does not affect the *peak or design heating load* and thus the size of a heating system. However, it has a major effect on the actual heating load, and solar radiation can reduce the annual heating energy consumption of a building considerably.

**FIGURE 16-21**

Determination of the relative humidity and the humidity ratio of air from the psychrometric chart when the wet-bulb and ambient temperatures are given.

### EXAMPLE 16-2 Summer and Winter Design Conditions for Atlanta

Determine the outdoor design conditions for Atlanta, Georgia, for summer for the 2.5 percent level and for winter for the 97.5 percent and 99 percent levels.

**SOLUTION** The climatic conditions for major cities in the United States are listed in Table 16-4, and for the indicated design levels we read

|         |  |                      |
|---------|--|----------------------|
| Winter: | $T_{\text{outdoor}} = -6^\circ\text{C}$  | (97.5 percent level) |
| Winter: | $T_{\text{outdoor}} = -8^\circ\text{C}$  | (99 percent level)   |
| Summer: | $T_{\text{outdoor}} = 33^\circ\text{C}$  |                      |
|         | $T_{\text{wet-bulb}} = 23^\circ\text{C}$ | (2.5 percent level)  |

Therefore, the heating and cooling systems in Atlanta for common applications should be sized for these outdoor conditions. Note that when the wet-bulb and ambient temperatures are available, the relative humidity and the humidity ratio of air can be determined from the psychrometric chart (Fig. 16-21).

## Sol-Air Temperature

The sun is the main heat source of the earth, and without the sun, the environment temperature would not be much higher than the deep space temperature of  $-270^\circ\text{C}$ . The solar energy stored in the atmospheric air, the ground, and the structures such as buildings during the day is slowly released at night, and thus

the variation of the outdoor temperature is governed by the *incident solar radiation* and the *thermal inertia* of the earth. Heat gain from the sun is the primary reason for installing cooling systems, and thus solar radiation has a major effect on the *peak or design cooling load* of a building, which usually occurs early in the afternoon as a result of the solar radiation entering through the glazing directly and the radiation absorbed by the walls and the roof that is released later in the day.

The effect of solar radiation for glazing such as windows is expressed in terms of the *solar heat gain factor* (SHGF), discussed later in this chapter. For opaque surfaces such as the walls and the roof, on the other hand, the effect of solar radiation is conveniently accounted for by considering the outside temperature to be higher by an amount equivalent to the effect of solar radiation. This is done by replacing the ambient temperature in the heat transfer relation through the walls and the roof by the **sol-air temperature**, which is defined as *the equivalent outdoor air temperature that gives the same rate of heat transfer to a surface as would the combination of incident solar radiation, convection with the ambient air, and radiation exchange with the sky and the surrounding surfaces* (Fig. 16-22).

Heat flow into an exterior surface of a building subjected to solar radiation can be expressed as

$$\begin{aligned}\dot{Q}_{\text{surface}} &= \dot{Q}_{\text{conv + rad}} + \dot{Q}_{\text{solar}} - \dot{Q}_{\text{radiation correction}} \\ &= h_o A_s (T_{\text{ambient}} - T_{\text{surface}}) + \alpha_s A_s \dot{q}_{\text{solar}} - \varepsilon A_s \sigma (T_{\text{ambient}}^4 - T_{\text{surr}}^4) \\ &= h_o A_s (T_{\text{sol-air}} - T_{\text{surface}})\end{aligned}\quad (16-15)$$

where  $\alpha_s$  is the *solar absorptivity* and  $\varepsilon$  is the *emissivity* of the surface,  $h_o$  is the combined convection and radiation heat transfer coefficient,  $\dot{q}_{\text{solar}}$  is the solar radiation incident on the surface (in  $\text{W/m}^2$  or  $\text{Btu/h} \cdot \text{ft}^2$ ) and

$$T_{\text{sol-air}} = T_{\text{ambient}} + \frac{\alpha_s \dot{q}_{\text{solar}}}{h_o} - \frac{\varepsilon \sigma (T_{\text{ambient}}^4 - T_{\text{surr}}^4)}{h_o} \quad (16-16)$$

is the sol-air temperature. The first term in Equation 16-15 represents the convection and radiation heat transfer to the surface when the average surrounding surface and sky temperature is equal to the ambient air temperature,  $T_{\text{surr}} = T_{\text{ambient}}$ , and the last term represents the correction for the radiation heat transfer when  $T_{\text{surr}} \neq T_{\text{ambient}}$ . The last term in the sol-air temperature relation represents the equivalent change in the ambient temperature corresponding to this radiation correction effect and ranges from about zero for vertical wall surfaces to  $4^\circ\text{C}$  (or  $7^\circ\text{F}$ ) for horizontal or inclined roof surfaces facing the sky. This difference is due to the low effective sky temperature.

The sol-air temperature for a surface obviously depends on the absorptivity of the surface for solar radiation, which is listed in Table 16-6 for common exterior surfaces. Being conservative and taking  $h_o = 17 \text{ W/m}^2 \cdot {}^\circ\text{C} = 3.0 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F}$ , the summer design values of the ratio  $\alpha_s/h_o$  for light- and dark-colored surfaces are determined to be (Fig. 16-23)

$$\left(\frac{\alpha_s}{h_o}\right)_{\text{light}} = \frac{0.45}{17 \text{ W/m}^2 \cdot {}^\circ\text{C}} = 0.026 \text{ m}^2 \cdot {}^\circ\text{C/W} = 0.15 \text{ h} \cdot \text{ft}^2 \cdot {}^\circ\text{F/Btu}$$

$$\left(\frac{\alpha_s}{h_o}\right)_{\text{dark}} = \frac{0.90}{17 \text{ W/m}^2 \cdot {}^\circ\text{C}} = 0.052 \text{ m}^2 \cdot {}^\circ\text{C/W} = 0.30 \text{ h} \cdot \text{ft}^2 \cdot {}^\circ\text{F/Btu}$$

**FIGURE 16-22**

The sol-air temperature represents the equivalent outdoor air temperature that gives the same rate of heat flow to a surface as would the combination of incident solar radiation and convection/radiation with the environment.

**FIGURE 16-23**

Dark-colored buildings absorb most of the incident solar radiation whereas light-colored ones reflect most of it.

**TABLE 16-6**

The reflectivity  $\rho_s$  and absorptivity  $\alpha_s$  of common exterior surfaces for solar radiation (from Kreider and Rabl, 1994, Table 6.1)

| Surface   | $\rho_s$ | $\alpha_s$ |
|---|----------|------------|
| <i>Natural Surfaces</i>                                   |          |            |
| Fresh snow  | 0.75     | 0.25       |
| Soils (clay, loam, etc.)                                  | 0.14     | 0.86       |
| Water   | 0.07     | 0.93       |
| <i>Artificial Surfaces</i>                                |          |            |
| Bituminous and gravel roof                                | 0.13     | 0.87       |
| Blacktop, old   | 0.10     | 0.90       |
| Dark building surfaces (red brick, dark paints, etc.)     | 0.27     | 0.73       |
| Light building surfaces (light brick, light paints, etc.) | 0.60     | 0.40       |
| New concrete  | 0.35     | 0.65       |
| Old concrete  | 0.25     | 0.75       |
| Crushed rock surface                                      | 0.20     | 0.80       |
| Earth roads   | 0.04     | 0.96       |
| <i>Vegetation</i>   |          |            |
| Coniferous forest (winter)                                | 0.07     | 0.93       |
| Dead leaves   | 0.30     | 0.70       |
| Forests in autumn, ripe field crops, plants, green grass  | 0.26     | 0.74       |
| Dry grass   | 0.20     | 0.80       |

where we have assumed conservative values of 0.45 and 0.90 for the solar absorptivities of light- and dark-colored surfaces, respectively. The sol-air temperatures for light- and dark-colored surfaces are listed in Table 16-7 for July 21 at 40° N latitude versus solar time. Sol-air temperatures for other dates and latitudes can be determined from Equation 16-16 by using appropriate temperature and incident solar radiation data.

Once the sol-air temperature is available, heat transfer through a wall (or similarly through a roof) can be expressed as

$$\dot{Q}_{\text{wall}} = UA_s(T_{\text{sol-air}} - T_{\text{inside}}) \quad (16-17)$$

where  $A_s$  is the wall area and  $U$  is the overall heat transfer coefficient of the wall. Therefore, the rate of heat transfer through the wall will go up by  $UA$  for each degree rise in equivalent outdoor temperature due to solar radiation. Noting that the temperature rise due to solar radiation is

$$\Delta T_{\text{solar}} = \frac{\alpha_s \dot{q}_{\text{solar}}}{h_o} \quad (16-18)$$

the rate of additional heat gain through the wall becomes

$$\dot{Q}_{\text{wall, solar}} = UA_s \Delta T_{\text{solar}} = UA_s \frac{\alpha_s \dot{q}_{\text{solar}}}{h_o} \quad (16-19)$$

The total solar radiation incident on the entire wall is  $\dot{Q}_{\text{solar}} = A_s \dot{q}_{\text{solar}}$ . Therefore, the fraction of incident solar heat transferred to the interior of the house is

$$\text{Solar fraction transferred} = \frac{\dot{Q}_{\text{wall, solar}}}{\dot{Q}_{\text{solar}}} = \frac{\dot{Q}_{\text{wall, solar}}}{A_s \dot{q}_{\text{solar}}} = U \frac{\alpha_s}{h_o} \quad (16-20)$$

### EXAMPLE 16-3

### Effect of Solar Heated Walls on Design Heat Load

The west masonry wall of a house is made of 4-in thick red face brick, 4-in-thick common brick,  $\frac{3}{4}$ -in-thick air space, and  $\frac{1}{2}$ -in thick gypsum board, and its overall heat transfer coefficient is 0.29 Btu/h · ft<sup>2</sup> · °F, which includes the effects of convection on both the interior and exterior surfaces (Fig. 16-24).

**TABLE 16-7**Sol-air temperatures for July 21 at 40° latitude (from ASHRAE *Handbook of Fundamentals*, Chap. 26, Table 1)

(a) SI units

Note: Sol-air temperatures are calculated based on a radiation correction of 7°F (3.9°C) for horizontal surfaces and 0°F (0°C) for vertical surfaces.

FIGURE 16-24

Schematic for Example 16-3.

FIGURE 16-25

The difference between the sol-air temperature and the ambient air temperature represents the equivalent temperature rise of ambient air due to solar heating.

The house is located at  $40^\circ\text{N}$  latitude, and its cooling system is to be sized on the basis of the heat gain at 15:00 hour (3 PM) solar time on July 21. The interior of the house is to be maintained at  $75^\circ\text{F}$ , and the exposed surface area of the wall is  $210 \text{ ft}^2$ . If the design ambient air temperature at that time at that location is  $90^\circ\text{F}$ , determine (a) the design heat gain through the wall, (b) the fraction of this heat gain due to solar heating, and (c) the fraction of incident solar radiation transferred into the house through the wall.

**SOLUTION** The west wall of a house is subjected to solar radiation at summer design conditions. The design heat gain, the fraction of heat gain due to solar heating, and the fraction of solar radiation that is transferred to the house are to be determined.

**Assumptions** 1 Steady conditions exist. 2 Thermal properties of the wall and the heat transfer coefficients are constant.

**Properties** The overall heat transfer coefficient of the wall is given to be  $0.29 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F}$ .

**Analysis** (a) The house is located at  $40^\circ\text{N}$  latitude, and thus we can use the sol-air temperature data directly from Table 16-7. At 15:00 the tabulated air temperature is  $95^\circ\text{F}$ , which is  $5^\circ\text{F}$  higher than the air temperature given in the problem. But we can still use the data in that table provided that we subtract  $5^\circ\text{F}$  from all temperatures. Therefore, the sol-air temperature on the west wall in this case is  $124 - 5 = 119^\circ\text{F}$ , and the heat gain through the wall is determined to be

$$\begin{aligned}\dot{Q}_{\text{wall}} &= UA_s(T_{\text{sol-air}} - T_{\text{inside}}) \\ &= (0.29 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F})(210 \text{ ft}^2)(119 - 75)^\circ\text{F} = \mathbf{2680 \text{ Btu/h}}\end{aligned}$$

(b) Heat transfer is proportional to the temperature difference, and the overall temperature difference in this case is  $119 - 75 = 44^\circ\text{F}$ . Also, the difference between the sol-air temperature and the ambient air temperature is (Fig. 16-25)

$$\Delta T_{\text{solar}} = T_{\text{sol-air}} - T_{\text{ambient}} = (119 - 90)^\circ\text{F} = 29^\circ\text{F}$$

which is the equivalent temperature rise of the ambient air due to solar heating. The fraction of heat gain due to solar heating is equal to the ratio of the solar temperature difference to the overall temperature difference, and is determined to be

$$\text{Solar fraction} = \frac{\dot{Q}_{\text{wall, solar}}}{\dot{Q}_{\text{wall, total}}} = \frac{UA_s \Delta T_{\text{solar}}}{UA_s \Delta T_{\text{total}}} = \frac{\Delta T_{\text{solar}}}{\Delta T_{\text{total}}} = \frac{29^\circ\text{F}}{44^\circ\text{F}} = \mathbf{0.66 \text{ (or 66%)}}$$

Therefore, almost two-thirds of the heat gain through the west wall in this case is due to solar heating of the wall.

(c) The outer layer of the wall is made of red brick, which is dark colored. Therefore, the value of  $\alpha_s/h_o$  is  $0.30 \text{ h} \cdot \text{ft}^2 \cdot {}^\circ\text{F/Btu}$ . Then the fraction of incident solar energy transferred to the interior of the house is determined directly from Equation 16-20 to be.

$$\begin{aligned}\text{Solar fraction transferred} &= U \frac{\alpha_s}{h_o} = (0.29 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F})(0.30 \text{ h} \cdot \text{ft}^2 \cdot {}^\circ\text{F/Btu}) \\ &= \mathbf{0.087}\end{aligned}$$

Therefore, less than 10 percent of the solar energy incident on the surface will be transferred to the house. Note that a glass wall would transmit about 10 times more energy into the house.

## 16-5 • HEAT GAIN FROM PEOPLE, LIGHTS, AND APPLIANCES

The conversion of chemical or electrical energy to thermal energy in a building constitutes the **internal heat gain** or **internal load** of a building. The primary sources of internal heat gain are people, lights, appliances, and miscellaneous equipment such as computers, printers, and copiers (Fig. 16-26). Internal heat gain is usually ignored in *design heating load* calculations to ensure that the heating system can do the job even when there is no heat gain, but it is always considered in *design cooling load* calculations since the internal heat gain usually constitutes a significant fraction of it.

### People

The average amount of heat given off by a person depends on the level of activity, and can range from about 100 W for a resting person to more than 500 W for a physically very active person. Typical rates of heat dissipation by people are given in Table 16-8 for various activities in various application areas. Note that *latent heat* constitutes about one-third of the total heat dissipated during resting, but rises to almost two-thirds the level during heavy

**FIGURE 16-26**

The heat given off by people, lights, and equipment represents the internal heat gain of a building.

**TABLE 16-8**

Heat gain from people in conditioned spaces (from ASHRAE *Handbook of Fundamentals*, Chap. 26, Table 3)

| Degree of activity                           | Typical application         | Total heat, W* |                             |                   |                 |
|--|-----------------------------|----------------|-----------------------------|-------------------|-----------------|

| Athletics                                    | Gymnasium                   | 585            | 525                         | 210               | 315             |

Note: Tabulated values are based on a room temperature of 24°C (75°F). For a room temperature of 27°C (80°F), the total heat gain remains the same but the sensible heat values should be decreased by about 20 percent, and the latent heat values should be increased accordingly. All values are rounded to nearest 5 W. The fraction of sensible heat that is radiant ranges from 54 to 60 percent in calm air ( $V < 0.2 \text{ m/s}$ ) and from 19 to 38 percent in moving air ( $0.2 < V < 4 \text{ m/s}$ ).

\*Multiply by 3.412 to convert to Btu/h.

<sup>1</sup>Adjusted heat gain is based on normal percentage of men, women, and children for the application listed, with the postulate that the gain from an adult female is 85 percent of that for an adult male and that the gain from a child is 75 percent of that for an adult male.

<sup>2</sup>Adjusted heat gain includes 18 W (60 Btu/h) for food per individual (9 W sensible and 9 W latent).

<sup>3</sup>Figure one person per alley actually bowling, and all others are sitting (117 W) or standing or walking slowly (231 W).

**FIGURE 16-27**

If the moisture leaving an average resting person's body in one day were collected and condensed it would fill a 1-L container.

physical work. Also, about 30 percent of the sensible heat is lost by convection and the remaining 70 percent by radiation. The *latent* and *convective* sensible heat losses represent the “instant” cooling load for people since they need to be removed immediately. The *radiative sensible heat*, on the other hand, is first absorbed by the surrounding surfaces and then released gradually with some delay.

It is interesting to note that an average person dissipates latent heat at a minimum rate of 30 W while resting. Noting that the enthalpy of vaporization of water at 33°C is 2424 kJ/kg, the amount of water an average person loses a day by evaporation at the skin and the lungs is (Fig. 16-27)

$$\begin{aligned}\text{Daily Water loss} &= \frac{\text{Latent heat loss per day}}{\text{Heat of vaporization}} \\ &= \frac{(0.030 \text{ kJ/s})(24 \times 3600 \text{ s/day})}{2424 \text{ kJ/kg}} = 1.07 \text{ kg/day}\end{aligned}$$

which justifies the sound advice that a person must drink at least 1 L of water every day. Therefore, a family of four will supply 4 L of water a day to the air in the house while just resting. This amount will be much higher during heavy work.

Heat given off by people usually constitutes a significant fraction of the sensible and latent heat gain of a building, and may dominate the cooling load in high occupancy buildings such as theaters and concert halls. The rate of heat gain from people given in Table 16-8 is quite accurate, but there is considerable uncertainty in the internal load due to people because of the difficulty in predicting the number of occupants in a building at any given time. The design cooling load of a building should be determined assuming full occupancy. In the absence of better data, the number of occupants can be estimated on the basis of one occupant per 1 m<sup>2</sup> in auditoriums, 2.5 m<sup>2</sup> in schools, 3–5 m<sup>2</sup> in retail stores, and 10–15 m<sup>2</sup> in offices.

## Lights

Lighting constitutes about 7 percent of the total energy use in residential buildings and 25 percent in commercial buildings. Therefore, lighting can have a significant impact on the heating and cooling loads of a building. Not counting the candle light used for emergencies and romantic settings, and the kerosene lamps used during camping, all modern lighting equipment is powered by electricity. The basic types of electric lighting devices are incandescent, fluorescent, and gaseous discharge lamps.

The amount of heat given off per lux of lighting varies greatly with the type of lighting, and thus we need to know the type of lighting installed in order to predict the lighting internal heat load accurately. The lighting efficacy of common types of lighting is given in Table 16-9. Note that incandescent lights are the least efficient lighting sources, and thus they will impose the greatest load on cooling systems (Fig. 16-28). So it is no surprise that practically all office buildings use high-efficiency fluorescent lights despite their higher initial cost. Note that incandescent lights waste energy by (1) consuming more electricity for the same amount of lighting and (2) making the cooling system work harder and longer to remove the heat given off. Office spaces are usually well lit, and the lighting energy consumption in office buildings is about 20 to 30 W/m<sup>2</sup> (2 to 3 W/ft<sup>2</sup>) of floor space.

**FIGURE 16-28**

A 15-W compact fluorescent lamp provides as much light as a 60-W incandescent lamp.

**TABLE 16-9**

Comparison of different lighting systems

| Type of lighting         | Efficacy, lumens/W | Life, h | Comments                                      |
|--------------------------|--------------------|---------|---|
| <i>Combustion</i>        |                    |         |   |
| Candle                   | 0.2                | 10      | Very inefficient. Best for emergencies.       |
| <i>Incandescent</i>      |                    |         |   |
| Ordinary                 | 5–20               | 1000    | Low initial cost; low efficiency.             |
| Halogen                  | 15–25              | 2000    | Better efficiency; excellent color rendition. |
| <i>Fluorescent</i>       |                    |         |   |
| Ordinary                 | 40–60              | 10,000  | Being replaced by high-output types.          |
| High output              | 70–90              | 10,000  | Commonly in offices and plants.               |
| Compact                  | 50–80              | 10,000  | Fits into the sockets of incandescent lights. |
| Metal halide             | 55–125             |         | High efficiency; good color rendition.        |
| <i>Gaseous Discharge</i> |                    |         |   |
| Mercury vapor            | 50–60              | 10,000  | Both indoor and outdoor use.                  |
| High-pressure sodium     | 100–150            | 15,000  | Good color rendition. Indoor and outdoor use. |
| Low-pressure sodium      | up to 200          |         | Distinct yellow light. Best for outdoor use.  |

The energy consumed by the lights is dissipated by convection and radiation. The convection component of the heat constitutes about 40 percent for fluorescent lamps, and it represents the instantaneous part of the cooling load due to lighting. The remaining part is in the form of radiation that is absorbed and reradiated by the walls, floors, ceiling, and the furniture, and thus they affect the cooling load with time delay. Therefore, lighting may continue contributing to the cooling load by reradiation even after the lights have been turned off. Sometimes it may be necessary to consider time lag effects when determining the design cooling load.

The ratio of the lighting wattage in use to the total wattage installed is called the **usage factor**, and it must be considered when determining the heat gain due to lighting at a given time since installed lighting does not give off heat unless it is on. For commercial applications such as supermarkets and shopping centers, the usage factor is taken to be unity.

## Equipment and Appliances

Most equipment and appliances are driven by electric motors, and thus the heat given off by an appliance in steady operation is simply the power consumed by its motor. For a fan, for example, part of the power consumed by the motor is transmitted to the fan to drive it, while the rest is converted to heat because of the inefficiency of the motor. The fan transmits the energy to the air molecules and increases their kinetic energy. But this energy is also converted to heat as the fast-moving molecules are slowed down by other molecules and stopped as a result of friction. Therefore, we can say that the entire energy consumed by the motor of the fan in a room is eventually converted to heat in that room. Of course, if the motor is in one room (say, room A) and the fan is in another (say, room B), then the heat gain of room B will be equal to the power transmitted to the fan only, while the heat gain of room A will be the heat generated by the motor due to its inefficiency (Fig. 16-29).

**FIGURE 16-29**

An 80 percent efficient motor that drives a 100-W fan contributes 25 W and 100 W to the heat loads of the motor and equipment rooms, respectively.

The power rating  $\dot{W}_{\text{motor}}$  on the label of a motor represents the power that the motor will supply under full load conditions. But a motor usually operates at part load, sometimes as low as 30 to 40 percent, and thus it consumes and delivers much less power than the label indicates. This is characterized by the **load factor**  $f_{\text{load}}$  of the motor during operation, which is  $f_{\text{load}} = 1.0$  for full load. Also, there is an inefficiency associated with the conversion of electrical energy to rotational mechanical energy. This is characterized by the **motor efficiency**  $\eta_{\text{motor}}$ , which decreases with decreasing load factor. Therefore, it is not a good idea to oversize the motor since oversized motors operate at a low load factor and thus at a lower efficiency. Another factor that affects the amount of heat generated by a motor is how long a motor actually operates. This is characterized by the **usage factor**  $f_{\text{usage}}$ , with  $f_{\text{usage}} = 1.0$  for continuous operation. Motors with very low usage factors such as the motors of dock doors can be ignored in calculations. Then the heat gain due to a motor inside a conditioned space can be expressed as

$$\dot{Q}_{\text{motor, total}} = \dot{W}_{\text{motor}} \times f_{\text{load}} \times f_{\text{usage}} / \eta_{\text{motor}} \quad (\text{W}) \quad (16-21)$$

Heat generated in conditioned spaces by electric, gas, and steam appliances such as a range, refrigerator, freezer, TV, dishwasher, clothes washer, drier, computers, printers, and copiers can be significant, and thus must be considered when determining the peak cooling load of a building. There is considerable uncertainty in the estimated heat gain from appliances owing to the variations in appliances and the varying usage schedules. The exhaust hoods in the kitchen complicate things further. Also, some office equipment such as printers and copiers consume considerable power in the standby mode. A 350-W laser printer, for example, may consume 175 W and a 600-W computer may consume 530 W when in standby mode.

The heat gain from office equipment in a typical office with computer terminals on most desks can be up to  $47 \text{ W/m}^2$ . This value can be 10 times as large for computer rooms that house mainframe computers. When the equipment inventory of a building is known, the equipment heat gain can be determined more accurately using the data given in the *ASHRAE Handbook of Fundamentals*.

The presence of thermostatic controls and typical usage practices make it highly unlikely for all the appliances in a conditioned space to operate at full load. A more realistic approach is to take 50 percent of the total nameplate ratings of the appliances to represent the maximum use. Therefore, the peak heat gain from appliances is taken to be

$$\dot{Q}_{\text{unhooded appliance}} = 0.5 \dot{Q}_{\text{appliance, input}} \quad (\text{W}) \quad (16-22)$$

regardless of the type of energy or fuel used. For cooling load estimate, about 34 percent of heat gain can be assumed to be latent heat, with the remaining 66 percent to be sensible in this case.

In hooded appliances, the air heated by convection and the moisture generated are removed by the hood. Therefore, the only heat gain from hooded appliances is radiation, which constitutes up to 32 percent of the energy consumed by the appliance (Fig. 16-30). Therefore, the design value of heat gain from hooded electric or steam appliances is simply half of this 32 percent.

**FIGURE 16-30**

In hooded appliances, about 68 percent of the generated heat is vented out with the heated and humidified air.

**EXAMPLE 16-4** Energy Consumption of Electric and Gas Burners

The efficiency of cooking equipment affects the internal heat gain from them since an inefficient appliance consumes a greater amount of energy for the same task, and the excess energy consumed shows up as heat in the living space. The efficiency of open burners is determined to be 73 percent for electric units and 38 percent for gas units (Fig. 16-31). Consider a 2-kW unhooded electric open burner in an area where the unit costs of electricity and natural gas are \$0.09/kWh and \$0.55/therm, respectively. Determine the amount of electrical energy used directly for cooking, the cost of energy per "utilized" kWh, and the contribution of this burner to the design cooling load. Repeat the calculations for the gas burner.

**SOLUTION** The efficiency of the electric heater is given to be 73 percent. Therefore, a burner that consumes 2 kW of electrical energy will supply

$$\dot{Q}_{\text{utilized}} = (\text{Energy input}) \times (\text{Efficiency}) = (2 \text{ kW})(0.73) = \mathbf{1.46 \text{ kW}}$$

of useful energy. The unit cost of utilized energy is inversely proportional to the efficiency and is determined from

$$\text{Cost of utilized energy} = \frac{\text{Cost of energy input}}{\text{Efficiency}} = \frac{\$0.09/\text{kWh}}{0.73} = \mathbf{\$0.123/\text{kWh}}$$

The design heat gain from an unhooded appliance is taken to be half of its rated energy consumption and is determined to be

$$\begin{aligned}\dot{Q}_{\text{unhooded appliance}} &= 0.5\dot{Q}_{\text{appliance, input}} \\ &= 0.5 \times (2 \text{ kW}) = \mathbf{1 \text{ kW}} \quad (\text{electric burner})\end{aligned}$$

Noting that the efficiency of a gas burner is 38 percent, the energy input to a gas burner that supplies utilized energy at the same rate (1.46 kW) is

$$\dot{Q}_{\text{input, gas}} = \frac{\dot{Q}_{\text{utilized}}}{\text{Efficiency}} = \frac{1.46 \text{ kW}}{0.38} = \mathbf{3.84 \text{ kW}} (=13,100 \text{ Btu/h})$$

since 1 kW = 3412 Btu/h. Therefore, a gas burner should have a rating of at least 13,100 Btu/h to perform as well as the electric unit.

Noting that 1 therm = 29.3 kWh, the unit cost of utilized energy in the case of a gas burner is determined similarly to be

$$\begin{aligned}\text{Cost of utilized energy} &= \frac{\text{Cost of energy input}}{\text{Efficiency}} = \frac{\$0.55/(29.3 \text{ kWh})}{0.38} \\ &= \mathbf{\$0.049/\text{kWh}}\end{aligned}$$

which is about one-quarter of the unit cost of utilized electricity. Therefore, despite its higher efficiency, cooking with an electric burner will cost four times as much compared to a gas burner in this case. This explains why cost-conscious consumers always ask for gas appliances, and it is not wise to use electricity for heating purposes.

Finally, the design heat gain from this unhooded gas burner is determined to be

$$\begin{aligned}\dot{Q}_{\text{unhooded appliance}} &= 0.5\dot{Q}_{\text{appliance, input}} \\ &= 0.5 \times (3.84 \text{ kW}) = \mathbf{1.92 \text{ kW}} \quad (\text{gas burner})\end{aligned}$$

**FIGURE 16-31**

Schematic of the 73 percent efficient electric heating unit and 38 percent efficient gas burner discussed in Example 16-4.

**FIGURE 16-32**

Schematic for Example 16-5.

| Winter condition                         |                        |                                  |   |
| (winds at 15 mph<br>or 24 km/h)          |                        | 34.0                             | — —   |
| Summer condition                         |                        |                                  |   |
| (winds at 7.5 mph<br>or 12 km/h)         |                        | 22.7                             | — —   |

\*Multiply by 0.176 to convert to  $\text{Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ . Surface resistance can be obtained from  $R = 1/h$ .

which is 92 percent larger than that of the electric burner. Therefore, an unhooded gas appliance will contribute more to the heat gain than a comparable electric appliance.

### EXAMPLE 16-5 Heat Gain of an Exercise Room

An exercise room has 10 weight-lifting machines that have no motors and 7 treadmills each equipped with a 2-hp motor (Fig. 16-32). The motors operate at an average load factor of 0.6, at which their efficiency is 0.75. During peak evening hours, 17 pieces of exercising equipment are used continuously, and there are also four people doing light exercises while waiting in line for one piece of the equipment. Determine the rate of heat gain of the exercise room from people and the equipment at peak load conditions. How much of this heat gain is in the latent form?

**SOLUTION** The 10 weight-lifting machines do not have any motors, and thus they do not contribute to the internal heat gain directly. The usage factors of the motors of the treadmills are taken to be unity since they are used constantly during peak periods. Noting that 1 hp = 746 W, the total heat generated by the motors is

$$\dot{Q}_{\text{motors}} = (\text{No. of motors}) \times \dot{W}_{\text{motor}} \times f_{\text{load}} \times f_{\text{usage}} / \eta_{\text{motor}} \\ = 7 \times (2 \times 746 \text{ W}) \times 0.60 \times 1.0 / 0.75 = 8355 \text{ W}$$

The average rate of heat dissipated by people in an exercise room is given in Table 16-8 to be 525 W, of which 315 W is in latent form. Therefore, the heat gain from 21 people is

$$\dot{Q}_{\text{people}} = (\text{No. of people}) \times \dot{Q}_{\text{person}} = 21 \times (525 \text{ W}) = 11,025 \text{ W}$$

Then the total rate of heat gain (or the internal heat load) of the exercise room during peak period becomes

$$\dot{Q}_{\text{total}} = \dot{Q}_{\text{motors}} + \dot{Q}_{\text{people}} = 8355 + 11,025 = 19,380 \text{ W}$$

The entire heat given off by the motors is in sensible form. Therefore, the latent heat gain is due to people only, which is determined to be

$$\dot{Q}_{\text{latent}} = (\text{No. of people}) \times \dot{Q}_{\text{latent, per person}} = 21 \times (315 \text{ W}) = 6615 \text{ W}$$

The remaining 12,765 W of heat gain is in the sensible form.

## 16-6 • HEAT TRANSFER THROUGH WALLS AND ROOFS

Under steady conditions, the rate of heat transfer through any section of a building wall or roof can be determined from

$$\dot{Q} = UA_s(T_i - T_o) = \frac{A_s(T_i - T_o)}{R} \quad (16-23)$$

where  $T_i$  and  $T_o$  are the indoor and outdoor air temperatures,  $A_s$  is the heat transfer area,  $U$  is the overall heat transfer coefficient (the  $U$ -factor), and  $R = 1/U$  is the overall unit thermal resistance (the  $R$ -value). Walls and roofs of buildings consist of various layers of materials, and the structure and operating conditions of the walls and the roofs may differ significantly from one building to another. Therefore, it is not practical to list the  $R$ -values (or  $U$ -factors) of different kinds of walls or roofs under different conditions. Instead, the overall  $R$ -value is determined from the thermal resistances of the individual components using the thermal resistance network. The overall thermal resistance of a structure can be determined most accurately in a lab by actually assembling the unit and testing it as a whole, but this approach is usually very time consuming and expensive. The analytical approach described here is fast and straightforward, and the results are usually in good agreement with the experimental values.

The unit thermal resistance of a plane layer of thickness  $L$  and thermal conductivity  $k$  can be determined from  $R = L/k$ . The thermal conductivity and other properties of common building materials are given in the appendix. The unit thermal resistances of various components used in building structures are listed in Table 16–10 for convenience.

Heat transfer through a wall or roof section is also affected by the convection and radiation heat transfer coefficients at the exposed surfaces. The effects of convection and radiation on the inner and outer surfaces of walls and

**TABLE 16–10**Unit thermal resistance (the  $R$ -value) of common components used in buildings

| Component  | R-Value                                    |  | R-Value  |  |

roofs are usually combined into the *combined convection and radiation heat transfer coefficients* (also called *surface conductances*)  $h_i$  and  $h_o$ , respectively, whose values are given in Table 16–11 for ordinary surfaces ( $\epsilon = 0.9$ ) and reflective surfaces ( $\epsilon = 0.2$  or  $0.05$ ). Note that surfaces having a low emittance also have a low surface conductance due to the reduction in radiation heat transfer. The values in the table are based on a surface temperature of  $21^\circ\text{C}$  ( $72^\circ\text{F}$ ) and a surface–air temperature difference of  $5.5^\circ\text{C}$  ( $10^\circ\text{F}$ ). Also, the equivalent surface temperature of the environment is assumed to be equal to the ambient air temperature. Despite the convenience it offers, this assumption is not quite accurate because of the additional radiation heat loss from the surface to the clear sky. The effect of sky radiation can be accounted for approximately by taking the outside temperature to be the average of the outdoor air and sky temperatures.

The inner surface heat transfer coefficient  $h_i$  remains fairly constant throughout the year, but the value of  $h_o$  varies considerably because of its dependence on the orientation and wind speed, which can vary from less than  $1 \text{ km/h}$  in calm weather to over  $40 \text{ km/h}$  during storms. The commonly used values of  $h_i$  and  $h_o$  for peak load calculations are

$$h_i = 8.29 \text{ W/m}^2 \cdot {}^\circ\text{C} = 1.46 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F} \quad (\text{winter and summer})$$

$$h_o = \begin{cases} 34.0 \text{ W/m}^2 \cdot {}^\circ\text{C} = 1.46 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F} & (\text{winter}) \\ 22.7 \text{ W/m}^2 \cdot {}^\circ\text{C} = 4.0 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F} & (\text{summer}) \end{cases}$$

**TABLE 16–12**

Emissivities  $\epsilon$  of various surfaces and the effective emissivity of air spaces (from ASHRAE *Handbook of Fundamentals*, Chap. 22, Table 3).

| Surface                           | Effective Emissivity of Air Space |                         |                         |

\*Surface emissivity of aluminum foil increases to 0.30 with barely visible condensation, and to 0.70 with clearly visible condensation.

which correspond to design wind conditions of  $24 \text{ km/h}$  (15 mph) for winter and  $12 \text{ km/h}$  (7.5 mph) for summer. The corresponding surface thermal resistances ( $R$ -values) are determined from  $R_i = 1/h_i$  and  $R_o = 1/h_o$ . The surface conductance values under still air conditions can be used for interior surfaces as well as exterior surfaces in calm weather.

Building components often involve *trapped air spaces* between various layers. Thermal resistances of such air spaces depend on the thickness of the layer, the temperature difference across the layer, the mean air temperature, the emissivity of each surface, the orientation of the air layer, and the direction of heat transfer. The emissivities of surfaces commonly encountered in buildings are given in Table 16–12. The **effective emissivity** of a plane-parallel air space is given by

$$\frac{1}{\epsilon_{\text{effective}}} = \frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1 \quad (16-24)$$

where  $\epsilon_1$  and  $\epsilon_2$  are the emissivities of the surfaces of the air space. Table 16–12 also lists the effective emissivities of air spaces for the cases where (1) the emissivity of one surface of the air space is  $\epsilon$  while the emissivity of the other surface is 0.9 (a building material) and (2) the emissivity of both surfaces is  $\epsilon$ . Note that the effective emissivity of an air space between building materials is  $0.82/0.03 = 27$  times that of an air space between surfaces covered with aluminum foil. For specified surface temperatures, radiation heat transfer through an air space is proportional to effective emissivity, and thus the rate of radiation heat transfer in the ordinary surface case is 27 times that of the reflective surface case.

Table 16–13 lists the thermal resistances of 20-mm-, 40-mm-, and 90-mm-(0.75-in, 1.5-in, and 3.5-in) thick air spaces under various conditions.

**TABLE 16-13**Unit thermal resistances ( $R$ -values) of well-sealed plane air spaces (from ASHRAE *Handbook of Fundamentals*, Chap. 22, Table 2)(a) SI units (in  $\text{m}^2 \cdot ^\circ\text{C/W}$ )

The thermal resistance values in the table are applicable to air spaces of uniform thickness bounded by plane, smooth, parallel surfaces with no air leakage. Thermal resistances for other temperatures, emissivities, and air spaces can be obtained by interpolation and moderate extrapolation. Note that the presence of a low-emissivity surface reduces radiation heat transfer across an air space and thus significantly increases the thermal resistance. The thermal effectiveness of a low-emissivity surface will decline, however, if the condition of the surface changes as a result of some effects such as condensation, surface oxidation, and dust accumulation.

The *R*-value of a wall or roof structure that involves layers of uniform thickness is determined easily by simply adding up the unit thermal resistances of the layers that are in series. But when a structure involves components such as wood studs and metal connectors, then the thermal resistance network involves parallel connections and possible two-dimensional effects. The overall *R*-value in this case can be determined by assuming (1) parallel heat flow paths through areas of different construction or (2) isothermal planes normal to the direction of heat transfer. The first approach usually over-predicts the overall thermal resistance, whereas the second approach usually underpredicts it. The parallel heat flow path approach is more suitable for wood frame walls and roofs, whereas the isothermal planes approach is more suitable for masonry or metal frame walls.

The thermal contact resistance between different components of building structures ranges between 0.01 and 0.1  $\text{m}^2 \cdot ^\circ\text{C}/\text{W}$ , which is negligible in most cases. However, it may be significant for metal building components such as steel framing members.

### **EXAMPLE 16-6      The *R*-Value of a Wood Frame Wall**

Determine the overall unit thermal resistance (the *R*-value) and the overall heat transfer coefficient (the *U*-factor) of a wood frame wall that is built around 38-mm  $\times$  90-mm (2  $\times$  4 nominal) wood studs with a center-to-center distance of 400 mm. The 90-mm-wide cavity between the studs is filled with glass fiber insulation. The inside is finished with 13-mm gypsum wallboard and the outside with 13-mm wood fiberboard and 13-mm  $\times$  200-mm wood bevel lapped siding. The insulated cavity constitutes 75 percent of the heat transmission area while the studs, plates, and sills constitute 21 percent. The headers constitute 4 percent of the area, and they can be treated as studs.

Also, determine the rate of heat loss through the walls of a house whose perimeter is 50 m and wall height is 2.5 m in Las Vegas, Nevada, whose winter design temperature is  $-2^\circ\text{C}$ . Take the indoor design temperature to be  $22^\circ\text{C}$  and assume 20 percent of the wall area is occupied by glazing.

**SOLUTION** The *R*-value and the *U*-factor of a wood frame wall as well as the rate of heat loss through such a wall in Las Vegas are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the wall is one-dimensional. 3 Thermal properties of the wall and the heat transfer coefficients are constant.

**Properties** The *R*-values of different materials are given in Table 16-10.

**Analysis** The schematic of the wall as well as the different elements used in its construction are shown below. Heat transfer through the insulation and

through the studs will meet different resistances, and thus we need to analyze the thermal resistance for each path separately. Once the unit thermal resistances and the  $U$ -factors for the insulation and stud sections are available, the overall average thermal resistance for the entire wall can be determined from

$$R_{\text{overall}} = 1/U_{\text{overall}}$$

where

$$U_{\text{overall}} = (U \times f_{\text{area}})_{\text{insulation}} + (U \times f_{\text{area}})_{\text{stud}}$$

and the value of the area fraction  $f_{\text{area}}$  is 0.75 for the insulation section and 0.25 for the stud section since the headers that constitute a small part of the wall are to be treated as studs. Using the available  $R$ -values from Table 16-10 and calculating others, the total  $R$ -values for each section can be determined in a systematic manner in the table:

### Schematic

| Construction                           | <i>R</i> -value,<br>$\text{m}^2 \cdot ^\circ\text{C}/\text{W}$ |             |
|--|--|-------------|
|  | Between<br>studs   | At<br>studs |
| 1. Outside surface,<br>24 km/h wind    | 0.030  | 0.030       |
| 2. Wood bevel lapped<br>siding         | 0.14   | 0.14        |
| 3. Wood fiberboard<br>sheeting, 13 mm  | 0.23   | 0.23        |
| 4a. Glass fiber<br>insulation, 90 mm   | 2.45   | —           |
| 4b. Wood stud, 38 mm $\times$<br>90 mm | —  | 0.63        |
| 5. Gypsum wallboard,<br>13 mm          | 0.079  | 0.079       |
| 6. Inside surface, still air           | 0.12   | 0.12        |

Total unit thermal resistance of each section,

$$R (\text{in } \text{m}^2 \cdot ^\circ\text{C}/\text{W}) \quad 3.05 \quad 1.23$$

$$\text{The } U\text{-factor of each section, } U = 1/R, \text{ in } \text{W}/\text{m}^2 \cdot ^\circ\text{C} \quad 0.328 \quad 0.813$$

$$\text{Area fraction of each section, } f_{\text{area}} \quad 0.75 \quad 0.25$$

$$\begin{aligned} \text{Overall } U\text{-factor: } U &= \sum f_{\text{area}, i} U_i = 0.75 \times 0.328 + 0.25 \times 0.813 \\ &= \mathbf{0.449 \text{ W/m}^2 \cdot ^\circ\text{C}} \end{aligned}$$

$$\text{Overall unit thermal resistance: } R = 1/U = \mathbf{2.23 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}}$$

We conclude that the overall unit thermal resistance of the wall is  $2.23 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ , and this value accounts for the effects of the studs and headers. It corresponds to an  $R$ -value of  $2.23 \times 5.68 = 12.7$  (or nearly  $R-13$ ) in English units. Note that if there were no wood studs and headers in the wall, the overall thermal resistance would be  $3.05 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ , which is 37 percent greater than  $2.23 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ . Therefore, the wood studs and headers in this case serve as thermal bridges in wood frame walls, and their effect must be considered in the thermal analysis of buildings.

The perimeter of the building is 50 m and the height of the walls is 2.5 m. Noting that glazing constitutes 20 percent of the walls, the total wall area is

$$A_{\text{wall}} = 0.80(\text{Perimeter})(\text{Height}) = 0.80(50 \text{ m})(2.5 \text{ m}) = 100 \text{ m}^2$$

Then the rate of heat loss through the walls under design conditions becomes

$$\begin{aligned}\dot{Q}_{\text{wall}} &= (UA)_{\text{wall}} (T_i - T_o) \\ &= (0.449 \text{ W/m}^2 \cdot ^\circ\text{C})(100 \text{ m}^2)[22 - (-2)^\circ\text{C}] \\ &= \mathbf{1078 \text{ W}}\end{aligned}$$

**Discussion** Note that a 1-kW resistance heater in this house will make up almost all the heat lost through the walls, except through the doors and windows, when the outdoor air temperature drops to  $-2^\circ\text{C}$ .

### EXAMPLE 16-7 The R-Value of a Wall with Rigid Foam

The 13-mm-thick wood fiberboard sheathing of the wood stud wall discussed in the previous example is replaced by a 25-mm-thick rigid foam insulation. Determine the percent increase in the *R*-value of the wall as a result.

**SOLUTION** The overall *R*-value of the existing wall was determined in Example 16-6 to be  $2.23 \text{ m}^2 \cdot ^\circ\text{C/W}$ . Noting that the *R*-values of the fiberboard and the foam insulation are  $0.23 \text{ m}^2 \cdot ^\circ\text{C/W}$  and  $0.98 \text{ m}^2 \cdot ^\circ\text{C/W}$ , respectively, and the added and removed thermal resistances are in series, the overall *R*-value of the wall after modification becomes

$$\begin{aligned}R_{\text{new}} &= R_{\text{old}} - R_{\text{removed}} + R_{\text{added}} \\ &= 2.23 - 0.23 + 0.98 \\ &= 2.98 \text{ m}^2 \cdot ^\circ\text{C/W}\end{aligned}$$

This represents an increase of  $(2.98 - 2.23)/2.23 = 0.34$  or **34 percent** in the *R*-value of the wall. This example demonstrated how to evaluate the new *R*-value of a structure when some structural members are added or removed.

### EXAMPLE 16-8 The R-Value of a Masonry Wall

Determine the overall unit thermal resistance (the *R*-value) and the overall heat transfer coefficient (the *U*-factor) of a masonry cavity wall that is built around 6-in-thick concrete blocks made of lightweight aggregate with 3 cores filled with perlite ( $R = 4.2 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ ). The outside is finished with 4-in face brick with  $\frac{1}{2}$ -in cement mortar between the bricks and concrete blocks. The inside finish consists of  $\frac{1}{2}$  in gypsum wallboard separated from the concrete block by  $\frac{3}{4}$ -in-thick (1-in  $\times$  3-in nominal) vertical furring ( $R = 4.2 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ ) whose center-to-center distance is 16 in. Both sides of the  $\frac{3}{4}$ -in-thick air space between the concrete block and the gypsum board are coated with reflective aluminum foil ( $\epsilon = 0.05$ ) so that the effective emissivity of the air space is 0.03. For a mean temperature of  $50^\circ\text{F}$  and a temperature difference of  $30^\circ\text{F}$ , the *R*-value of the air space is  $2.91 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ . The reflective air

space constitutes 80 percent of the heat transmission area, while the vertical furring constitutes 20 percent.

**SOLUTION** The  $R$ -value and the  $U$ -factor of a masonry cavity wall are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the wall is one-dimensional. 3 Thermal properties of the wall and the heat transfer coefficients are constant.

**Properties** The  $R$ -values of different materials are given in Table 16–10.

**Analysis** The schematic of the wall as well as the different elements used in its construction are shown below. Following the approach described above and using the available  $R$ -values from Table 16–10, the overall  $R$ -value of the wall is determined in the table below.

### Schematic

| Construction                                  | <i>R</i> -value,<br>$h \cdot ft^2 \cdot ^\circ F/Btu$ |               |
|---|---|---------------|
|   | Between<br>furring                                    | At<br>furring |
| 1. Outside surface,<br>15 mph wind            | 0.17  | 0.17          |
| 2. Face brick, 4 in                           | 0.43  | 0.43          |
| 3. Cement mortar, 0.5 in                      | 0.10  | 0.10          |
| 4. Concrete block, 6 in                       | 4.20  | 4.20          |
| 5a. Reflective air space,<br>$\frac{3}{4}$ in | 2.91  | —             |
| 5b. Nominal 1 × 3 vertical<br>furring         | —   | 0.94          |
| 6. Gypsum wallboard,<br>0.5 in                | 0.45  | 0.45          |
| 7. Inside surface, still air                  | 0.68  | 0.68          |

Total unit thermal resistance of each section,  $R$       8.94      6.97

The  $U$ -factor of each section,  $U = 1/R$ , in

Btu/h · ft<sup>2</sup> · °F      0.112      0.143

Area fraction of each section,  $f_{area}$       0.80      0.20

$$\begin{aligned} \text{Overall } U\text{-factor: } U &= \sum f_{area,i} U_i = 0.80 \times 0.112 + 0.20 \times 0.143 \\ &= 0.118 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ \text{F} \end{aligned}$$

$$\text{Overall unit thermal resistance: } R = 1/U = 8.46 \text{ h} \cdot \text{ft}^2 \cdot ^\circ \text{F/Btu}$$

Therefore, the overall unit thermal resistance of the wall is 8.46 h · ft<sup>2</sup> · °F/Btu and the overall  $U$ -factor is 0.118 Btu/h · ft<sup>2</sup> · °F. These values account for the effects of the vertical furring.

### EXAMPLE 16–9 The $R$ -Value of a Pitched Roof

Determine the overall unit thermal resistance (the  $R$ -value) and the overall heat transfer coefficient (the  $U$ -factor) of a 45° pitched roof built around nominal 2-in × 4-in wood studs with a center-to-center distance of 16 in. The 3.5-in-wide

air space between the studs does not have any reflective surface and thus its effective emissivity is 0.84. For a mean temperature of 90°F and a temperature difference of 30°F, the  $R$ -value of the air space is  $0.86 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ . The lower part of the roof is finished with  $\frac{1}{2}$ -in gypsum wallboard and the upper part with  $\frac{5}{8}$ -in plywood, building paper, and asphalt shingle roofing. The air space constitutes 75 percent of the heat transmission area, while the studs and headers constitute 25 percent.

**SOLUTION** The  $R$ -value and the  $U$ -factor of a 45° pitched roof are to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the roof is one-dimensional. 3 Thermal properties of the roof and the heat transfer coefficients are constant.

**Properties** The  $R$ -values of different materials are given in Table 16–10.

**Analysis** The schematic of the pitched roof as well as the different elements used in its construction are shown below. Following the approach described above and using the available  $R$ -values from Table 16–10, the overall  $R$ -value of the roof can be determined in the table below.

**Schematic**

| Construction   | <i>R</i> -value,<br>$\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ |             |
|--|---|-------------|
|  | Between<br>studs  | At<br>studs |
| 1. Outside surface, 15 mph wind  | 0.17  | 0.17        |
| 2. Asphalt shingle roofing   | 0.44  | 0.44        |
| 3. Building paper  | 0.10  | 0.10        |
| 4. Plywood deck, $\frac{5}{8}$ in  | 0.78  | 0.78        |
| 5a. Nonreflective air space, 3.5 in  | 0.86  | —           |
| 5b. Wood stud, 2 in $\times$ 4 in  | —   | 3.58        |
| 6. Gypsum wallboard, 0.5 in  | 0.45  | 0.45        |
| 7. Inside surface, 45° slope, still air  | 0.63  | 0.63        |
| Total unit thermal resistance of each section, $R$   | 3.43  | 6.15        |
| The $U$ -factor of each section, $U = 1/R$ , in $\text{Btu}/(\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F})$ | 0.292   | 0.163       |
| Area fraction of each section, $f_{\text{area}}$   | 0.75  | 0.25        |
| Overall $U$ -factor: $U = \sum f_{\text{area}, i} U_i = 0.75 \times 0.292 + 0.25 \times 0.163$                 |   |             |
|  | $= 0.260 \text{ Btu}/(\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F})$   |             |
| Overall unit thermal resistance:   | $R = 1/U = 3.85 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$     |             |

Therefore, the overall unit thermal resistance of this pitched roof is  $3.85 \text{ h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$  and the overall  $U$ -factor is  $0.260 \text{ Btu}/(\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F})$ . Note that the wood studs offer much larger thermal resistance to heat flow than the air space between the studs.

The construction of wood frame flat ceilings typically involve 2-in  $\times$  6-in joists on 400-mm (16-in) or 600-mm (24-in) centers. The fraction of framing is usually taken to be 0.10 for joists on 400-mm centers and 0.07 for joists on 600-mm centers.

Most buildings have a combination of a ceiling and a roof with an attic space in between, and the determination of the *R*-value of the roof–attic–ceiling combination depends on whether the attic is vented or not. For adequately ventilated attics, the attic air temperature is practically the same as the outdoor air temperature, and thus heat transfer through the roof is governed by the *R*-value of the ceiling only. However, heat is also transferred between the roof and the ceiling by radiation, and it needs to be considered (Fig. 16–33). The major function of the roof in this case is to serve as a radiation shield by blocking off solar radiation. Effectively ventilating the attic in summer should not lead one to believe that heat gain to the building through the attic is greatly reduced. This is because most of the heat transfer through the attic is by radiation.

Radiation heat transfer between the ceiling and the roof can be minimized by covering at least one side of the attic (the roof or the ceiling side) by a reflective material, called *radiant barrier*, such as aluminum foil or aluminum-coated paper. Tests on houses with *R*-19 attic floor insulation have shown that radiant barriers can reduce summer ceiling heat gains by 16 to 42 percent compared to an attic with the same insulation level and no radiant barrier. Considering that the ceiling heat gain represents about 15 to 25 percent of the total cooling load of a house, radiant barriers will reduce the air conditioning costs by 2 to 10 percent. Radiant barriers also reduce the heat loss in winter through the ceiling, but tests have shown that the percentage reduction in heat losses is less. As a result, the percentage reduction in heating costs will be less than the reduction in the air-conditioning costs. Also, the values given are for new and undusted radiant barrier installations, and percentages will be lower for aged or dusty radiant barriers.

Some possible locations for attic radiant barriers are given in Fig. 16–34. In whole house tests on houses with *R*-19 attic floor insulation, radiant barriers have reduced the ceiling heat gain by an average of 35 percent when the radiant barrier is installed on the attic floor, and by 24 percent when it is attached to the bottom of roof rafters. Test cell tests also demonstrated that the best location for radiant barriers is the attic floor, provided that the attic is not used as a storage area and is kept clean.

For unvented attics, any heat transfer must occur through (1) the ceiling, (2) the attic space, and (3) the roof (Fig. 16–35). Therefore, the overall *R*-value

**FIGURE 16–33**

Ventilation paths for a naturally ventilated attic and the appropriate size of the flow areas around the radiant barrier for proper air circulation.

FIGURE 16-35

Thermal resistance network for a pitched roof–attic–ceiling combination for the case of an unvented attic.

of the roof–ceiling combination with an unvented attic depends on the combined effects of the  $R$ -value of the ceiling and the  $R$ -value of the roof as well as the thermal resistance of the attic space. The attic space can be treated as an air layer in the analysis. But a more practical way of accounting for its effect is to consider surface resistances on the roof and ceiling surfaces facing each other. In this case, the  $R$ -values of the ceiling and the roof are first determined separately (by using convection resistances for the still-air case for the attic surfaces). Then it can be shown that the overall  $R$ -value of the ceiling–roof combination per unit area of the ceiling can be expressed as

$$R = R_{\text{ceiling}} + R_{\text{roof}} \left( \frac{A_{\text{ceiling}}}{A_{\text{roof}}} \right) \quad (16-25)$$

where  $A_{\text{ceiling}}$  and  $A_{\text{roof}}$  are the ceiling and roof areas, respectively. The area ratio is equal to 1 for flat roofs and is less than 1 for pitched roofs. For a  $45^\circ$  pitched roof, the area ratio is  $A_{\text{ceiling}}/A_{\text{roof}} = 1/\sqrt{2} = 0.707$ . Note that the pitched roof has a greater area for heat transfer than the flat ceiling, and the area ratio accounts for the reduction in the unit  $R$ -value of the roof when expressed per unit area of the ceiling. Also, the direction of heat flow is up in winter (heat loss through the roof) and down in summer (heat gain through the roof).

The  $R$ -value of a structure determined by analysis assumes that the materials used and the quality of workmanship meet the standards. Poor workmanship and substandard materials used during construction may result in  $R$ -values that deviate from predicted values. Therefore, some engineers use a safety factor in their designs based on experience in critical applications.

## 16-7 • HEAT LOSS FROM BASEMENT WALLS AND FLOORS

The floors and the underground portion of the walls of a basement are in direct contact with the ground, which is usually at a different temperature than the basement, and thus there is heat transfer between the basement and the ground. This is *conduction heat transfer* because of the direct contact between the walls and the floor, and it depends on the temperature difference between the basement and the ground, the construction of the walls and the floor, and the thermal conductivity of the surrounding earth. There is considerable uncertainty in the ground heat loss calculations, and they probably constitute the least accurate part of heat load estimates of a building because of the large thermal mass of the ground and the large variation of the thermal conductivity of the soil [it varies between 0.5 and 2.5 W/m · °C (or 0.3 to 1.4 Btu/h · ft · °F), depending on the composition and moisture content]. However, ground heat losses are a small fraction of total heat load of a large building, and thus it has little effect on the overall heat load.

Temperature measurements of uninsulated basements indicate that heat conduction through the ground is not one-dimensional, and thus it cannot be estimated by a simple one-dimensional heat conduction analysis. Instead, heat conduction is observed to be two-dimensional with nearly circular concentric heat flow lines centered at the intersection of the wall and the earth (Fig. 16-36). When partial insulation is applied to the walls, the heat flow lines

FIGURE 16-36

Radial isotherms and circular heat flow lines during heat flow from uninsulated basement.

tend to be straight lines rather than being circular. Also, a basement wall whose top portion is exposed to ambient air may act as a thermal bridge, conducting heat upward and dissipating it to the ambient from its top part. This vertical heat flow may be significant in some cases.

Despite its complexity, heat loss through the below-grade section of **basement walls** can be determined easily from

$$\dot{Q}_{\text{basement walls}} = U_{\text{wall, avg}} A_{\text{wall}} (T_{\text{basement}} - T_{\text{ground surface}}) \quad (\text{W}) \quad (16-26)$$

where

$U_{\text{wall, avg}}$  = Average overall heat transfer coefficient between the basement wall and the surface of the ground

$A_{\text{wall, avg}}$  = Wall surface area of the basement (underground portion)

$T_{\text{basement}}$  = Interior air temperature of the basement

$T_{\text{ground surface}}$  = Mean ground surface temperature in winter

The overall heat transfer coefficients at different depths are given in Table 16-14a for depth increments of 0.3 m (or 1 ft) for uninsulated and insulated concrete walls. These values are based on a soil thermal conductivity of  $1.38 \text{ W/m} \cdot ^\circ\text{C}$  ( $0.8 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ ). Note that the heat transfer coefficient values decrease with increasing depth since the heat at a lower section must pass through a longer path to reach the ground surface. For a specified wall,  $U_{\text{wall, avg}}$  is simply the arithmetic average of the  $U_{\text{wall}}$  values corresponding to the different sections of the wall. Also note that heat loss through a depth increment is equal to the  $U_{\text{wall}}$  value of the increment multiplied by the perimeter of the building, the depth increment, and the temperature difference.

The interior air temperature of the basement can vary considerably, depending on whether it is being heated or not. In the absence of reliable data, the basement temperature can be taken to be  $10^\circ\text{C}$  since the heating system, water heater, and heating ducts are often located in the basement. Also, the ground surface temperature fluctuates about the mean winter ambient temperature by an amplitude  $A$  that varies with geographic location and the condition of the surface, as shown in Fig. 16-37. Therefore, a reasonable value for the design temperature of ground surface can be obtained by subtracting  $A$  for the specified location from the mean winter air temperature. That is,

$$T_{\text{ground surface}} = T_{\text{winter, mean}} - A \quad (16-27)$$

Heat loss through the **basement floor** is much smaller since the heat flow path to the ground surface is much longer in this case. It is calculated in a similar manner from

$$\dot{Q}_{\text{basement floor}} = U_{\text{floor}} A_{\text{floor}} (T_{\text{basement}} - T_{\text{ground surface}}) \quad (\text{W}) \quad (16-28)$$

where  $U_{\text{floor}}$  is the overall heat transfer coefficient at the basement floor whose values are listed in Table 16-14b,  $A_{\text{floor}}$  is the floor area, and the temperature difference is the same as the one used for the basement wall.

The temperature of an unheated below-grade basement is between the temperatures of the rooms above and the ground temperature. Heat losses from the water heater and the space heater located in the basement usually keep the air near the basement ceiling sufficiently warm. Heat losses from the rooms above to the basement can be neglected in such cases. This will not be the case, however, if the basement has windows.

**EXAMPLE 16–10 Heat Loss from a Below-Grade Basement**

Consider a basement in Chicago, where the mean winter temperature is  $2.4^{\circ}\text{C}$ . The basement is 8.5 m wide and 12 m long, and the basement floor is 2.1 m below grade (the ground level). The top 0.9-m section of the wall below the grade is insulated with  $R=2.20 \text{ m}^2 \cdot ^{\circ}\text{C}/\text{W}$  insulation. Assuming the interior temperature of the basement is  $22^{\circ}\text{C}$ , determine the peak heat loss from the basement to the ground through its walls and floor.

**SOLUTION** The peak heat loss from a below-grade basement in Chicago to the ground through its walls and the floor is to be determined.

**Assumption** Steady operating conditions exist.

**Properties** The heat transfer coefficients are given in Table 16–14.

**Analysis** The schematic of the basement is given in Fig. 16–38. The floor and wall areas of the basement are

$$A_{\text{wall}} = \text{Height} \times \text{Perimeter} = 2 \times (2.1 \text{ m})(8.5 + 12)\text{m} = 86.1 \text{ m}^2$$

$$A_{\text{floor}} = \text{Length} \times \text{Width} = (8.5 \text{ m})(12 \text{ m}) = 102 \text{ m}^2$$

The amplitude of the annual soil temperature is determined from Fig. 16–37 to be  $12^{\circ}\text{C}$ . Then the ground surface temperature for the design heat loss becomes

$$T_{\text{ground surface}} = T_{\text{winter, mean}} - A = 2.4 - 12 = -9.6^{\circ}\text{C}$$

The top 0.9-m section of the wall below the grade is insulated with  $R=2.2$ , and the heat transfer coefficients through that section are given in Table 16–14a to be 1.27, 1.20, and 1.00  $\text{W/m}^2 \cdot ^{\circ}\text{C}$  through the first, second, and third 0.3-m-wide depth increments, respectively. The heat transfer coefficients through the uninsulated section of the wall that extends from the 0.9-m to the 2.1-m level are determined from the same table to be 2.23, 1.80, 1.50, and 1.30  $\text{W/m}^2 \cdot ^{\circ}\text{C}$  for each of the remaining 0.3-m-wide depth increments. The average overall heat transfer coefficient is

$$U_{\text{wall, avg}} = \frac{\sum U_{\text{wall}}}{\text{No. of increments}} = \frac{1.27 + 1.2 + 1.0 + 2.23 + 1.8 + 1.5 + 1.3}{7} \\ = 1.47 \text{ W/m}^2 \cdot ^{\circ}\text{C}$$

Then the heat loss through the basement wall becomes

$$\dot{Q}_{\text{basement walls}} = U_{\text{wall, avg}} A_{\text{wall}} (T_{\text{basement}} - T_{\text{ground surface}}) \\ = (1.47 \text{ W/m}^2 \cdot ^{\circ}\text{C})(86.1 \text{ m}^2)[22 - (-9.6)^{\circ}\text{C}] = 4000 \text{ W}$$

The shortest width of the house is 8.5 m, and the depth of the foundation below grade is 2.1 m. The floor heat transfer coefficient is given in Table 16–14b to be  $0.13 \text{ W/m}^2 \cdot ^{\circ}\text{C}$ . Then the heat loss through the floor of the basement becomes

$$\dot{Q}_{\text{basement floor}} = U_{\text{floor}} A_{\text{floor}} (T_{\text{basement}} - T_{\text{ground surface}}) \\ = (0.13 \text{ W/m}^2 \cdot ^{\circ}\text{C})(102 \text{ m}^2)[22 - (-9.6)]^{\circ}\text{C} = 419 \text{ W}$$

which is considerably less than the heat loss through the wall. The total heat loss from the basement is then determined to be

$$\dot{Q}_{\text{basement}} = \dot{Q}_{\text{basement walls}} + \dot{Q}_{\text{basement floor}} = 4000 + 419 = \mathbf{4419 \text{ W}}$$

**FIGURE 16–38**

Schematic for Example 16–10.

This is the *design* or *peak* rate of heat transfer from the below-grade section of the basement, and this is the value to be used when sizing the heating system. The actual heat loss from the basement will be much less than that most of the time.

## Concrete Floors on Grade (at Ground Level)

Many residential and commercial buildings do not have a basement, and the floor sits directly on the ground at or slightly above the ground level. Research indicates that heat loss from such floors is mostly through the perimeter to the outside air rather than through the floor into the ground, as shown in Fig. 16-39. Therefore, total heat loss from a concrete slab floor is proportional to the perimeter of the slab instead of the area of the floor and is expressed as

$$\dot{Q}_{\text{floor on grade}} = U_{\text{grade}} p_{\text{floor}} (T_{\text{indoor}} - T_{\text{outdoor}}) \quad (\text{W}) \quad (16-29)$$

where  $U_{\text{grade}}$  represents the rate of heat transfer from the slab per unit temperature difference between the indoor temperature  $T_{\text{indoor}}$  and the outdoor temperature  $T_{\text{outdoor}}$  and per unit length of the perimeter  $p_{\text{floor}}$  of the building.

Typical values of  $U_{\text{grade}}$  are listed in Table 16-14c for four common types of slab-on-grade construction for mild, moderate, and severe weather conditions. The ground temperature is not involved in the formulation since the slab is located above the ground level and heat loss to the ground is negligible. Note from the table that perimeter insulation of slab-on-grade reduces heat losses considerably, and thus it saves energy while enhancing comfort. Insulation is a must for radiating floors that contain heated pipes or ducts through which hot water or air is circulated since heat loss in the uninsulated case is about three times that of the insulated case. This is also the case when base board heaters are used on the floor near the exterior walls. Heat transfer through the floors and the basement is usually ignored in cooling load calculations.

**FIGURE 16-39**

An on-grade concrete floor with insulated foundation wall.

## Heat Loss from Crawl Spaces

A crawl space can be considered to be a small basement except that it may be vented year round to prevent the accumulation of moisture and radioactive gases such as radon. Venting the crawl space during the heating season creates a low temperature region underneath the house and causes considerable heat loss through the floor. The ceiling of the crawl space (i.e., the floor of the building) in such cases must be insulated. If the vents are closed during the heating season, then the walls of the crawl space can be insulated instead.

The temperature of the crawl space will be very close to the ambient air temperature when it is well ventilated. The heating ducts and hot water pipes passing through the crawl space must be adequately insulated in this case. In severe climates, it may even be necessary to insulate the cold water pipes to prevent freezing. The temperature of the crawl space will approach the indoor temperature when the vents are closed for the heating season. The air infiltration in this case is estimated to be 0.67 air change per hour.

When the crawl space temperature is known, heat loss through the **floor of the building** is determined from

$$\dot{Q}_{\text{building floor}} = U_{\text{building floor}} A_{\text{floor}} (T_{\text{indoor}} - T_{\text{crawl}}) \quad (\text{W}) \quad (16-30)$$

where  $U_{\text{building floor}}$  is the overall heat transfer coefficient for the floor,  $A_{\text{floor}}$  is the floor area, and  $T_{\text{indoor}}$  and  $T_{\text{crawl}}$  are the indoor and crawl space temperatures, respectively.

Overall heat transfer coefficients associated with the walls, floors, and ceilings of typical crawl spaces are given in Table 16–15. Note that heat loss through the uninsulated floor to the crawl space is three times that of the insulated floor. The ground temperature can be taken to be 10°C when calculating heat loss from the crawl space to the ground. Also, the infiltration heat loss from the crawl space can be determined from

$$\dot{Q}_{\text{infiltration, crawl}} = (\rho c_p \dot{V})_{\text{air}} (T_{\text{crawl}} - T_{\text{ambient}}) \\ = \rho c_p (\text{ACH})(V_{\text{crawl}})(T_{\text{crawl}} - T_{\text{ambient}}) \quad (\text{J/h}) \quad (16-31)$$

where ACH is the air changes per hour,  $V_{\text{crawl}}$  is the volume of the crawl space, and  $T_{\text{crawl}}$  and  $T_{\text{ambient}}$  are the crawl space and ambient temperatures, respectively.

In the case of *closed vents*, the steady state temperature of the crawl space will be between the indoors and outdoors temperatures and can be determined from the energy balance expressed as

$$\dot{Q}_{\text{floor}} + \dot{Q}_{\text{infiltration}} + \dot{Q}_{\text{ground}} + \dot{Q}_{\text{wall}} = 0 \quad (\text{W}) \quad (16-32)$$

and assuming all heat transfer to be toward the crawl space for convenience in formulation.

### EXAMPLE 16-11 Heat Loss to the Crawl Space through Floors

Consider a crawl space that is 8-m wide, 21-m long, and 0.70-m high, as shown in Fig. 16-40, whose vent is kept open. The interior of the house is maintained at 22°C and the ambient temperature is –5°C. Determine the rate of heat loss through the floor of the house to the crawl space for the cases of (a) an insulated and (b) an uninsulated floor.

**SOLUTION** The vent of the crawl space is kept open. The rate of heat loss to the crawl space through insulated and uninsulated floors is to be determined.

**Assumption** Steady operating conditions exist.

**Properties** The overall heat transfer coefficient for the insulated floor is given in Table 16–15 to be 0.432 W/m<sup>2</sup> · °C.

**Analysis** (a) The floor area of the house (or the ceiling area of the crawl space) is

$$A_{\text{floor}} = \text{Length} \times \text{Width} = (8 \text{ m})(12 \text{ m}) = 96 \text{ m}^2$$

Then the heat loss from the house to the crawl space becomes

$$\dot{Q}_{\text{insulated floor}} = U_{\text{insulated floor}} A_{\text{floor}} (T_{\text{indoor}} - T_{\text{crawl}}) \\ = (0.432 \text{ W/m}^2 \cdot ^\circ\text{C})(96 \text{ m}^2)[(22 - (-5)]^\circ\text{C} = 1120 \text{ W}$$

(b) The heat loss for the uninsulated case is determined similarly to be

$$\dot{Q}_{\text{uninsulated floor}} = U_{\text{uninsulated floor}} A_{\text{floor}} (T_{\text{indoor}} - T_{\text{crawl}}) \\ = (1.42 \text{ W/m}^2 \cdot ^\circ\text{C})(96 \text{ m}^2)[(22 - (-5)]^\circ\text{C} = 3681 \text{ W}$$

TABLE 16-15

Estimated  $U$ -values for insulated and uninsulated crawl spaces (from ASHRAE *Handbook of Fundamentals*, Chap. 25, Table 13)

| Application             | Un-insulated <sup>1</sup> | In-sulated <sup>2</sup> |
|-------------------------|---------------------------|-------------------------|
| Floor above crawl space | 1.42                      | 0.432                   |
| Ground of crawl, space  | 0.437                     | 0.437                   |
| Wall of crawl space     | 2.77                      | 1.07                    |

<sup>1</sup>Multiply given values by 0.176 to convert them to  $\text{Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ .

<sup>2</sup>An insulation  $R$ -value of 1.94 m<sup>2</sup> · °C/W is used on the floor, and 0.95 m<sup>2</sup> · °C/W on the walls.

FIGURE 16-40

which is more than three times the heat loss through the insulated floor. Therefore, it is a good practice to insulate floors when the crawl space is ventilated to conserve energy and enhance comfort

## 16–8 ▪ HEAT TRANSFER THROUGH WINDOWS

Windows are *glazed apertures* in the building envelope that typically consist of single or multiple glazing (glass or plastic), framing, and shading. In a building envelope, windows offer the least resistance to heat transfer. In a typical house, about one-third of the total heat loss in winter occurs through the windows. Also, most air infiltration occurs at the edges of the windows. The solar heat gain through the windows is responsible for much of the cooling load in summer. The net effect of a window on the heat balance of a building depends on the characteristics and orientation of the window as well as the solar and weather data. Workmanship is very important in the construction and installation of windows to provide effective sealing around the edges while allowing them to be opened and closed easily.

Despite being so undesirable from an energy conservation point of view, windows are an essential part of any building envelope since they enhance the appearance of the building, allow daylight and solar heat to come in, and allow people to view and observe outside without leaving their home. For low-rise buildings, windows also provide easy exit areas during emergencies such as fire. Important considerations in the selection of windows are *thermal comfort* and *energy conservation*. A window should have a good light transmittance while providing effective resistance to heat transfer. The lighting requirements of a building can be minimized by maximizing the use of natural daylight. Heat loss in winter through the windows can be minimized by using airtight double- or triple-pane windows with spectrally selective films or coatings, and letting in as much solar radiation as possible. Heat gain and thus cooling load in summer can be minimized by using effective internal or external shading on the windows.

Even in the absence of solar radiation and air infiltration, heat transfer through the windows is more complicated than it appears to be. This is because the structure and properties of the frame are quite different than the glazing. As a result, heat transfer through the frame and the edge section of the glazing adjacent to the frame is two-dimensional. Therefore, it is customary to consider the window in three regions when analyzing heat transfer through it: (1) the *center-of-glass*, (2) the *edge-of-glass*, and (3) the *frame* regions, as shown in Fig. 16–41. Then the total rate of heat transfer through the window is determined by adding the heat transfer through each region as

$$\begin{aligned}\dot{Q}_{\text{window}} &= \dot{Q}_{\text{center}} + \dot{Q}_{\text{edge}} + \dot{Q}_{\text{frame}} \\ &= U_{\text{window}} A_{\text{window}} (T_{\text{indoors}} - T_{\text{outdoors}})\end{aligned}\quad (16-33)$$

where

$$U_{\text{window}} = (U_{\text{center}} A_{\text{center}} + U_{\text{edge}} A_{\text{edge}} + U_{\text{frame}} A_{\text{frame}})/A_{\text{window}} \quad (16-34)$$

**FIGURE 16–41**

The three regions of a window considered in heat transfer analysis.

is the ***U-factor*** or the **overall heat transfer coefficient** of the window;  $A_{\text{window}}$  is the window area;  $A_{\text{center}}$ ,  $A_{\text{edge}}$ , and  $A_{\text{frame}}$  are the areas of the center, edge, and frame sections of the window, respectively; and  $U_{\text{center}}$ ,  $U_{\text{edge}}$ , and  $U_{\text{frame}}$  are the heat transfer coefficients for the center, edge, and frame sections of the window. Note that  $A_{\text{window}} = A_{\text{center}} + A_{\text{edge}} + A_{\text{frame}}$ , and the overall *U*-factor of the window is determined from the area-weighted *U*-factors of each region of the window. Also, the inverse of the *U*-factor is the *R*-value, which is the unit thermal resistance of the window (thermal resistance for a unit area).

Consider steady one-dimensional heat transfer through a single-pane glass of thickness  $L$  and thermal conductivity  $k$ . The thermal resistance network of this problem consists of surface resistances on the inner and outer surfaces and the conduction resistance of the glass in series, as shown in Fig. 16-42, and the total resistance on a unit area basis can be expressed as

$$R_{\text{total}} = R_{\text{inside}} + R_{\text{glass}} + R_{\text{outside}} = \frac{1}{h_i} + \frac{L_{\text{glass}}}{k_{\text{glass}}} + \frac{1}{h_o} \quad (16-35)$$

Using common values of 3 mm for the thickness and  $0.92 \text{ W/m} \cdot ^{\circ}\text{C}$  for the thermal conductivity of the glass and the winter design values of 8.29 and  $34.0 \text{ W/m}^2 \cdot ^{\circ}\text{C}$  for the inner and outer surface heat transfer coefficients, the thermal resistance of the glass is determined to be

$$\begin{aligned} R_{\text{total}} &= \frac{1}{8.29 \text{ W/m}^2 \cdot ^{\circ}\text{C}} + \frac{0.003 \text{ m}}{0.92 \text{ W/m} \cdot ^{\circ}\text{C}} + \frac{1}{34.0 \text{ W/m}^2 \cdot ^{\circ}\text{C}} \\ &= 0.121 + 0.003 + 0.029 = 0.153 \text{ m}^2 \cdot ^{\circ}\text{C/W} \end{aligned}$$

Note that the ratio of the glass resistance to the total resistance is

$$\frac{R_{\text{glass}}}{R_{\text{total}}} = \frac{0.003 \text{ m}^2 \cdot ^{\circ}\text{C/W}}{0.153 \text{ m}^2 \cdot ^{\circ}\text{C/W}} = 2.0\%$$

That is, the glass layer itself contributes about 2 percent of the total thermal resistance of the window, which is negligible. The situation would not be much different if we used acrylic, whose thermal conductivity is  $0.19 \text{ W/m} \cdot ^{\circ}\text{C}$ , instead of glass. Therefore, we cannot reduce the heat transfer through the window effectively by simply increasing the thickness of the glass. But we can reduce it by trapping still air between two layers of glass. The result is a **double-pane window**, which has become the norm in window construction.

The thermal conductivity of air at room temperature is  $k_{\text{air}} = 0.025 \text{ W/m} \cdot ^{\circ}\text{C}$ , which is one-thirtieth that of glass. Therefore, the thermal resistance of 1-cm-thick still air is equivalent to the thermal resistance of a 30-cm-thick glass layer. Disregarding the thermal resistances of glass layers, the thermal resistance and *U*-factor of a double-pane window can be expressed as (Fig. 16-43)

$$\frac{1}{U_{\text{double-pane (center region)}}} \cong \frac{1}{h_i} + \frac{1}{h_{\text{space}}} + \frac{1}{h_o} \quad (16-36)$$

where  $h_{\text{space}} = h_{\text{rad, space}} + h_{\text{conv, space}}$  is the combined radiation and convection heat transfer coefficient of the space trapped between the two glass layers.

Roughly half of the heat transfer through the air space of a double-pane window is by radiation and the other half is by conduction (or convection, if

FIGURE 16-42

FIGURE 16-43

The thermal resistance network for heat transfer through the center section of a double-pane window (the resistances of the glasses are neglected).

there is any air motion). Therefore, there are two ways to minimize  $h_{\text{space}}$  and thus the rate of heat transfer through a double-pane window:

- Minimize radiation heat transfer through the air space.* This can be done by reducing the emissivity of glass surfaces by coating them with low-emissivity (or “low-e” for short) material. Recall that the *effective emissivity* of two parallel plates of emissivities  $\varepsilon_1$  and  $\varepsilon_2$  is given by

$$\varepsilon_{\text{effective}} = \frac{1}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1}$$

The emissivity of an ordinary glass surface is 0.84. Therefore, the effective emissivity of two parallel glass surfaces facing each other is 0.72. But when the glass surfaces are coated with a film that has an emissivity of 0.1, the effective emissivity reduces to 0.05, which is one-fourteenth of 0.72. Then for the same surface temperatures, radiation heat transfer will also go down by a factor of 14. Even if only one of the surfaces is coated, the overall emissivity reduces to 0.1, which is the emissivity of the coating. Thus it is no surprise that about one-fourth of all windows sold for residences have a low-e coating. The heat transfer coefficient  $h_{\text{space}}$  for the air space trapped between the two vertical parallel glass layers is given in Table 16-16 for 13-mm- ( $\frac{1}{2}$ -in) and 6-mm- ( $\frac{1}{4}$ -in) thick air spaces for various effective emissivities and temperature differences.

It can be shown that coating just one of the two parallel surfaces facing each other by a material of emissivity  $\varepsilon$  reduces the effective emissivity nearly to  $\varepsilon$ . Therefore, it is usually more economical to coat only one of the facing surfaces. Note from Fig. 16-44 that coating one of the interior surfaces of a double-pane window with a material having an emissivity of 0.1 reduces the rate of heat transfer through the center section of the window by half.

TABLE 16-16

\*Multiply by 0.176 to convert to Btu/h · ft<sup>2</sup> · °F.

**FIGURE 16-44**

The variation of the  $U$ -factor for the center section of double- and triple-pane windows with uniform spacing between the panes.

(From ASHRAE Handbook of Fundamentals, Chap. 27, Fig. 1.)

- Minimize conduction heat transfer through air space. This can be done by increasing the distance  $d$  between the two glasses. However, this cannot be done indefinitely since increasing the spacing beyond a critical value initiates convection currents in the enclosed air space, which increases the heat transfer coefficient and thus defeats the purpose. Besides, increasing the spacing also increases the thickness of the necessary framing and the cost of the window.

Experimental studies have shown that when the spacing  $d$  is less than about 13 mm, there is no convection, and heat transfer through the air is by conduction. But as the spacing is increased further, convection currents appear in the air space, and the increase in heat transfer coefficient offsets any benefit obtained by the thicker air layer. As a result, the heat transfer coefficient remains nearly constant, as shown in Fig. 16-44. Therefore, it makes no sense to use an air space thicker than 13 mm in a double-pane window unless a thin polyester film is used to divide the air space into two halves to suppress convection currents. The film provides added insulation without adding much to the weight or cost of the double-pane window. The thermal resistance of the window can be increased further by using triple- or quadruple-pane windows whenever it is economical to do so. Note that using a triple-pane window instead of a double-pane reduces the rate of heat transfer through the center section of the window by about one-third.

Another way of reducing conduction heat transfer through a double-pane window is to use a *less-conducting fluid* such as argon or krypton to fill the gap between the glasses instead of air. The gap in this case needs to be well sealed to prevent the gas from leaking outside. Of course, another alternative is to evacuate the gap between the glasses completely, but it is not practical to do so.

**FIGURE 16-45**

The edge-of-glass  $U$ -factor relative to the center-of glass  $U$ - for windows with various spacers.

(From ASHRAE Handbook of fundamentals, Chap. 27, Fig. 2.)

## Edge-of-Glass $U$ -Factor of a Window

The glasses in double- and triple-pane windows are kept apart from each other at a uniform distance by **spacers** made of metals or insulators like aluminum, fiberglass, wood, and butyl. Continuous spacer strips are placed around the glass perimeter to provide edge seal as well as uniform spacing. However, the spacers also serve as undesirable “thermal bridges” between the glasses, which are at different temperatures, and this short-circuiting may increase heat transfer through the window considerably. Heat transfer in the edge region of a window is two-dimensional, and lab measurements indicate that the edge effects are limited to a 6.5-cm-wide band around the perimeter of the glass.

The  $U$ -factor for the edge region of a window is given in Fig. 16-45 relative to the  $U$ -factor for the center region of the window. The curve would be a straight diagonal line if the two  $U$ -values were equal to each other. Note that this is almost the case for insulating spacers such as wood and fiberglass. But the  $U$ -factor for the edge region can be twice that of the center region for conducting spacers such as those made of aluminum. Values for steel spacers fall between the two curves for metallic and insulating spacers. The edge effect is not applicable to single-pane windows.

## Frame $U$ -Factor

The framing of a window consists of the entire window except the glazing. Heat transfer through the framing is difficult to determine because of the different window configurations, different sizes, different constructions, and different combination of materials used in the frame construction. The type of glazing such as single pane, double pane, and triple pane affects the thickness of the framing and thus heat transfer through the frame. Most frames are made of *wood*, *aluminum*, *vinyl*, or *fiberglass*. However, using a combination of these materials (such as aluminum-clad wood and vinyl-clad aluminum) is also common to improve appearance and durability.

Aluminum is a popular framing material because it is inexpensive, durable, and easy to manufacture, and does not rot or absorb water like wood. However, from a heat transfer point of view, it is the least desirable framing material because of its high thermal conductivity. It will come as no surprise that the  $U$ -factor of solid aluminum frames is the highest, and thus a window with aluminum framing will lose much more heat than a comparable window with wood or vinyl framing. Heat transfer through the aluminum framing members can be reduced by using plastic inserts between components to serve as thermal barriers. The thickness of these inserts greatly affects heat transfer through the frame. For aluminum frames without the plastic strips, the primary resistance to heat transfer is due to the interior surface heat transfer coefficient. The  $U$ -factors for various frames are listed in Table 16-17 as a function of spacer materials and the glazing unit thicknesses. Note that the  $U$ -factor of metal framing and thus the rate of heat transfer through a metal window frame is more than three times that of a wood or vinyl window frame.

## Interior and Exterior Surface Heat Transfer Coefficients

Heat transfer through a window is also affected by the convection and radiation heat transfer coefficients between the glass surfaces and surroundings. The effects of convection and radiation on the inner and outer surfaces of glazings are usually combined into the combined convection and radiation heat

transfer coefficients  $h_i$  and  $h_o$ , respectively. Under still air conditions, the combined heat transfer coefficient at the inner surface of a vertical window can be determined from

$$h_i = h_{\text{conv}} + h_{\text{rad}} = 1.77(T_g - T_i)^{0.25} + \frac{\varepsilon_g \sigma (T_g^4 - T_i^4)}{T_g - T_i} \quad (\text{W/m}^2 \cdot ^\circ\text{C}) \quad (16-37)$$

where  $T_g$  = glass temperature in K,  $T_i$  = indoor air temperature in K,  $\varepsilon_g$  = emissivity of the inner surface of the glass exposed to the room (taken to be 0.84 for uncoated glass), and  $\sigma = 5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$  is the Stefan–Boltzmann constant. Here the temperature of the interior surfaces facing the window is assumed to be equal to the indoor air temperature. This assumption is reasonable when the window faces mostly interior walls, but it becomes questionable when the window is exposed to heated or cooled surfaces or to other windows. The commonly used value of  $h_i$  for peak load calculation is

$$h_i = 8.29 \text{ W/m}^2 \cdot ^\circ\text{C} = 1.46 \text{ Btu/h}^2 \cdot ^\circ\text{F} \quad (\text{winter and summer})$$

which corresponds to the winter design conditions of  $T_i = 22^\circ\text{C}$  and  $T_g = -7^\circ\text{C}$  for uncoated glass with  $\varepsilon_g = 0.84$ . But the same value of  $h_i$  can also be used for summer design conditions as it corresponds to summer conditions of  $T_i = 24^\circ\text{C}$  and  $T_g = 32^\circ\text{C}$ . The values of  $h_i$  for various temperatures and glass emissivities are given in Table 16–18. The commonly used values of  $h_o$  for peak load calculations are the same as those used for outer wall surfaces (34.0 W/m<sup>2</sup> · °C for winter and 22.7 W/m<sup>2</sup> · °C for summer).

## Overall *U*-Factor of Windows

The overall *U*-factors for various kinds of windows and skylights are evaluated using computer simulations and laboratory testing for winter design conditions; representative values are given in Table 16–19. Test data may provide more accurate information for specific products and should be preferred when available. However, the values listed in the table can be used to obtain satisfactory results under various conditions in the absence of product-specific data. The *U*-factor of a fenestration product that differs considerably from the ones in the table can be determined by (1) determining the fractions of the area that are frame, center-of-glass, and edge-of-glass (assuming a 65-mm-wide band around the perimeter of each glazing), (2) determining the *U*-factors for each section (the center-of-glass and edge-of-glass *U*-factors can be taken from the first two columns of Table 16–19 and the frame *U*-factor can be taken from Table 16–18 or other sources), and (3) multiplying the area fractions and the *U*-factors for each section and adding them up (or from Eq. 16–34 for  $U_{\text{window}}$ ).

Glazed wall systems can be treated as fixed windows. Also, the data for double-door windows can be used for single-glass doors. Several observations can be made from the data in the table:

1. Skylight *U*-factors are considerably greater than those of vertical windows. This is because the skylight area, including the curb, can be 13 to 240 percent greater than the rough opening area. The slope of the skylight also has some effect.

TABLE 16-18

Combined convection and radiation heat transfer coefficient  $h_i$  at the inner surface of a vertical glass under still air conditions (in  $\text{W/m}^2 \cdot ^\circ\text{C}$ )\*

| $T_i$ , °C | $T_o$ , °C | Glass emissivity, $\varepsilon_g$ |      |      |
|------------|------------|-----------------------------------|------|------|
|            |            | 0.05                              | 0.20 | 0.84 |
| 20         | 17         | 2.6                               | 3.5  | 7.1  |

Notes:

(1) Multiply by 0.176 to obtain *U*-factors in  $\text{Btu}/\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ .

(2) The *U*-factors in this table include the effects of surface heat transfer coefficients and are based on winter conditions of  $-18^\circ\text{C}$  outdoor air and  $21^\circ\text{C}$  indoor air temperature, with  $24 \text{ km/h}$  (15 mph) winds outdoors and zero solar flux. Small changes in indoor and outdoor temperatures will not affect the overall *U*-factors much. Windows are assumed to be vertical, and the skylights are tilted  $20^\circ$  from the horizontal with upward heat flow. Insulation spacers are wood, fiberglass, or butyl. Edge-of-glass effects are assumed to extend the 65-mm band around perimeter of each glazing. The product sizes are  $1.2 \text{ m} \times 1.8 \text{ m}$  for fixed windows,  $1.8 \text{ m} \times 2.0 \text{ m}$  for double-door windows, and  $1.2 \text{ m} \times 0.6 \text{ m}$  for the skylights, but the values given can also be used for products of similar sizes. All data are based on 3-mm ( $\frac{1}{8}$  in) glass unless noted otherwise.

2. The  $U$ -factor of multiple-glazed units can be reduced considerably by filling cavities with argon gas instead of dry air. The performance of  $\text{CO}_2$ -filled units is similar to those filled with argon. The  $U$ -factor can be reduced even further by filling the glazing cavities with krypton gas.
3. Coating the glazing surfaces with low-e (low-emissivity) films reduces the  $U$ -factor significantly. For multiple-glazed units, it is adequate to coat one of the two surfaces facing each other.
4. The thicker the air space in multiple-glazed units, the lower the  $U$ -factor, for a thickness of up to 13 mm ( $\frac{1}{2}$  in) of air space. For a specified number of glazings, the window with thicker air layers will have a lower  $U$ -factor. For a specified overall thickness of glazing, the higher the number of glazings, the lower the  $U$ -factor. Therefore, a triple-pane window with air spaces of 6.4 mm (two such air spaces) will have a lower  $U$ -value than a double-pane window with an air space of 12.7 mm.
5. Wood or vinyl frame windows have a considerably lower  $U$ -value than comparable metal-frame windows. Therefore, wood or vinyl frame windows are called for in energy-efficient designs.

FIGURE 16-46

Schematic of Example 16-12.

**EXAMPLE 16-12  $U$ -Factor for Center-of-Glass Section of Windows**

Determine the  $U$ -factor for the center-of-glass section of a double-pane window with a 6-mm air space for winter design conditions (Fig. 16-46). The glazings are made of clear glass that has an emissivity of 0.84. Take the average air space temperature at design conditions to be  $0^\circ\text{C}$ .

**SOLUTION** The  $U$ -factor for the center-of-glass section of a double-pane window is to be determined.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the window is one-dimensional. 3 The thermal resistance of glass sheets is negligible.

**Properties** The emissivity of clear glass is 0.84.

**Analysis** Disregarding the thermal resistance of glass sheets, which are small, the  $U$ -factor for the center region of a double-pane window is determined from

$$\frac{1}{U_{\text{center}}} \cong \frac{1}{h_i} + \frac{1}{h_{\text{space}}} + \frac{1}{h_o}$$

where  $h_i$ ,  $h_{\text{space}}$ , and  $h_o$  are the heat transfer coefficients at the inner surface of the window, the air space between the glass layers, and the outer surface of the window, respectively. The values of  $h_i$  and  $h_o$  for winter design conditions were given earlier to be  $h_i = 8.29 \text{ W/m}^2 \cdot ^\circ\text{C}$  and  $h_o = 34.0 \text{ W/m}^2 \cdot ^\circ\text{C}$ . The effective emissivity of the air space of the double-pane window is

$$\varepsilon_{\text{effective}} = \frac{1}{1/\varepsilon_1 + 1/\varepsilon_2 - 1} = \frac{1}{1/0.84 + 1/0.84 - 1} = 0.72$$

For this value of emissivity and an average air space temperature of  $0^\circ\text{C}$ , we read  $h_{\text{space}} = 7.2 \text{ W/m}^2 \cdot ^\circ\text{C}$  from Table 16-16 for 6-mm-thick air space. Therefore,

$$\frac{1}{U_{\text{center}}} = \frac{1}{8.29} + \frac{1}{7.2} + \frac{1}{34.0} \rightarrow U_{\text{center}} = 3.46 \text{ W/m}^2 \cdot ^\circ\text{C}$$

**Discussion** The center-of-glass  $U$ -factor value of  $3.24 \text{ W/m}^2 \cdot ^\circ\text{C}$  in Table 16-19 (fourth row and second column) is obtained by using a standard value of  $h_o = 29 \text{ W/m}^2 \cdot ^\circ\text{C}$  (instead of  $34.0 \text{ W/m}^2 \cdot ^\circ\text{C}$ ) and  $h_{\text{space}} = 6.5 \text{ W/m}^2 \cdot ^\circ\text{C}$  at an average air space temperature of  $-15^\circ\text{C}$ .

FIGURE 16-47

Schematic for Example 16-13.

### Example 16-13 Heat Loss through Aluminum-Framed Windows

A fixed aluminum-framed window with glass glazing is being considered for an opening that is 4 ft high and 6 ft wide in the wall of a house that is maintained at  $72^\circ\text{F}$  (Fig. 16-47). Determine the rate of heat loss through the window and the inner surface temperature of the window glass facing the room when the outdoor air temperature is  $15^\circ\text{F}$  if the window is selected to be (a)  $\frac{1}{8}$ -in single glazing, (b) double glazing with an air space of  $\frac{1}{2}$  in, and (c) low-e-coated triple glazing with an air space of  $\frac{1}{2}$  in.

**SOLUTION** The rate of heat loss through an aluminum-framed window and the inner surface temperature are to be determined from the cases of single-pane, double-pane, and low-e triple-pane windows.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the window is one-dimensional. 3 Thermal properties of the windows and the heat transfer coefficients are constant.

**Properties** The  $U$ -factors of the windows are given in Table 16-19.

**Analysis** The rate of heat transfer through the window can be determined from

$$\dot{Q}_{\text{window}} = U_{\text{overall}} A_{\text{window}} (T_i - T_o)$$

where  $T_i$  and  $T_o$  are the indoor and outdoor air temperatures, respectively;  $U_{\text{overall}}$  is the  $U$ -factor (the overall heat transfer coefficient) of the window; and  $A_{\text{window}}$  is the window area, which is determined to be

$$A_{\text{window}} = \text{Height} \times \text{Width} = (4 \text{ ft})(6 \text{ ft}) = 24 \text{ ft}^2$$

The  $U$ -factors for the three cases can be determined directly from Table 16-19 to be 6.63, 3.51, and 1.92  $\text{W/m}^2 \cdot ^\circ\text{C}$ , respectively, to be multiplied by the factor 0.176 to convert them to  $\text{Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ . Also, the inner surface temperature of the window glass can be determined from

$$\dot{Q}_{\text{window}} = h_i A_{\text{window}} (T_i - T_{\text{glass}}) \rightarrow T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}}$$

where  $h_i$  is the heat transfer coefficient on the inner surface of the window, which is determined from Table 16-18 to be  $h_i = 8.3 \text{ W/m}^2 \cdot ^\circ\text{C} = 1.46 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ . Then the rate of heat loss and the interior glass temperature for each case are determined as follows:

(a) Single glazing:

$$\dot{Q}_{\text{window}} = (6.63 \times 0.176 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F})(24 \text{ ft}^2)(72 - 15)^\circ\text{F} = 1596 \text{ Btu/h}$$

$$T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}} = 72^\circ\text{F} - \frac{1596 \text{ Btu/h}}{(1.46 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F})(24 \text{ ft}^2)} = 26.5^\circ\text{F}$$

(b) Double glazing ( $\frac{1}{2}$  in air space):

$$\dot{Q}_{\text{window}} = (3.51 \times 0.176 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F})(24 \text{ ft}^2)(72 - 15) {}^\circ\text{F} = 845 \text{ Btu/h}$$

$$T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}} = 72 {}^\circ\text{F} - \frac{845 \text{ Btu/h}}{(1.46 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F})(24 \text{ ft}^2)} = 47.9 {}^\circ\text{F}$$

(c) Triple glazing ( $\frac{1}{2}$  in air space, low-e coated):

$$\dot{Q}_{\text{window}} = (1.92 \times 0.176 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F})(24 \text{ ft}^2)(72 - 15) {}^\circ\text{F} = 462 \text{ Btu/h}$$

$$T_{\text{glass}} = T_i - \frac{\dot{Q}_{\text{window}}}{h_i A_{\text{window}}} = 72 {}^\circ\text{F} - \frac{462 \text{ Btu/h}}{(1.46 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F})(24 \text{ ft}^2)} = 58.8 {}^\circ\text{F}$$

Therefore, heat loss through the window will be reduced by 47 percent in the case of double glazing and by 71 percent in the case of triple glazing relative to the single-glazing case. Also, in the case of single glazing, the low inner-glass surface temperature will cause considerable discomfort in the occupants because of the excessive heat loss from the body by radiation. It is raised from 26.5°F, which is below freezing, to 47.9°F in the case of double glazing and to 58.8°F in the case of triple glazing.

### EXAMPLE 16-14 U-Factor of a Double-Door Window

Determine the overall *U*-factor for a double-door-type, wood-framed double-pane window with metal spacers, and compare your result to the value listed in Table 16-19. The overall dimensions of the window are 1.80 m × 2.00 m, and the dimensions of each glazing are 1.72 m × 0.94 m (Fig. 16-48).

**SOLUTION** The overall *U*-factor for a double-door type window is to be determined and the result is to be compared to the tabulated value.

**Assumptions** 1 Steady operating conditions exist. 2 Heat transfer through the window is one-dimensional.

**Properties** The *U*-factors for the various sections of windows are given in Tables 16-17 and 16-19.

**Analysis** The areas of the window, the glazing, and the frame are

$$A_{\text{window}} = \text{Height} \times \text{Width} = (1.8 \text{ m})(2.0 \text{ m}) = 3.60 \text{ m}^2$$

$$A_{\text{glazing}} = 2 \times (\text{Height} \times \text{Width}) = 2(1.72 \text{ m})(0.94 \text{ m}) = 3.23 \text{ m}^2$$

$$A_{\text{frame}} = A_{\text{window}} - A_{\text{glazing}} = 3.60 - 3.23 = 0.37 \text{ m}^2$$

The edge-of-glass region consists of a 6.5-cm-wide band around the perimeter of the glazings, and the areas of the center and edge sections of the glazing are determined to be

$$A_{\text{center}} = 2 \times (\text{Height} \times \text{Width}) = 2(1.72 - 0.13 \text{ m})(0.94 - 0.13 \text{ m}) = 2.58 \text{ m}^2$$

$$A_{\text{edge}} = A_{\text{glazing}} - A_{\text{center}} = 3.23 - 2.58 = 0.65 \text{ m}^2$$

The *U*-factor for the frame section is determined from Table 16-17 to be  $U_{\text{frame}} = 2.8 \text{ W/m}^2 \cdot {}^\circ\text{C}$ . The *U*-factors for the center and edge sections are

FIGURE 16-48

Schematic for Example 16-14.

determined from Table 16-19 (fifth row, second and third columns) to be  $U_{\text{center}} = 3.24 \text{ W/m}^2 \cdot ^\circ\text{C}$  and  $U_{\text{edge}} = 3.71 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Then the overall  $U$ -factor of the entire window becomes

$$\begin{aligned} U_{\text{window}} &= (U_{\text{center}} A_{\text{center}} + U_{\text{edge}} A_{\text{edge}} + U_{\text{frame}} A_{\text{frame}})/A_{\text{window}} \\ &= (3.24 \times 2.58 + 3.71 \times 0.65 + 2.8 \times 0.37)/3.60 \\ &= \mathbf{3.28 \text{ W/m}^2 \cdot ^\circ\text{C}} \end{aligned}$$

The overall  $U$ -factor listed in Table 16-19 for the specified type of window is  $3.20 \text{ W/m}^2 \cdot ^\circ\text{C}$ , which is sufficiently close to the value obtained above.

## 16-9 ■ SOLAR HEAT GAIN THROUGH WINDOWS

The sun is the primary heat source of the earth, and the solar irradiance on a surface normal to the sun's rays beyond the earth's atmosphere at the mean earth–sun distance of 149.5 million km is called the **solar constant**. The accepted value of the solar constant is  $1373 \text{ W/m}^2$  ( $435.4 \text{ Btu/h} \cdot \text{ft}^2$ ), but its value changes by 3.5 percent from a maximum of  $1418 \text{ W/m}^2$  on January 3 when the earth is farthest away from the sun, to a minimum of  $1325 \text{ W/m}^2$  on July 4 when the earth is closest to the sun. The spectral distribution of solar radiation beyond the earth's atmosphere resembles the energy emitted by a blackbody at  $5782^\circ\text{C}$ , with about 9 percent of the energy contained in the ultraviolet region (at wavelengths between  $0.29$  to  $0.4 \mu\text{m}$ ), 39 percent in the visible region ( $0.4$  to  $0.7 \mu\text{m}$ ), and the remaining 52 percent in the near-infrared region ( $0.7$  to  $3.5 \mu\text{m}$ ). The peak radiation occurs at a wavelength of about  $0.48 \mu\text{m}$ , which corresponds to the green color portion of the visible spectrum. Obviously a glazing material that transmits the visible part of the spectrum while absorbing the infrared portion is ideally suited for an application that calls for maximum daylight and minimum solar heat gain. Surprisingly, the ordinary window glass approximates this behavior remarkably well (Fig. 16-49).

- 1. 3 mm regular sheet
- 2. 6 mm gray heat-absorbing plate/float
- 3. 6 mm green heat-absorbing plate/float

**FIGURE 16-49**

The variation of the transmittance of typical architectural glass with wavelength. (From ASHRAE Handbook of Fundamentals, Chap. 27, Fig. 11.)

Part of the solar radiation entering the earth's atmosphere is scattered and absorbed by air and water vapor molecules, dust particles, and water droplets in the clouds, and thus the solar radiation incident on earth's surface is less than the solar constant. The extent of the attenuation of solar radiation depends on the length of the path of the rays through the atmosphere as well as the composition of the atmosphere (the clouds, dust, humidity, and smog) along the path. Most ultraviolet radiation is absorbed by the ozone in the upper atmosphere. At a solar altitude of  $41.8^\circ$ , the total energy of direct solar radiation incident at sea level on a clear day consists of about 3 percent ultraviolet, 38 percent visible, and 59 percent infrared radiation.

The part of solar radiation that reaches the earth's surface without being scattered or absorbed is the direct radiation. Solar radiation that is scattered or reemitted by the constituents of the atmosphere is the diffuse radiation. Direct radiation comes directly from the sun following a straight path, whereas diffuse radiation comes from all directions in the sky. The entire radiation reaching the ground on an overcast day is diffuse radiation. The radiation reaching a surface, in general, consists of three components: direct radiation, diffuse radiation, and

radiation reflected onto the surface from surrounding surfaces (Fig. 16–50). Common surfaces such as grass, trees, rocks, and concrete reflect about 20 percent of the radiation while absorbing the rest. Snow-covered surfaces, however, reflect 70 percent of the incident radiation. Radiation incident on a surface that does not have a direct view of the sun consists of diffuse and reflected radiation. Therefore, at solar noon, solar radiations incident on the east, west, and north surfaces of a south-facing house are identical since they all consist of diffuse and reflected components. The difference between the radiations incident on the south and north walls in this case gives the magnitude of direct radiation incident on the south wall.

When solar radiation strikes a glass surface, part of it (about 8 percent for uncoated clear glass) is reflected back to outdoors, part of it (5 to 50 percent, depending on composition and thickness) is absorbed within the glass, and the remainder is transmitted indoors, as shown in Fig. 16–51. The conservation of energy principle requires that the sum of the transmitted, reflected, and absorbed solar radiations be equal to the incident solar radiation. That is,

$$\tau_s + \rho_s + \alpha_s = 1$$

where  $\tau_s$  is the transmissivity,  $\rho_s$  is the reflectivity, and  $\alpha_s$  is the absorptivity of the glass for solar energy, which are the fractions of incident solar radiation transmitted, reflected, and absorbed, respectively. The standard 3-mm- ( $\frac{1}{8}$ -in) thick single-pane double-strength clear window glass transmits 86 percent, reflects 8 percent, and absorbs 6 percent of the solar energy incident on it. The radiation properties of materials are usually given for normal incidence, but can also be used for radiation incident at other angles since the transmissivity, reflectivity, and absorptivity of the glazing materials remain essentially constant for incidence angles up to about  $60^\circ$  from the normal.

The hourly variation of solar radiation incident on the walls and windows of a house is given in Table 16–20. Solar radiation that is transmitted indoors is partially absorbed and partially reflected each time it strikes a surface, but all of it is eventually absorbed as sensible heat by the furniture, walls, people, and so forth. Therefore, the solar energy transmitted inside a building represents a heat gain for the building. Also, the solar radiation absorbed by the glass is subsequently transferred to the indoors and outdoors by convection and radiation. The sum of the *transmitted* solar radiation and the portion of the *absorbed* radiation that flows indoors constitutes the **solar heat gain** of the building.

The fraction of incident solar radiation that enters through the glazing is called the **solar heat gain coefficient** SHGC and is expressed as

$$\begin{aligned} \text{SHGC} &= \frac{\text{Solar heat gain through the window}}{\text{Solar radiation incident on the window}} \\ &= \frac{\dot{q}_{\text{solar, gain}}}{\dot{q}_{\text{solar, incident}}} = \tau + f_i \alpha_s \end{aligned} \quad (16-38)$$

where  $\alpha_s$  is the solar absorptivity of the glass and  $f_i$  is the inward flowing fraction of the solar radiation absorbed by the glass. Therefore, the dimensionless quantity SHGC is the sum of the fractions of the directly transmitted ( $\tau_s$ ) and

FIGURE 16-50

Direct, diffuse, and reflected components of solar radiation incident on a window.

FIGURE 16-51

Distribution of solar radiation incident on a clear glass.

**TABLE 16-20**

Hourly variation of solar radiation incident on various surfaces and the daily totals throughout the year at 40° latitude  
(from ASHRAE *Handbook of Fundamentals*, Chap. 27, Table 15)

| Date | Direction of surface | Solar radiation incident on the surface,* W/m <sup>2</sup> |     |     |     |     |     |     |         |     |     |     |     |     |     |    | Daily total |  |

\* Multiply by 0.3171 to convert to Btu/h · ft<sup>2</sup>.

the absorbed and reemitted ( $f_i \alpha_s$ ) portions of solar radiation incident on the window. The value of SHGC ranges from 0 to 1, with 1 corresponding to an opening in the wall (or the ceiling) with no glazing. When the SHGC of a window is known, the total solar heat gain through that window is determined from

$$\dot{Q}_{\text{solar, gain}} = \text{SHGC} \times A_{\text{glazing}} \times \dot{q}_{\text{solar, incident}} \quad (\text{W}) \quad (16-39)$$

where  $A_{\text{glazing}}$  is the glazing area of the window and  $\dot{q}_{\text{solar, incident}}$  is the solar heat flux incident on the outer surface of the window, in  $\text{W/m}^2$ .

Another way of characterizing the solar transmission characteristics of different kinds of glazing and shading devices is to compare them to a well known glazing material that can serve as a base case. This is done by taking the standard 3-mm- ( $\frac{1}{8}$ -in) thick double-strength clear window glass sheet whose SHGC is 0.87 as the *reference glazing* and defining a **shading coefficient** SC as

$$\begin{aligned} \text{SC} &= \frac{\text{Solar heat gain of product}}{\text{Solar heat gain of reference glazing}} \\ &= \frac{\text{SHGC}}{\text{SHGC}_{\text{ref}}} = \frac{\text{SHGC}}{0.87} = 1.15 \times \text{SHGC} \end{aligned} \quad (16-40)$$

Therefore, the shading coefficient of a single-pane clear glass window is  $\text{SC} = 1.0$ . The shading coefficients of other commonly used fenestration products are given in Table 16-21 for summer design conditions. The values for winter design conditions may be slightly lower because of the higher heat transfer coefficients on the outer surface due to high winds and thus higher rate of outward flow of solar heat absorbed by the glazing, but the difference is small.

Note that the larger the shading coefficient, the smaller the shading effect, and thus the larger the amount of solar heat gain. A glazing material with a large shading coefficient allows a large fraction of solar radiation to come in.

Shading devices are classified as *internal shading* and *external shading*, depending on whether the shading device is placed *inside* or *outside*. External shading devices are more effective in reducing the solar heat gain since they intercept the sun's rays before they reach the glazing. The solar heat gain through a window can be reduced by as much as 80 percent by exterior shading. Roof overhangs have long been used for exterior shading of windows. The sun is high in the horizon in summer and low in winter. A properly sized roof overhang or a horizontal projection blocks off the sun's rays completely in summer while letting in most of them in winter, as shown in Fig. 16-52. Such shading structures can reduce the solar heat gain on the south, southeast, and southwest windows in the northern hemisphere considerably. A window can also be shaded from outside by vertical or horizontal or architectural

TABLE 16-21

Shading coefficient SC and solar transmissivity  $\tau_{\text{solar}}$  for some common glass types for summer design conditions (from ASHRAE *Handbook of Fundamentals*, Chap. 27, Table 11)

| Type of glazing           | Nominal thickness |               |                       |      |
|---------------------------|-------------------|---------------|-----------------------|------|
|                           | mm                | in            | $\tau_{\text{solar}}$ | SC*  |
| <i>(a) Single Glazing</i> |                   |               |                       |      |

<sup>a</sup>The thickness of each pane of glass.

<sup>b</sup>Combined transmittance for assembled unit.

<sup>c</sup>Refers to gray-, bronze-, and green-tinted heat-absorbing float glass.

Notes on Table 16-20: Values given are for the 21st of the month for average days with no clouds. The values can be up to 15 percent higher at high elevations under very clear skies and up to 30 percent lower at very humid locations with very dusty industrial atmospheres. Daily totals are obtained using Simpson's rule for integration with 10-minute time intervals. Solar reflectance of the ground is assumed to be 0.2, which is valid for old concrete, crushed rock, and bright green grass. For a specified location, use solar radiation data obtained for that location. The direction of a surface indicates the direction a vertical surface is facing. For example, W represent the solar radiation incident on a west-facing wall per unit area of the wall.

Solar time may deviate from the local time. Solar noon at a location is the time when the sun is at the highest location (and thus when the shadows are shortest). Solar radiation data are symmetric about the solar noon: the value on a west wall two hours before the solar noon is equal to the value on an east wall two hours after the solar noon.

**FIGURE 16-52**

A properly sized overhang blocks off the sun's rays completely in summer while letting them in winter.

projections, insect or shading screens, and sun screens. To be effective, air must be able to move freely around the exterior device to carry away the heat absorbed by the shading and the glazing materials.

Some type of internal shading is used in most windows to provide privacy and aesthetic effects as well as some control over solar heat gain. Internal shading devices reduce solar heat gain by reflecting transmitted solar radiation back through the glazing before it can be absorbed and converted into heat in the building.

*Drapery* reduces the annual heating and cooling loads of a building by 5 to 20 percent, depending on the type and the user habits. In summer, they reduce heat gain primarily by reflecting back direct solar radiation (Fig. 16-53). The semiclosed air space formed by the draperies serves as an additional barrier against heat transfer, resulting in a lower *U-factor* for the window and thus a lower rate of heat transfer in summer and winter. The solar optical properties of draperies can be measured accurately, or they can be obtained directly from the manufacturers. The shading coefficient of draperies depends on the openness factor, which is the ratio of the open area between the fibers that permits the sun's rays to pass freely, to the total area of the fabric. Tightly woven fabrics allow little direct radiation to pass through, and thus they have a small openness factor. The *reflectance* of the surface of the drapery facing the glazing has a major effect on the amount of solar heat gain. *Light-colored* draperies made of closed or tightly woven fabrics maximize the back reflection and thus minimize the solar gain. *Dark-colored* draperies made of open or semi-open woven fabrics, on the other hand, minimize the back reflection and thus maximize the solar gain.

The shading coefficients of drapes also depend on the way they are hung. Usually, the width of drapery used is twice the width of the draped area to allow folding of the drapes and to give them their characteristic "full" or "wavy" appearance. A flat drape behaves like an ordinary window shade. A flat drape has a higher reflectance and thus a lower shading coefficient than a full drape.

*External shading devices* such as overhangs and tinted glazings do not require operation, and provide reliable service over a long time without significant degradation during their service life. Their operation does not depend on a person or an automated system, and these passive shading devices are considered fully effective when determining the peak cooling load and the annual energy use. The effectiveness of manually operated shading devices, on the other hand, varies greatly depending on the user habits, and this variation should be considered when evaluating performance.

The primary function of an indoor shading device is to provide *thermal comfort* for the occupants. An unshaded window glass allows most of the incident solar radiation in, and also dissipates part of the solar energy it absorbs by emitting infrared radiation to the room. The emitted radiation and the transmitted direct sunlight may bother the occupants near the window. In winter, the temperature of the glass is lower than the room air temperature, causing excessive heat loss by radiation from the occupants. A shading device allows the control of direct solar and infrared radiation while providing various degrees of privacy and outward vision. The shading device is also at a higher temperature than the glass in winter, and thus reduces radiation loss from occupants. *Glare* from draperies can be minimized by using off-white colors.

**FIGURE 16-53**

Drapery reduces heat gain in summer by reflecting back solar radiation, and reduces heat loss in winter by forming an air space before the window.

Indoor shading devices, especially draperies made of a closed-weave fabric, are effective in reducing *sounds* that originate in the room, but they are not as effective against the sounds coming from outside.

The type of climate in an area usually dictates the type of windows to be used in buildings. In *cold climates* where the heating load is much larger than the cooling load, the windows should have the highest transmissivity for the entire solar spectrum, and a high reflectivity (or low emissivity) for the far infrared radiation emitted by the walls and furnishings of the room. Low-e windows are well suited for such heating-dominated buildings. Properly designed and operated windows allow more heat into the building over a heating season than it loses, making them energy contributors rather than energy losers. In *warm climates* where the cooling load is much larger than the heating load, the windows should allow the visible solar radiation (light) in, but should block off the infrared solar radiation. Such windows can reduce the solar heat gain by 60 percent with no appreciable loss in daylighting. This behavior is approximated by window glazings that are coated with a heat-absorbing film outside and a low-e film inside (Fig. 16-54). Properly selected windows can reduce the cooling load by 15 to 30 percent compared to windows with clear glass.

Note that radiation heat transfer between a room and its windows is proportional to the emissivity of the glass surface facing the room,  $\varepsilon_{\text{glass}}$ , and can be expressed as

$$\dot{Q}_{\text{rad, room-window}} = \varepsilon_{\text{glass}} A_{\text{glass}} \sigma (T_{\text{room}}^4 - T_{\text{glass}}^4)$$

Therefore, a low-e interior glass will reduce the heat loss by radiation in winter ( $T_{\text{glass}} < T_{\text{room}}$ ) and heat gain by radiation in summer ( $T_{\text{glass}} > T_{\text{room}}$ ).

Tinted glass and glass coated with reflective films reduce solar heat gain in summer and heat loss in winter. The conductive heat gains or losses can be minimized by using multiple-pane windows. Double-pane windows are usually called for in climates where the winter design temperature is less than 7°C (45°F). Double-pane windows with tinted or reflective films are commonly used in buildings with large window areas. Clear glass is preferred for showrooms since it affords maximum visibility from outside, but bronze-, gray-, and green-colored glass are preferred in office buildings since they provide considerable privacy while reducing glare.

### EXAMPLE 16-15 Installing Reflective Films on Windows

A manufacturing facility located at 40°N latitude has a glazing area of 40 m<sup>2</sup> that consists of double-pane windows made of clear glass (SHGC = 0.766). To reduce the solar heat gain in summer, a reflective film that reduces the SHGC to 0.261 is considered. The cooling season consists of June, July, August, and September, and the heating season October through April. The average daily solar heat fluxes incident on the west side at this latitude are 1.86, 2.66, 3.43, 4.00, 4.36, 5.13, 4.31, 3.93, 3.28, 2.80, 1.84, and 1.54 kWh/day · m<sup>2</sup> for January through December, respectively. Also, the unit cost of electricity and natural gas are \$0.08/kWh and \$0.50/therm, respectively. If the coefficient of performance of the cooling system is 2.5 and efficiency of the furnace is 0.8, determine the net annual cost savings due to installing reflective coating on the windows. Also, determine the simple payback period if the installation cost of reflective film is \$20/m<sup>2</sup> (Fig. 16-55).

FIGURE 16-54

Radiation heat transfer between a room and its window is proportional to the emissivity of the glass surface, and low-e coatings on the inner surface of the windows reduce heat loss in winter and heat gain in summer.

FIGURE 16-55

Schematic for Example 16-15.

**SOLUTION** The net annual cost savings due to installing reflective film on the west windows of a building and the simple payback period are to be determined.

**Assumptions** 1 The calculations given below are for an average year. 2 The unit costs of electricity and natural gas remain constant.

**Analysis** Using the daily averages for each month and noting the number of days of each month, the total solar heat flux incident on the glazing during summer and winter months are determined to be

$$\begin{aligned} Q_{\text{solar, summer}} &= 5.13 \times 30 + 4.31 \times 31 + 3.93 \times 31 + 3.28 \times 30 \\ &= 508 \text{ kWh/year} \end{aligned}$$

$$\begin{aligned} Q_{\text{solar, winter}} &= 2.80 \times 31 + 1.84 \times 30 + 1.54 \times 31 + 1.86 \times 31 \\ &\quad + 2.66 \times 28 + 3.43 \times 31 + 4.00 \times 30 \\ &= 548 \text{ kWh/year} \end{aligned}$$

Then the decrease in the annual cooling load and the increase in the annual heating load due to the reflective film become

$$\begin{aligned} \text{Cooling load decrease} &= Q_{\text{solar, summer}} A_{\text{glazing}} (\text{SHGC}_{\text{without film}} - \text{SHGC}_{\text{with film}}) \\ &= (508 \text{ kWh/year})(40 \text{ m}^2)(0.766 - 0.261) \\ &= 10,262 \text{ kWh/year} \end{aligned}$$

$$\begin{aligned} \text{Heating load increase} &= Q_{\text{solar, winter}} A_{\text{glazing}} (\text{SHGC}_{\text{without film}} - \text{SHGC}_{\text{with film}}) \\ &= (548 \text{ kWh/year})(40 \text{ m}^2)(0.766 - 0.261) \\ &= 11,070 \text{ kWh/year} = 377.7 \text{ therms/year} \end{aligned}$$

since 1 therm = 29.31 kWh. The corresponding decrease in cooling costs and the increase in heating costs are

$$\begin{aligned} \text{Decrease in cooling costs} &= (\text{Cooling load decrease}) \\ &\quad \times (\text{Unit cost of electricity})/\text{COP} \\ &= (10,262 \text{ kWh/year})(\$0.08/\text{kWh})/2.5 = \$328/\text{year} \end{aligned}$$

$$\begin{aligned} \text{Increase in heating costs} &= (\text{Heating load increase})(\text{Unit cost of fuel})/ \\ &\quad \text{Efficiency} \\ &= (377.7 \text{ therms/year})(\$0.50/\text{therm})/0.80 = \$236/\text{year} \end{aligned}$$

Then the net annual cost savings due to the reflective film become

$$\begin{aligned} \text{Cost savings} &= \text{Decrease in cooling costs} - \text{Increase in heating costs} \\ &= \$328 - \$236 = \$92/\text{year} \end{aligned}$$

The implementation cost of installing films is

$$\text{Implementation cost} = (\$20/\text{m}^2)(40 \text{ m}^2) = \$800$$

This gives a simple payback period of

$$\text{Simple payback period} = \frac{\text{Implementation cost}}{\text{Annual cost saving}} = \frac{\$800}{\$92/\text{year}} = 8.7 \text{ years}$$

**Discussion** The reflective film will pay for itself in this case in about nine years. This may be unacceptable to most manufacturers since they are not usually interested in any energy conservation measure that does not pay for itself within three years. But the enhancement in thermal comfort and thus the resulting increase in productivity often makes it worthwhile to install reflective film

## 16-10 • INFILTRATION HEAT LOAD AND WEATHERIZING

Most older homes and some poorly constructed new ones have numerous cracks, holes, and openings through which cold outdoor air exchanges with the warm air inside a building in winter, and vice versa in summer. This uncontrolled entry of outside air into a building through unintentional openings is called infiltration, and it wastes a significant amount of energy since the air entering must be heated in winter and cooled in summer (Fig. 16-56). The warm air leaving the house represents energy loss. This is also the case for cool air leaving in summer since some electricity is used to cool that air. In homes that have not been properly weatherized, the air leaks account for about 30-40 percent of the total heat lost from the house in winter. That is, about one-third of the heating bill of such a house is due to the air leaks.

The rate of infiltration depends on the *wind velocity* and the *temperature difference* between the inside and the outside, and thus it varies throughout the year. The infiltration rates are much higher in winter than they are in summer because of the higher winds and larger temperature differences in winter. Therefore, distinction should be made between the *design infiltration rate* at design conditions, which is used to size heating or cooling equipment, and the *seasonal average infiltration rate*, which is used to properly estimate the seasonal energy consumption for heating or cooling. Infiltration appears to be providing “fresh outdoor air” to a building, but it is not a reliable ventilation mechanism since it depends on the weather conditions and the size and location of the cracks.

The air infiltration rate of a building can be determined by direct measurements by (1) *injecting a tracer gas* into a building and observing the decline of its concentration with time or (2) *pressurizing the building* to 10 to 75 Pa gage pressure by a large fan mounted on a door or window, and measuring the air flow required to maintain a specified indoor-outdoor pressure difference. The larger the air flow to maintain a pressure difference, the more the building may leak. Sulfur hexafluoride ( $SF_6$ ) is commonly used as a tracer gas because it is inert, nontoxic, and easily detectable at concentrations as low as 1 part per billion. Pressurization testing is easier to conduct, and thus preferable to tracer gas testing. Pressurization test results for a whole house are given in Fig. 16-57.

Despite their accuracy, direct measurement techniques are inconvenient, expensive, and time consuming. A practical alternative is to *predict* the air infiltration rate on the basis of extensive data available on existing buildings. One way of predicting the air infiltration rate is by determining the type and size of all the cracks at all possible locations (around doors and windows, lighting fixtures, wall-floor joints, etc., as shown in Fig. 16-58), as well as the pressure differential across the cracks at specified conditions, and calculating the air flow rates. This is known as the **crack method**.

A simpler and more practical approach is to “estimate” how many times the entire air in a building is replaced by the outside air per hour on the basis of experience with similar buildings under similar conditions. This is called the **air-change method**, and the infiltration rate in this case is expressed in terms of **air changes per hour** (ACH), defined as

$$ACH = \frac{\text{Flow rate of indoor air into the building (per hour)}}{\text{Internal volume of the building}} = \frac{\dot{V}(\text{m}^3/\text{h})}{V(\text{m}^3)} \quad (16-41)$$

**FIGURE 16-56**

When cold outdoor air enters a building in winter, an equivalent amount of warm air must leave the house. This represents energy loss by infiltration.

**FIGURE 16-57**

Typical data from a whole house pressurization test for the variation of air flow rate with pressure difference.

(From ASHRAE Handbook of Fundamentals, Chap. 23, Fig. 8.)

**FIGURE 16-58**

Typical air-leakage sites of a house.

(From U.S. Department of Energy pamphlet, FS 203, 1992.)

The mass of air corresponding to 1 ACH is determined from  $m = \rho V$  where  $\rho$  is the density of air whose value is determined at the *outdoor* temperature and pressure. Therefore, the quantity ACH represents the number of building volumes of outdoor air that infiltrates (and eventually exfiltrates) per hour. At sea-level standard conditions of 1 atm (101.3 kPa or 14.7 psia) and 20°C (68°F), the density of air is

$$\rho_{\text{air, standard}} = 1.20 \text{ kg/m}^3 = 0.075 \text{ lbm/ft}^3$$

However, the atmospheric pressure and thus the density of air will drop by about 20 percent at 1500 m (5000 ft) elevation at 20°C, and by about 10 percent when the temperature rises to 50°C at 1 atm pressure. Therefore, local air density should be used in calculations to avoid such errors.

Infiltration rate values for hundreds of buildings throughout the United States have been measured during the last two decades, and the seasonal average infiltration rates have been observed to vary from about 0.2 ACH for newer energy-efficient tight buildings to about 2.0 ACH for older buildings. Therefore, infiltration rates can easily vary by a factor of 10 from one building to another. Seasonal average infiltration rates as low as 0.02 have been recorded. A study that involved 312 mostly new homes determined the average infiltration rate to be about 0.5 ACH. Another study that involved 266 mostly older homes determined the average infiltration rate to be about 0.9 ACH. The infiltration rates of some new office buildings with no outdoor air intake are measured to be between 0.1 and 0.6 ACH. Occupancy is estimated to add 0.1 to 0.15 ACH to unoccupied infiltration rate values. Also, the infiltration rate of a building can vary by a factor of 5, depending on the weather.

A minimum of 0.35 ACH is required to meet the *fresh air requirements* of residential buildings and to maintain indoor air quality, provided that at least 7.5 L/s (15 ft<sup>3</sup>/min) of fresh air is supplied per occupant to keep the indoor CO<sub>2</sub>

concentration level below 1000 parts per million (0.1 percent). Usually the infiltration rates of houses are above 0.35 ACH, and thus we do not need to be concerned about *mechanical ventilation*. However, the infiltration rates of some of today's energy-efficient buildings are below the required minimum, and additional fresh air must be supplied to such buildings by mechanical ventilation. It may be necessary to install a central ventilating system in addition to the bathroom and kitchen fans to bring the air quality to desired levels.

Venting the cold outside air directly into the house will obviously increase the heating load in winter. But part of the energy in the warm air vented out can be recovered by installing an *air-to-air heat exchanger* (also called an "economizer" or "heat recuperator") that transfers the heat from the exhausted stale air to the incoming fresh air without any mixing (Fig. 16-59). Such heat exchangers are commonly used in superinsulated houses, but the benefits of such heat exchangers must be weighed against the cost and complexity of their installation. The effectiveness of such heat exchangers is typically low (about 40 percent) because of the small temperature differences involved.

The primary cause of excessive infiltration is *poor workmanship*, but it may also be the settling and aging of the house. Infiltration is likely to develop where two surfaces meet such as the wall–foundation joint. Large differences between indoor and outdoor humidity and temperatures may aggravate the problem. Winds exert a dynamic pressure on the house, which forces the outside air through the cracks inside the house.

Infiltration should not be confused with **ventilation**, which is the *intentional* and *controlled* mechanism of air flow into or out of a building. Ventilation can be *natural* or *forced* (or *mechanical*), depending on how it is achieved. Ventilation accomplished by the opening of windows or doors is natural ventilation, whereas ventilation accomplished by an air mover such as a fan is forced ventilation. Forced ventilation gives the designer the greatest control over the magnitude and distribution of air flow throughout a building. The airtightness or air exchange rate of a building at any given time usually includes the effects of natural and forced ventilation as well as infiltration.

Air exchange, or the supply of fresh air, has a significant role on health, air quality, thermal comfort, and energy consumption. The *supply of fresh air* is a double-edged sword: too little of it will cause health and comfort problems such as the sick-building syndrome that was experienced in super-airtight buildings, and too much of it will waste energy. Therefore, the rate of fresh air supply should be just enough to maintain the indoor air quality at an acceptable level. The infiltration rate of older buildings is several times the required minimum flow rate of fresh air, and thus there is a high energy penalty associated with it.

Infiltration increases the *energy consumption* of a building in two ways: First, the incoming outdoor air must be heated (or cooled in summer) to the indoor air temperature. This represents the **sensible heat load** of infiltration and is expressed as

$$\dot{Q}_{\text{infiltration, sensible}} = \rho_o c_p \dot{V}(T_i - T_o) \\ = \rho_o c_p (\text{ACH})(V_{\text{building}})(T_i - T_o) \quad (16-42)$$

where  $\rho_o$  is the density of outdoor air;  $c_p$  is the specific heat of air (about  $1 \text{ kJ/kg} \cdot ^\circ\text{C}$  or  $0.24 \text{ Btu/lbm} \cdot ^\circ\text{F}$ );  $\dot{V} = (\text{ACH})(V_{\text{building}})$  is the volumetric flow rate of air, which is the number of air changes per hour times the volume of the building; and  $T_i - T_o$  is the temperature difference between the indoor and outdoor air. Second, the moisture content of outdoor air, in general, is different

**FIGURE 16-59**

An air-to-air heat exchanger recuperates some of the energy of warm indoor air vented out of a building.

**FIGURE 16-60**

The energy removed while water vapor in the air is condensed constitutes the latent heat load of an air-conditioning system.

than that of indoor air, and thus the incoming air may need to be humidified or dehumidified. This represents the **latent heat load** of infiltration and is expressed as (Fig. 16-60)

$$\begin{aligned}\dot{Q}_{\text{infiltration, latent}} &= \rho_o h_{fg} \dot{V}(\omega_i - \omega_o) \\ &= \rho_o h_{fg} (\text{ACH})(V_{\text{building}})(\omega_i - \omega_o)\end{aligned}\quad (16-43)$$

where  $h_{fg}$  is the latent heat of vaporization at the indoor temperature (about 2340 kJ/kg or 1000 Btu/lbm) and  $\omega_i - \omega_o$  is the humidity ratio difference between the indoor and outdoor air, which can be determined from the psychrometric charts. The latent heat load is particularly significant in summer months in hot and humid regions such as Florida and coastal Texas. In winter, the humidity ratio of outdoor air is usually much lower than that of indoor air, and the latent infiltration load in this case represents the energy needed to vaporize the required amount of water to raise the humidity of indoor air to the desired level.

## Preventing Infiltration

Infiltration accounts for a significant part of the total heat loss, and sealing the sites of air leaks by *caulking* or *weather-stripping* should be the first step to reduce energy waste and heating and cooling costs. Weatherizing requires some work, of course, but it is relatively easy and inexpensive to do.

**Caulking** can be applied with a caulking gun inside and outside where two stationary surfaces such as a wall and a window frame meet. It is easy to apply and is very effective in fixing air leaks. Potential sites of air leaks that can be fixed by caulking are entrance points of electrical wires, plumbing, and telephone lines; the sill plates where walls meet the foundation; joints between exterior window frames and siding; joints between door frames and walls; and around exhaust fans.

**Weather-stripping** is a narrow piece of metal, vinyl, rubber, felt, or foam that seals the contact area between the fixed and movable sections of a joint. Weather-stripping is best suited for sites that involve moving parts such as doors and windows. It minimizes air leakage by closing off the gaps between the moving parts and their fixed frames when they are closed. All exterior doors and windows should be weatherized. There are various kinds of weather-stripping, and some kinds are more suitable for particular kinds of gaps. Some common types of weather-stripping are shown in Fig. 16-61.

**FIGURE 16-61**

Some common types of weather-stripping.

### EXAMPLE 16-16 Reducing Infiltration Losses by Winterizing

The average atmospheric pressure in Denver, Colorado (elevation = 5300 ft), is 12.1 psia, and the average winter temperature is 38°F. The pressurization test of a 9-ft-high, 2500 ft<sup>2</sup> older home revealed that the seasonal average infiltration rate of the house is 1.8 ACH (Fig. 16-62). It is suggested that the infiltration rate of the house can be reduced by one-third to 1.2 ACH by winterizing the doors and the windows. If the house is heated by natural gas whose unit cost is \$0.58/therm and the heating season can be taken to be six months, determine how much the home owner will save from the heating costs per year by this winterization project. Assume the house is maintained at 70°F at all times and the efficiency of the furnace is 0.75. Also, the latent heat load during the heating season in Denver is negligible.

**SOLUTION** A winterizing project will reduce the infiltration rate of a house from 1.8 ACH to 1.2 ACH. The resulting cost savings are to be determined.

**Assumptions** 1 The house is maintained at 70°F at all times. 2 The latent heat load during the heating season is negligible. 3 The infiltrating air is heated to 70°F before it exfiltrates.

**Properties** The specific heat of air at room temperature is 0.24 Btu/lbm · °F. The molar mass of air is 0.3704 psia · ft<sup>3</sup>/lbm · R.

**Analysis** The density of air at the outdoor conditions is

$$\rho_o = \frac{P_o}{RT_o} = \frac{12.1 \text{ psia}}{(0.3704 \text{ psia} \cdot \text{ft}^3/\text{lbm} \cdot \text{R})(498 \text{ R})} = 0.0656 \text{ lbm/ft}^3$$

The volume of the building is

$$V_{\text{building}} = (\text{Floor area})(\text{Height}) = (2500 \text{ ft}^2)(9 \text{ ft}) = 22,500 \text{ ft}^3$$

The sensible infiltration heat load corresponding to the reduction in the infiltration rate of 0.6 ACH is

$$\begin{aligned}\dot{Q}_{\text{infiltration, saved}} &= \rho_o c_p (\text{ACH}_{\text{saved}}) (V_{\text{building}}) (T_i - T_o) \\ &= (0.0656 \text{ lbm/ft}^3)(0.24 \text{ Btu/lbm} \cdot \text{°F})(0.6/\text{h})(22,500 \text{ ft}^3) \\ &\quad (70 - 38) \text{ °F} \\ &= 6800 \text{ Btu/h} = 0.068 \text{ therm/h}\end{aligned}$$

since 1 therm = 100,000 Btu. The number of hours during a six-month period is  $6 \times 30 \times 24 = 4320$  h. Noting that the furnace efficiency is 0.75 and the unit cost of natural gas is \$0.58/therm, the energy and money saved during the six-month period are

$$\begin{aligned}\text{Energy savings} &= (\dot{Q}_{\text{infiltration, saved}})(\text{No. of hours per year})/\text{Efficiency} \\ &= (0.068 \text{ therm/h})(4320 \text{ h/year})/0.75 \\ &= 392 \text{ therms/year}\end{aligned}$$

$$\begin{aligned}\text{Cost savings} &= (\text{Energy savings})(\text{Unit cost of energy}) \\ &= (392 \text{ therms/year})(\$0.58/\text{therm}) \\ &= \$227/\text{year}\end{aligned}$$

Therefore, reducing the infiltration rate by one-third will reduce the heating costs of this home owner by \$227 per year.

**FIGURE 16–62**

Schematic for Example 16–16.

## 16–11 • ANNUAL ENERGY CONSUMPTION

In the thermal analysis of buildings, two quantities of major interest are (1) the *size* or *capacity* of the heating and the cooling system and (2) the *annual energy consumption*. The size of a heating or cooling system is based on the *most demanding* situations under the anticipated *worst weather* conditions, whereas the average annual energy consumption is based on *average usage* situations under *average weather* conditions. Therefore, the calculation procedure of annual energy usage is quite different than that of design heating or cooling loads.

**FIGURE 16-63**

The heating and cooling cost of a commercial building constitutes about 1 percent of the total cost. Therefore, thermal comfort and thus productivity should not be risked to conserve energy.

An analysis of annual energy consumption and cost usually accompanies the design heat load calculations and plays an important role in the selection of a heating or cooling system. Often a choice must be made among several systems that have the same capacity but different efficiencies and initial costs. More efficient systems usually consume less energy and money per year, but they cost more to purchase and install. The purchase of a more efficient but more expensive heating or cooling system can be economically justified only if the system saves more in the long run from energy costs than its initial cost differential.

The impact on the *environment* may also be an important consideration on the selection process: A system that consumes less fuel pollutes the environment less, and thus reduces all the adverse effects associated with environmental pollution. But it is difficult to quantify the environmental impact in an economic analysis unless a price is put on it.

One way of reducing the initial and operating costs of a heating or cooling system is to compromise the *thermal comfort* of occupants. This option should be avoided, however, since a small loss in employee productivity due to thermal discomfort can easily offset any potential gains from reduced energy use. The U.S. Department of Energy periodically conducts comprehensive energy surveys to determine the energy usage in residential as well as nonresidential buildings and the industrial sector. Two 1983 reports (DOE/EIA-0246 and DOE/EIA-0318) indicate that the national average natural gas usage of all commercial buildings in the United States is  $70,000 \text{ Btu}/\text{ft}^2 \cdot \text{year}$ , which is worth about  $\$0.50/\text{ft}^2$  or  $\$5/\text{m}^2$  per year. The reports also indicate that the average annual electricity consumption of commercial buildings due to air-conditioning is about  $12 \text{ kWh}/\text{ft}^2 \cdot \text{year}$ , which is worth about  $\$1/\text{ft}^2$  or  $\$10/\text{m}^2$  per year. Therefore, the average cost of heating and cooling of commercial buildings is about  $\$15/\text{m}^2$  per year. This corresponds to  $\$300/\text{year}$  for a  $20 \text{ m}^2$  floor space, which is large enough for an average office worker. But noting that the average salary and benefits of a worker are no less than  $\$30,000$  a year, it appears that the heating and cooling cost of a commercial building constitutes about 1 percent of the total cost (Fig. 16-63). Therefore, even a 1 percent loss in productivity due to thermal discomfort may cost the business owner more than the entire cost of energy. Likewise, the loss of business in retail stores due to unpleasant thermal conditions will cost the store owner many times what he or she is saving from energy. Thus, the message to the HVAC engineer is clear: *in the design of heating and cooling systems of commercial buildings, treat the thermal comfort conditions as design constraints rather than as variables. The cost of energy is a very small fraction of the goods and services produced, and thus, do not incorporate any energy conservation measures that may result in a loss of productivity or loss of revenues.*

When trying to minimize annual energy consumption, it is helpful to have a general idea about where most energy is used. A breakdown of energy usage in residential and commercial buildings is given in Fig. 16-64. Note that space heating accounts for most energy usage in all buildings, followed by water heating in residential buildings and lighting in commercial buildings. Therefore, any conservation measure dealing with them will have the greatest impact.

For *existing buildings*, the amount and cost of energy (fuel or electricity) used for heating and cooling of a building can be determined by simply

**FIGURE 16-64**

Breakdown of energy consumption in residential and commercial buildings in 1986.

(From U.S. Department of Energy.)

analyzing the *utility bills* for a typical year. For example, if a house uses natural gas for space and water heating, the natural gas consumption for space heating can be determined by estimating the average monthly usage for water heating from summer bills, multiplying it by 12 to estimate the yearly usage, and subtracting it from the total annual natural gas usage. Likewise, the annual electricity usage and cost for air-conditioning can be determined by simply evaluating the excess electricity usage during the cooling months and adding them up. If the bills examined are not for a typical year, corrections can be made by comparing the weather data for that year to the average weather data.

For buildings that are at the design or construction stage, the evaluation of annual energy consumption involves the determination of (1) the *space load* for heating or cooling due to heat transfer through the building envelope and infiltration, (2) the *efficiency* of the furnace where the fuel is burned or the COP of cooling or heat pump systems, and (3) the *parasitic energy* consumed by the distribution system (pumps or fans) and the energy lost or gained from the pipes or ducts (Fig. 16-65). The determination of the space load is similar to the determination of the peak load, except the average conditions are used for the weather instead of design conditions. The space heat load is usually based on the average temperature difference between the indoors and the outdoors, but internal heat gains and solar effects must also be considered for better accuracy. Very accurate results can be obtained by using hourly data for a whole year and by making a computer simulation using one of the commercial building energy analysis software packages.

The simplest and most intuitive way of estimating the annual energy consumption of a building is the **degree-day** (or **degree-hour**) method, which is a *steady-state* approach. It is based on constant indoor conditions during the heating or cooling season and assumes the efficiency of the heating or cooling equipment is not affected by the variation of outdoor temperature. These conditions will be closely approximated if all the thermostats in a building are set at the same temperature at the beginning of a heating or cooling season and are never changed, and a seasonal average efficiency is used (rather than the full-load or design efficiency) for the furnaces or coolers.

You may think that anytime the outdoor temperature  $T_o$  drops below the indoor temperature  $T_i$  at which the thermostat is set, the heater will turn on to make up for the heat losses to the outside. However, the internal heat generated by people, lights, and appliances in occupied buildings as well as the heat gain from the sun during the day,  $\dot{Q}_{gain}$ , will be sufficient to compensate for the heat losses from the building until the outdoor temperature drops below a certain value. The *outdoor temperature* above which no heating is required is called the **balance point temperature**  $T_{balance}$  (or the *base temperature*) and is determined from (Fig. 16-66)

$$K_{overall}(T_i - T_{balance}) = \dot{Q}_{gain} \rightarrow T_{balance} = T_i - \frac{\dot{Q}_{gain}}{K_{overall}} \quad (16-44)$$

where  $K_{overall}$  is the *overall heat transfer coefficient* of the building in  $\text{W}/\text{°C}$  or  $\text{Btu}/\text{h} \cdot \text{°F}$ . There is considerable uncertainty associated with the determination of the balance point temperature, but based on the observations of typical buildings, it is usually taken to be  $18^\circ\text{C}$  in Europe and  $65^\circ\text{F}$  ( $18.3^\circ\text{C}$ ) in the

FIGURE 16-65

The various quantities involved in the evaluation of the annual energy consumption of a building.

FIGURE 16-66

The heater of a building will not turn on as long as the internal heat gain makes up for the heat loss from a building (the *balance point* outdoor temperature).

United States for convenience. The rate of energy consumption of the heating system is

$$\dot{Q}_{\text{heating}} = \frac{K_{\text{overall}}}{\eta_{\text{heating}}} (T_{\text{balance}} - T_o)^+ \quad (16-45)$$

where  $\eta_{\text{heating}}$  is the efficiency of the heating system, which is equal to 1.0 for electric resistance heating systems, COP for the heat pumps, and combustion efficiency (about 0.6 to 0.95) for furnaces. If  $K_{\text{overall}}$ ,  $T_{\text{balance}}$ , and  $\eta_{\text{heating}}$ , are taken to be constants, the annual energy consumption for heating can be determined by integration (or by summation over daily or hourly averages) as

$$Q_{\text{heating, year}} = \frac{K_{\text{overall}}}{\eta_{\text{heating}}} \int [T_{\text{balance}} - T_o(t)]^+ dt \cong \frac{K_{\text{overall}}}{\eta_{\text{heating}}} DD_{\text{heating}} \quad (16-46)$$

where  $DD_{\text{heating}}$  is the **heating degree-days**. The + sign above the parenthesis indicates that only positive values are to be counted, and the temperature difference is to be taken to be zero when  $T_o > T_{\text{balance}}$ . The number of degree-days for a heating season is determined from

$$DD_{\text{heating}} = (1 \text{ day}) \sum (T_{\text{balance}} - T_{o,\text{avg,day}})^+ \quad (\text{C-day}) \quad (16-47)$$

where  $T_{o,\text{avg,day}}$  is the *average* outdoor temperature for each day (without considering temperatures above  $T_{\text{balance}}$ ), and the summation is performed daily (Fig. 16-67). Similarly, we can also define *heating degree-hours* by using hourly average outdoor temperatures and performing the summation hourly. Note that the number of degree-hours is equal to 24 times the number of degree-days. Heating degree-days for each month and the yearly total for a balance point temperature of 65°F are given in Table 16-5 for several cities. *Cooling degree-days* are defined in the same manner to evaluate the annual energy consumption for cooling, using the same balance point temperature.

Expressing the design energy consumption of a building for heating as  $\dot{Q}_{\text{design}} = K_{\text{overall}}(T_i - T_o)_{\text{design}}/\eta_{\text{heating}}$  and comparing it to the annual energy consumption gives the following relation between energy consumption at designed conditions and the annual energy consumption (Table 16-22),

$$\frac{\dot{Q}_{\text{heating, year}}}{\dot{Q}_{\text{design}}} = \frac{DD_{\text{heating}}}{(T_i - T_o)_{\text{design}}} \quad (16-48)$$

where  $(T_i - T_o)_{\text{design}}$  is the design indoor-outdoor temperature difference.

Despite its simplicity, remarkably accurate results can be obtained with the *degree-day method* for most houses and single-zone buildings using a hand calculator. Besides, the degree-days characterize the *severity* of the weather at a location accurately, and the degree-day method serves as a valuable tool for gaining an *intuitive understanding* of annual energy consumption. But when the efficiency of the HVAC equipment changes considerably with the outdoor temperature, or the balance-point temperature varies significantly with time, it may be necessary to consider several bands (or “bins”) of outdoor temperatures and to determine the energy consumption for each band using the equipment efficiency for those outdoor temperatures and the number of hours those

The outdoor temperatures for a day during which the heating degree-day is 25°F-day.

**TABLE 16-22**

The ratio of annual energy consumption to the hourly energy consumption at design conditions at several locations for  $T_i = 70^\circ\text{F}$  (from Eq. 16-48).

| City        | $T_{o,\text{design}}$ | °F-days | Ratio |
|-------------|-----------------------|---------|-------|
| Tucson      | 32°F                  | 1800    | 1137  |
| Las Vegas   | 28°F                  | 2709    | 1548  |
| Charleston  | 11°F                  | 4476    | 1821  |
| Cleveland   | 5°F                   | 6351    | 2345  |
| Minneapolis | -12°F                 | 8382    | 2453  |
| Anchorage   | -18°F                 | 10,864  | 2963  |

temperatures are in effect. Then the annual energy consumption is obtained by adding the results of all bands. This modified degree-day approach is known as the **bin method**, and the calculations can still be performed using a hand calculator.

The steady-state methods become too crude and unreliable for buildings that experience large daily fluctuations, such as a typical, well-lit, crowded office building that is open Monday through Friday from 8 AM to 5 PM. This is especially the case when the building is equipped with programmable thermostats that utilize night setback to conserve energy. Also, the efficiency of a heat pump varies considerably with the outdoor temperatures, and the efficiencies of boilers and chillers are lower at part load. Further, the internal heat gain and necessary ventilation rate of commercial buildings vary greatly with occupancy. In such cases, it may be necessary to use a *dynamic method* such as the **transfer function method** to predict the annual energy consumption accurately. Such dynamic methods are based on performing *hourly calculations* for the entire year and adding the results. Obviously they require the use of a computer with a well-developed and hopefully user-friendly program. Very accurate results can be obtained with dynamic methods since they consider the hourly variation of indoor and outdoor conditions as well as the solar radiation, the thermal inertia of the building, the variation of the heat loss coefficient of the building, and the variation of equipment efficiency with outdoor temperatures. Even when a dynamic method is used to determine the annual energy consumption, the simple degree-day method can still be used as a check to ensure that the results obtained are in the proper range.

Some simple practices can result in significant *energy savings* in residential buildings while causing minimal discomfort. The annual energy consumption can be reduced by up to 50 percent by setting the thermostat back in winter and up in summer, and setting it back further at nights (Table 16–23). Reducing the thermostat setting in winter by 4°F (2.2°C) alone can save 12 to 18 percent; setting the thermostat back by 10°F (5.6°C) alone for 8 h on winter nights can save 7 to 13 percent. Setting the thermostat up in summer by 4°F (2.2°C) can reduce the energy consumption of residential cooling units by 18 to 32 percent. Cooling energy consumption can be reduced by up to 25 percent by sun screening and by up to 9 percent by attic ventilation (ASHRAE *Handbook of Fundamentals*, p. 28.14).

**TABLE 16–23**

Approximate percent savings from thermostat setback from 65°F for 14 hours per night and the entire weekends (from National Frozen Food Association/U.S. Department of Energy, “Reducing Energy Costs Means a Better Bottom Line”)

| °F-days | Amount of setback, °F |      |      |      |
|---------|-----------------------|------|------|------|
|         | 5°F                   | 10°F | 15°F | 20°F |
| 1000    | 13%                   | 25%  | 38%  | 50%  |
| 2000    | 12                    | 24   | 36   | 48   |
| 3000    | 11                    | 22   | 33   | 44   |
| 4000    | 10                    | 20   | 30   | 40   |
| 5000    | 9                     | 19   | 28   | 38   |
| 6000    | 8                     | 16   | 24   | 32   |
| 7000    | 7                     | 15   | 22   | 30   |
| 8000    | 7                     | 13   | 19   | 26   |
| 9000    | 6                     | 11   | 16   | 22   |
| 10,000  | 5                     | 9    | 14   | 18   |

### EXAMPLE 16–17 Energy and Money Savings by Winterization

You probably noticed that the heating bills are highest in December and January because the temperatures are the lowest in those months. Imagine that you have moved to Cleveland, Ohio, and your roommate offered to pay the remaining heating bills if you pay the December and January bills only. Should you accept this offer?

**SOLUTION** It makes sense to accept this offer if the cost of heating in December and January is less than half of the heating bill for the entire winter. The energy consumption of a building for heating is proportional to the heating degree-days. For Cleveland, they are listed in Table 16–5 to be 1088°F-day for December, 1159°F-day for January, and 6351°F-day for the entire year

**TABLE 16-24**

Monthly heating degree-days for Cleveland, Ohio, and the yearly total (Example 16-17).

| Month        | Degree-days<br>°F-days | Degree-days<br>°C-days |
|--------------|------------------------|------------------------|
| July         | 9                      | 5                      |
| August       | 25                     | 14                     |
| September    | 105                    | 58                     |
| October      | 384                    | 213                    |
| November     | 738                    | 410                    |
| December     | 1088                   | 604                    |
| January      | 1159                   | 644                    |
| February     | 1047                   | 582                    |
| March        | 918                    | 510                    |
| April        | 552                    | 307                    |
| May          | 260                    | 144                    |
| June         | 66                     | 37                     |
| Yearly total | 6351                   | 3528                   |

**FIGURE 16-68**

Schematic for Example 16-18.

(Table 16-24). The ratio of December–January degree-days to the annual degree-days is

$$\frac{DD_{\text{heating, Dec-Jan}}}{DD_{\text{heating, annual}}} = \frac{(1088 + 1159)^\circ\text{F-day}}{6351^\circ\text{F-day}} = 0.354$$

which is less than half. Therefore, this is a good offer and **should be accepted**.

### EXAMPLE 16-18 Annual Heating Cost of a House

Using indoor and outdoor winter design temperatures of 70°F and 8°F, respectively, the design heat load of a 3000-ft<sup>2</sup> house in Salt Lake City, Utah, is determined to be 72,000 Btu/h (Fig. 16-68). The house is to be heated by natural gas that is to be burned in an 80 percent efficient furnace. If the unit cost of natural gas is \$0.55/therm, estimate the annual gas consumption of this house and its cost.

**SOLUTION** The annual gas consumption and its cost for a house in Salt Lake City with a design heat load of 72,000 Btu/h are to be determined.

**Assumption** The house is maintained at 70°F at all times during the heating season.

**Analysis** The rate of gas consumption of the house for heating at design conditions is

$$\begin{aligned}\dot{Q}_{\text{design}} &= \dot{Q}_{\text{design,load}}/\eta_{\text{heating}} \\ &= (70,000 \text{ Btu/h})/0.80 = 87,500 \text{ Btu/h} = 0.875 \text{ therm/h}\end{aligned}$$

The annual heating degree-days of Salt Lake City are listed in Table 16-5 to be 6052°F-day. Then the annual natural gas usage of the house can be determined from Equation 16-48 to be

$$\begin{aligned}\dot{Q}_{\text{heating, year}} &= \frac{DD_{\text{heating}}}{(T_i - T_o)_{\text{design}}} \dot{Q}_{\text{design}} \\ &= \frac{6052^\circ\text{F-day}}{(70 - 8)^\circ\text{F}} \left( \frac{24\text{h}}{1\text{day}} \right) (0.875 \text{ therm/h}) = 2050 \text{ therms/year}\end{aligned}$$

whose cost is

$$\begin{aligned}\text{Annual heating cost} &= (\text{Annual energy consumption})(\text{Unit cost of energy}) \\ &= (2050 \text{ therms/year})(\$0.55/\text{therm}) = \$1128/\text{year}\end{aligned}$$

Therefore, it will cost \$1128 per year to heat this house.

### EXAMPLE 16-19 Choosing the Most Economical Air Conditioner

Consider a house whose annual air-conditioning load is estimated to be 40,000 kWh in an area where the unit cost of electricity is \$0.09/kWh. Two air conditioners are considered for the house. Air conditioner A has a seasonal average COP of 2.5 and costs \$2500 to purchase and install. Air conditioner B

has a seasonal average COP of 5.0 and costs \$4000 to purchase and install. If all else is equal, determine which air conditioner is a better buy (Fig. 16–69).

**SOLUTION** A decision is to be made between a cheaper but inefficient and an expensive but efficient air conditioner for a house.

**Assumption** The two air conditioners are comparable in all aspects other than the initial cost and the efficiency.

**Analysis** The unit that will cost less during its lifetime is a better buy. The total cost of a system during its lifetime (the initial, operation, maintenance, etc.) can be determined by performing a life cycle cost analysis. A simpler alternative is to determine the simple payback period. The energy and cost savings of the more efficient air conditioner in this case are

$$\begin{aligned}\text{Energy savings} &= (\text{Annual energy usage of A}) - (\text{Annual energy usage of B}) \\ &= (\text{Annual cooling load})(1/\text{COP}_A - 1/\text{COP}_B) \\ &= (40,000 \text{ kWh/year})(1/2.5 - 1/5.0) \\ &= 8000 \text{ kWh/year}\end{aligned}$$

$$\begin{aligned}\text{Cost savings} &= (\text{Energy savings})(\text{Unit cost of energy}) \\ &= (8000 \text{ kWh/year})(\$0.09/\text{kWh}) = \$720/\text{year}\end{aligned}$$

Therefore, the more efficient air conditioner will pay for the \$1500 cost differential in this case in about two years. A cost-conscious consumer will have no difficulty in deciding that the more expensive but more efficient air conditioner B is clearly a better buy in this case since air conditioners last at least 15 years. But the decision would not be so easy if the unit cost of electricity at that location was \$0.03/kWh instead of \$0.09/kWh, or if the annual air-conditioning load of the house was just 10,000 kWh instead of 40,000 kWh.

**FIGURE 16–69**

Schematic for Example 16–19.

## SUMMARY

In a broad sense, *air-conditioning* means to condition the air to the desired level by heating, cooling, humidifying, dehumidifying, cleaning, and deodorizing. The purpose of the air-conditioning system of a building is to provide complete thermal comfort for its occupants. The metabolic heat generated in the body is dissipated to the environment through the skin and lungs by convection and radiation as *sensible heat* and by evaporation as *latent heat*. The total *sensible heat loss* can be expressed by combining convection and radiation heat losses as

$$\begin{aligned}\dot{Q}_{\text{conv+rad}} &= (h_{\text{conv}} + h_{\text{rad}})A_{\text{clothing}}(T_{\text{clothing}} - T_{\text{operative}}) \\ &= \frac{A_{\text{clothing}}(T_{\text{skin}} - T_{\text{clothing}})}{R_{\text{clothing}}}\end{aligned}$$

where  $R_{\text{clothing}}$  is the *unit thermal resistance of clothing*, which involves the combined effects of conduction, convection, and radiation between the skin and the outer surface of clothing. The *operative temperature*  $T_{\text{operative}}$  is approximately the arithmetic average of the ambient and surrounding surface

temperatures. Another environmental index used in thermal comfort analysis is the *effective temperature*, which combines the effects of temperature and humidity.

The desirable ranges of temperatures, humidities, and ventilation rates for indoors constitute the typical *indoor design conditions*. The set of extreme outdoor conditions under which a heating or cooling system must be able to maintain a building at the indoor design conditions is called the *outdoor design conditions*. The *heating or cooling loads* of a building represent the heat that must be supplied to or removed from the interior of a building to maintain it at the desired conditions. The effect of solar heating on opaque surfaces is accounted for by replacing the ambient temperature in the heat transfer relation through the walls and the roof by the *sol-air temperature*, which is defined as the equivalent outdoor air temperature that gives the same rate of heat flow to a surface as would the combination of incident solar radiation, convection with the ambient air, and radiation exchange with the sky and the surrounding surfaces.

Heat flow into an exterior surface of a building subjected to solar radiation can be expressed as

$$\dot{Q}_{\text{surface}} = h_o A_s (T_{\text{sol-air}} - T_{\text{surface}})$$

where

$$T_{\text{sol-air}} = T_{\text{ambient}} + \frac{\alpha_s \dot{q}_{\text{solar}}}{h_o} - \frac{\varepsilon \sigma (T_{\text{ambient}}^4 - T_{\text{sur}}^4)}{h_o}$$

and  $\alpha_s$  is the *solar absorptivity* and  $\varepsilon$  is the *emissivity* of the surface,  $h_o$  is the combined convection and radiation heat transfer coefficient, and  $\dot{q}_{\text{solar}}$  is the solar radiation incident on the surface.

The conversion of chemical or electrical energy to thermal energy in a building constitutes the *internal heat gain* of a building. The primary sources of internal heat gain are people, lights, appliances, and miscellaneous equipment such as computers, printers, and copiers. The average amount of heat given off by a person depends on the level of activity and can range from about 100 W for a resting person to more than 500 W for a physically very active person. The heat gain due to a motor inside a conditioned space can be expressed as

$$\dot{Q}_{\text{motor,total}} = \dot{W}_{\text{motor}} \times f_{\text{load}} \times f_{\text{usage}} / \eta_{\text{motor}}$$

where  $\dot{W}_{\text{motor}}$  is the power rating of the motor,  $f_{\text{load}}$  is the *load factor* of the motor during operation,  $f_{\text{usage}}$  is the *usage factor*, and  $\eta_{\text{motor}}$  is the *motor efficiency*.

Under steady conditions, the rate of heat transfer through any section of a *building wall* or *roof* can be determined from

$$\dot{Q} = UA_s(T_i - T_o) = \frac{A_s(T_i - T_o)}{R}$$

where  $T_i$  and  $T_o$  are the indoor and outdoor air temperatures,  $A_s$  is the heat transfer area,  $U$  is the overall heat transfer coefficient (the *U-factor*), and  $R = 1/U$  is the overall unit thermal resistance (the *R-value*). The overall *R-value* of a wall or roof can be determined from the thermal resistances of the individual components using the thermal resistance network. The *effective emissivity* of a plane-parallel air space is given by

$$\frac{1}{\varepsilon_{\text{effective}}} = \frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1$$

where  $\varepsilon_1$  and  $\varepsilon_2$  are the emissivities of the surfaces of the air space.

Heat losses through the below-grade section of a *basement wall* and through the *basement floor* are given as

$$\dot{Q}_{\text{basement walls}} = U_{\text{wall, ave}} A_{\text{wall}} (T_{\text{basement}} - T_{\text{ground surface}})$$

$$\dot{Q}_{\text{basement floor}} = U_{\text{floor}} A_{\text{floor}} (T_{\text{basement}} - T_{\text{ground surface}})$$

where  $U_{\text{wall, ave}}$  is the average overall heat transfer coefficient between the basement wall and the surface of the ground and  $U_{\text{floor}}$  is the overall heat transfer coefficient at the basement

floor. Heat loss from floors that sit directly on the ground at or slightly above the ground level is mostly through the perimeter to the outside air rather than through the floor into the ground and is expressed as

$$\dot{Q}_{\text{floor on grade}} = U_{\text{grade}} p_{\text{floor}} (T_{\text{indoor}} - T_{\text{outdoor}})$$

where  $U_{\text{grade}}$  represents the rate of heat transfer from the slab per unit temperature difference between the indoor temperature  $T_{\text{indoor}}$  and the outdoor temperature  $T_{\text{outdoor}}$  and per unit length of the perimeter  $p_{\text{floor}}$  of the building. When the crawl space temperature is known, heat loss through the *floor of the building* is determined from

$$\dot{Q}_{\text{building floor}} = U_{\text{building floor}} A_{\text{floor}} (T_{\text{indoor}} - T_{\text{crawl}})$$

where  $U_{\text{building floor}}$  is the overall heat transfer coefficient for the floor.

Windows are considered in three regions when analyzing heat transfer through them: (1) the *center-of-glass*, (2) the *edge-of-glass*, and (3) the *frame* regions. Total rate of heat transfer through the window is determined by adding the heat transfer through each region as

$$\begin{aligned}\dot{Q}_{\text{window}} &= \dot{Q}_{\text{center}} + \dot{Q}_{\text{edge}} + \dot{Q}_{\text{frame}} \\ &= U_{\text{window}} A_{\text{window}} (T_{\text{indoors}} - T_{\text{outdoors}})\end{aligned}$$

where

$$U_{\text{window}} = (U_{\text{center}} A_{\text{center}} + U_{\text{edge}} A_{\text{edge}} + U_{\text{frame}} A_{\text{frame}}) / A_{\text{window}}$$

is the *U-factor* or the *overall heat transfer coefficient* of the window;  $A_{\text{window}}$  is the window area;  $A_{\text{center}}$ ,  $A_{\text{edge}}$ , and  $A_{\text{frame}}$  are the areas of the center, edge, and frame sections of the window, respectively; and  $U_{\text{center}}$ ,  $U_{\text{edge}}$ , and  $U_{\text{frame}}$  are the heat transfer coefficients for the center, edge, and frame sections of the window.

The sum of the transmitted solar radiation and the portion of the absorbed radiation that flows indoors constitutes the *solar heat gain* of the building. The fraction of incident solar radiation that enters through the glazing is called the *solar heat gain coefficient* SHGC, and the total solar heat gain through that window is determined from

$$\dot{Q}_{\text{solar,gain}} = \text{SHGC} \times A_{\text{glazing}} \times \dot{q}_{\text{solar,incident}}$$

where  $A_{\text{glazing}}$  is the glazing area of the window and  $\dot{q}_{\text{solar,incident}}$  is the solar heat flux incident on the outer surface of the window. Using the standard 3-mm-thick double-strength clear window glass sheet whose SHGC is 0.87 as the reference glazing, the *shading coefficient* SC is defined as

$$\text{SC} = \frac{\text{Solar heat gain of product}}{\text{Solar heat gain of reference glazing}}$$

$$= \frac{\text{SHGC}}{\text{SHGC}_{\text{ref}}} = \frac{\text{SHGC}}{0.87} = 1.15 \times \text{SHGC}$$

Shading devices are classified as *internal shading* and *external shading*, depending on whether the shading device is placed inside or outside.

The uncontrolled entry of outside air into a building through unintentional openings is called *infiltration*, and it wastes a significant amount of energy since the air entering must be heated in winter and cooled in summer. The *sensible* and *latent heat load* of infiltration are expressed as

$$\begin{aligned}\dot{Q}_{\text{infiltration, sensible}} &= \rho_o c_p \dot{V}(T_i - T_o) = \rho_o c_p (\text{ACH}) \\ &\quad \times (V_{\text{building}})(T_i - T_o) \\ \dot{Q}_{\text{infiltration, latent}} &= \rho_o h_{fg} \dot{V}(\omega_i - \omega_o) = \rho_o h_{fg} (\text{ACH}) \\ &\quad \times (V_{\text{building}})(\omega_i - \omega_o)\end{aligned}$$

where  $\rho_o$  is the density of outdoor air;  $c_p$  is the specific heat of air (about 1 kJ/kg · °C or 0.24 Btu/lbm · °F);  $\dot{V} = (\text{ACH}) \times (V_{\text{building}})$  is the volumetric flow rate of air, which is the number of air changes per hour times the volume of the building; and  $T_i - T_o$  is the temperature difference between the indoor and outdoor air.

Also,  $h_{fg}$  is the latent heat of vaporization at indoor temperature (about 2340 kJ/kg or 1000 Btu/lbm) and  $\omega_i - \omega_o$  is the humidity ratio difference between the indoor and outdoor air.

The *annual energy consumption* of a building depends on the space load for heating or cooling, the efficiency of the heating or cooling equipment, and the parasitic energy consumed by the pumps or fans and the energy lost or gained from the pipes or ducts. The annual energy consumption of a building can be estimated using the *degree-day method* as

$$\dot{Q}_{\text{heating, year}} = \frac{K_{\text{overall}}}{\eta_{\text{heating}}} DD_{\text{heating}}$$

where  $DD_{\text{heating}}$  is the *heating degree-days*,  $K_{\text{overall}}$  is the overall heat transfer coefficient of the building in W/°C or Btu/h · °F, and  $\eta_{\text{heating}}$  is the efficiency of the heating system, which is equal to 1.0 for electric resistance heating systems, COP for the heat pumps, and combustion efficiency (about 0.6 to 0.95) for furnaces.

## PROBLEMS\*

### A Brief History

**16-1C** In 1775, Dr. William Cullen made ice in Scotland by evacuating the air in a water tank. Explain how that device works, and discuss how the process can be made more efficient.

**16-2C** When was the first ammonia-absorption refrigeration system developed? Who developed the formulas related to dry-bulb, wet-bulb, and dew-point temperatures, and when?

**16-3C** When was the concept of heat pump conceived and by whom? When was the first heat pump built, and when were the heat pumps mass produced?

\*Problems designated by a "C" are concept questions, and students are encouraged to answer them all. Problems designated by an "E" are in English units, and the SI users can ignore them.

### Human Body and Thermal Comfort

**16-4C** What is metabolism? What is the range of metabolic rate for an average man? Why are we interested in metabolic rate of the occupants of a building when we deal with heating and air conditioning?

**16-5C** Why is the metabolic rate of women, in general, lower than that of men? What is the effect of clothing on the environmental temperature that feels comfortable?

**16-6C** What is asymmetric thermal radiation? How does it cause thermal discomfort in the occupants of a room?

**16-7C** How do (a) draft and (b) cold floor surfaces cause discomfort for a room's occupants?

**16-8C** What is stratification? Is it likely to occur at places with low or high ceilings? How does it cause thermal discomfort for a room's occupants? How can stratification be prevented?

**16-9C** Why is it necessary to ventilate buildings? What is the effect of ventilation on energy consumption for heating in winter and for cooling in summer? Is it a good idea to keep the bathroom fans on all the time? Explain.

### Heat Transfer from the Human Body

**16-10C** Consider a person who is resting or doing light work. Is it fair to say that roughly one-third of the metabolic heat generated in the body is dissipated to the environment by convection, one-third by evaporation, and the remaining one-third by radiation?

**16-11C** What is sensible heat? How is the sensible heat loss from a human body affected by (a) skin temperature, (b) environment temperature, and (c) air motion?

**16-12C** What is latent heat? How is the latent heat loss from the human body affected by (a) skin wettedness and (b) relative humidity of the environment? How is the rate of evaporation from the body related to the rate of latent heat loss?

**16-13C** How is the insulating effect of clothing expressed? How does clothing affect heat loss from the body by convection, radiation, and evaporation? How does clothing affect heat gain from the sun?

**16-14C** Explain all the different mechanisms of heat transfer from the human body (a) through the skin and (b) through the lungs.

**16-15C** What is operative temperature? How is it related to the mean ambient and radiant temperatures? How does it differ from effective temperature?

**16-16** The convection heat transfer coefficient for a clothed person while walking in still air at a velocity of 0.5 to 2 m/s is given by  $h = 8.6V^{0.53}$  where  $V$  is in m/s and  $h$  is in  $\text{W/m}^2 \cdot ^\circ\text{C}$ . Plot the convection coefficient against the walking velocity, and compare the convection coefficients in that range to the average radiation coefficient of about  $5 \text{ W/m}^2 \cdot ^\circ\text{C}$ .

**16-17** A clothed or unclothed person feels comfortable when the skin temperature is about  $33^\circ\text{C}$ . Consider an average man wearing summer clothes whose thermal resistance is 1.1 clo. The man feels very comfortable while standing in a room maintained at  $20^\circ\text{C}$ . If this man were to stand in that room unclothed, determine the temperature at which the room must be maintained for him to feel thermally comfortable. Assume the latent heat loss from the person to remain the same.

*Answer:  $27.8^\circ\text{C}$*

**16-18E** An average person produces 0.50 lbm of moisture while taking a shower and 0.12 lbm while bathing in a tub. Consider a family of four who shower once a day in a bathroom that is not ventilated. Taking the heat of vaporization of water to be 1050 Btu/lbm, determine the contribution of showers to the latent heat load of the air conditioner in summer per day.

FIGURE P16-18E

**16-19** An average (1.82 kg or 4.0 lbm) chicken has a basal metabolic rate of 5.47 W and an average metabolic rate of 10.2 W (3.78 W sensible and 6.42 W latent) during normal activity. If there are 100 chickens in a breeding room, determine the rate of total heat generation and the rate of moisture production in the room. Take the heat of vaporization of water to be 2430 kJ/kg.

**16-20** Consider a large classroom with 90 students on a hot summer day. All the lights with 2.0 kW of rated power are kept on. The room has no external walls, and thus heat gain through the walls and the roof is negligible. Chilled air is available at  $15^\circ\text{C}$ , and the temperature of the return air is not to exceed  $25^\circ\text{C}$ . The average rate of metabolic heat generation by a person sitting or doing light work is 115 W (70 W sensible and 45 W latent). Determine the required flow rate of air in kg/s, that needs to be supplied to the room. *Answer: 0.83 kg/s*

**16-21** A smoking lounge is to accommodate 15 heavy smokers. Determine the minimum required flow rate of fresh air that needs to be supplied to the lounge. *Answer: 0.45 m<sup>3</sup>/s*

**16-22** A person feels very comfortable in his house in light clothing when the thermostat is set at  $22^\circ\text{C}$  and the mean radiation temperature (the average temperature of the surrounding surfaces) is also  $22^\circ\text{C}$ . During a cold day, the average mean radiation temperature drops to  $18^\circ\text{C}$ . To what value must the

FIGURE P16-22

indoor air temperature be raised to maintain the same level of comfort in the same clothing?

**16-23** A car mechanic is working in a shop whose interior space is not heated. Comfort for the mechanic is provided by two radiant heaters that radiate heat at a total rate of 4 kJ/s. About 5 percent of this heat strikes the mechanic directly. The shop and its surfaces can be assumed to be at the ambient temperature, and the emissivity and absorptivity of the mechanic can be taken to be 0.95 and the surface area to be 1.8 m<sup>2</sup>. The mechanic is generating heat at a rate of 350 W, half of which is latent, and is wearing medium clothing with a thermal resistance of 0.7 clo. Determine the lowest ambient temperature in which the mechanic can work comfortably.

FIGURE P16-23

### Design Conditions for Heating and Cooling

**16-24C** What is winter outdoor design temperature? How does it differ from average winter outdoor temperature? How do 97.5 percent and 99 percent winter outdoor design temperatures differ from each other?

**16-25C** Weather data for two different cities A and B are compared. Is it possible for city A to have a lower winter design temperature but a higher average winter temperature? Explain.

**16-26C** What is the effect of solar radiation on (a) the design heating load in winter and (b) the annual energy consumption for heating? Answer the same question for the heat generated by people, lights, and appliances.

**16-27C** What is the effect of solar radiation on (a) the design cooling load in summer and (b) the annual energy consumption for cooling? Answer the same question for the heat generated by people, lights, and appliances.

**16-28C** Does the moisture level of the outdoor air affect the cooling load in summer, or can it just be ignored? Explain. Answer the same question for the heating load in winter.

**16-29C** The recommended design heat transfer coefficients for combined convection and radiation on the outer surface of a building are 34 W/m<sup>2</sup> · °C for winter and 22.7 W/m<sup>2</sup> · °C for summer. What is the reason for different values?

**16-30C** What is sol-air temperature? What is it used for? What is the effect of solar absorptivity of the outer surface of a wall on the sol-air temperature?

**16-31C** Consider the solar energy absorbed by the walls of a brick house. Will most of this energy absorbed by the wall be transferred to indoors or lost to the outdoors? Why?

**16-32** Determine the outdoor design conditions for Lincoln, Nebraska, for summer for the 2.5 percent level and for winter for the 97.5 percent level.

**16-33** Specify the indoor and outdoor design conditions for a hospital in Wichita, Kansas.

**16-34** The south masonry wall of a house is made of 10-cm-thick red face brick, 10-cm-thick common brick, 19-mm-thick air space, and 13-mm-thick gypsum board, and its overall heat transfer coefficient is 1.6 W/m<sup>2</sup> · °C, which includes the effects of convection on both sides. The house is located at 40°N latitude, and its cooling system is to be sized on the basis of the heat gain at 3 PM solar time on July 21. The interior of the house is to be maintained at 22°C, and the area of the wall is 20 m<sup>2</sup>. If the design ambient air temperature at that time is 35°C, determine (a) the design heat gain through the wall, (b) the fraction of this heat gain due to solar heating, and (c) the fraction of incident solar radiation transferred into the house through the wall.

FIGURE P16-34

**16-35E** The west wall of a shopping center in Pittsburgh, Pennsylvania (40°N latitude), is 150 ft long and 12 ft high. The 2.5 percent summer design temperature of Pittsburgh is 86°F, and the interior of the building is maintained at 72°F. The wall is made of face brick and concrete block with cement mortar in between, reflective air space, and a gypsum wallboard. The overall heat transfer coefficient of the wall is 0.14 Btu/h · ft<sup>2</sup> · °F, which includes the effects of convection on both sides. The cooling system is to be sized on the basis of the heat gain at 16:00 hour (4 PM) solar time in late July. Determine (a) the design heat gain through the wall and (b) the fraction of this heat gain due to solar heating.

**16-36** The roof of a building in Istanbul, Turkey (40°N latitude), is made of a 30-cm-thick horizontal layer of concrete, painted white to minimize solar gain, with a layer of plaster inside. The overall heat transfer coefficient of the roof is 1.8 W/m<sup>2</sup> · °C, which includes the effects of convection on both

the interior and exterior surfaces. The cooling system is to be sized on the basis of the heat gain at 16:00 hour solar time in late July. The interior of the building is to be maintained at 22°C, and the summer design temperature of Istanbul is 30°C. If the exposed surface area of the roof is 150 m<sup>2</sup>, determine (a) the design heat gain through the roof and (b) the fraction of this heat gain due to solar heating.

*Answers:* (a) 4320 W, (b) 50 percent

FIGURE P16-36

### Heat Gain from People, Lights, and Appliances

**16-37C** Is the heat given off by people in a concert hall an important consideration in the sizing of the air-conditioning system for that building or can it be ignored? Explain.

**16-38C** During a lighting retrofitting project, all the incandescent lamps of a building are replaced by high-efficiency fluorescent lamps. Explain how this retrofit will affect the (a) design cooling load, (b) annual energy consumption for cooling, and (c) annual energy consumption for heating for the building.

**16-39C** Give two good reasons why it is usually a good idea to replace incandescent light bulbs by compact fluorescent bulbs that may cost 40 times as much to purchase.

**16-40C** Explain how the motors and appliances in a building affect the (a) design cooling load, (b) annual energy consumption for cooling, and (c) annual energy consumption for heating of the building.

**16-41C** Define motor efficiency, and explain how it affects the design cooling load of a building and the annual energy consumption for cooling.

**16-42C** Consider a hooded range in a kitchen with a powerful fan that exhausts all the air heated and humidified by the range. Does the heat generated by this range still need to be considered in the determination of the cooling load of the kitchen or can it just be ignored since all the heated air is exhausted?

**16-43** Consider a 3-kW hooded electric open burner in an area where the unit costs of electricity and natural gas are \$0.09/kWh and \$1.10/therm, respectively. The efficiency of

open burners can be taken to be 73 percent for electric burners and 38 percent for gas burners. Determine the amount of the electrical energy used directly for cooking, the cost of energy per "utilized" kWh, and the contribution of this burner to the design cooling load. Repeat the calculations for the gas burner.

FIGURE P16-43

**16-44** An exercise room has eight weight-lifting machines that have no motors and four treadmills each equipped with a 2.5-hp motor. The motors operate at an average load factor of 0.7, at which their efficiency is 0.77. During peak evening hours, all 12 pieces of exercising equipment are used continuously, and there are also two people doing light exercises while waiting in line for one piece of the equipment. Determine the rate of heat gain of the exercise room from people and the equipment at peak load conditions. How much of this heat gain is in the latent form?

**16-45** A 75-hp motor with an efficiency of 91.0 percent is worn out and is replaced by a high-efficiency motor having an efficiency of 95.4 percent. Determine the reduction in the rate of internal heat gain due to higher efficiency under full-load conditions. *Answer: 2836 W*

**16-46** The efficiencies of commercial hot plates are 48 and 23 percent for electric and gas models, respectively. For the same amount of "utilized" energy, determine the ratio of internal heat generated by gas hot plates to that by electric ones.

**16-47** Consider a classroom for 40 students and one instructor. Lighting is provided by 18 fluorescent light bulbs, 40 W each, and the ballasts consume an additional 10 percent. Determine the rate of internal heat generation in this classroom when it is fully occupied. *Answer: 5507 W*

**16-48** A 60-hp electric car is powered by an electric motor mounted in the engine compartment. If the motor has an average efficiency of 88 percent, determine the rate of heat supply by the motor to the engine compartment at full load.

**16-49** A room is cooled by circulating chilled water through a heat exchanger located in a room. The air is circulated

FIGURE P16-48

through the heat exchanger by a 0.25-hp fan. Typical efficiency of small electric motors driving 0.25-hp equipment is 54 percent. Determine the contribution of the fan-motor assembly to the cooling load of the room. *Answer: 345 W*

**16-50** Consider an office room that is being cooled adequately by a 12,000 Btu/h window air conditioner. Now it is decided to convert this room into a computer room by installing several computers, terminals, and printers with a total rated power of 3.5 kW. The facility has several 4000 Btu/h air conditioners in storage that can be installed to meet the additional cooling requirements. Assuming a usage factor of 0.4 (i.e., only 40 percent of the rated power will be consumed at any given time) and additional occupancy of four people, determine how many of these air conditioners need to be installed in the room.

FIGURE P16-50

**16-51** A restaurant purchases a new 8-kW electric range for its kitchen. Determine the increase in the design cooling load of the kitchen if the range is (a) hooded and (b) unhooded.

*Answers: (a) 4.0 kW, (b) 1.28 kW*

**16-52** A department store expects to have 80 customers and 15 employees at peak times in summer. Determine the contribution of people to the sensible, latent, and total cooling load of the store.

**16-53E** In a movie theater in winter, 500 people are watching a movie. The heat losses through the walls, windows, and the roof are estimated to be 150,000 Btu/h. Determine if the theater needs to be heated or cooled.

## Heat Transfer through the Walls and Roofs

**16-54C** What is the *R*-value of a wall? How does it differ from the unit thermal resistance of the wall? How is it related to the *U*-factor?

**16-55C** What is effective emissivity for a plane-parallel air space? How is it determined? How is radiation heat transfer through the air space determined when the effective emissivity is known?

**16-56C** The unit thermal resistances (*R*-values) of both 40-mm and 90-mm vertical air spaces are given in Table 16-13 to be  $0.22 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ , which implies that more than doubling the thickness of air space in a wall has no effect on heat transfer through the wall. Do you think this is a typing error? Explain.

**16-57C** What is a radiant barrier? What kind of materials are suitable for use as radiant barriers? Is it worthwhile to use radiant barriers in the attics of homes?

**16-58C** Consider a house whose attic space is ventilated effectively so that the air temperature in the attic is the same as the ambient air temperature at all times. Will the roof still have any effect on heat transfer through the ceiling? Explain.

**16-59** Determine the summer *R*-value and the *U*-factor of a wood frame wall that is built around 38-mm  $\times$  140-mm wood studs with a center-to-center distance of 400 mm. The 140-mm-wide cavity between the studs is filled with mineral fiber batt insulation. The inside is finished with 13-mm gypsum wall-board and the outside with 13-mm wood fiberboard and 13-mm  $\times$  200-mm wood bevel lapped siding. The insulated cavity constitutes 80 percent of the heat transmission area, while the studs, headers, plates, and sills constitute 20 percent.

*Answers:  $3.213 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ ,  $0.311 \text{ W/m}^2 \cdot ^\circ\text{C}$*

FIGURE P16-59

**16-60** The 13-mm-thick wood fiberboard sheathing of the wood stud wall in Prob. 16-59 is replaced by a 25-mm-thick rigid foam insulation. Determine the percent increase in the *R*-value of the wall as a result.

**16-61E** Determine the winter *R*-value and the *U*-factor of a masonry cavity wall that is built around 4-in-thick concrete

blocks made of lightweight aggregate. The outside is finished with 4-in face brick with  $\frac{1}{2}$ -in cement mortar between the bricks and concrete blocks. The inside finish consists of  $\frac{1}{2}$ -in gypsum wallboard separated from the concrete block by  $\frac{3}{4}$ -in-thick (1-in  $\times$  3-in nominal) vertical furring whose center-to-center distance is 16 in. Neither side of the  $\frac{3}{4}$ -in-thick air space between the concrete block and the gypsum board is coated with any reflective film. When determining the *R*-value of the air space, the temperature difference across it can be taken to be 30°F with a mean air temperature of 50°F. The air space constitutes 80 percent of the heat transmission area, while the vertical furring and similar structures constitute 20 percent.

FIGURE P16-61E

**16-62** Consider a flat ceiling that is built around 38-mm  $\times$  90-mm wood studs with a center-to-center distance of 400 mm. The lower part of the ceiling is finished with 13-mm gypsum wallboard, while the upper part consists of a wood subfloor ( $R = 0.166 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ ), a 16-mm plywood, a layer of felt ( $R = 0.011 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ ), and linoleum ( $R = 0.009 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ ). Both sides of the ceiling are exposed to still air. The air space constitutes 82 percent of the heat transmission area, while the studs and headers constitute 18 percent. Determine

FIGURE P16-62

the winter *R*-value and the *U*-factor of the ceiling assuming the 90-mm-wide air space between the studs (a) does not have any reflective surface, (b) has a reflective surface with  $\epsilon = 0.05$  on one side, and (c) has reflective surfaces with  $\epsilon = 0.05$  on both sides. Assume a mean temperature of 10°C and a temperature difference of 5.6°C for the air space.

**16-63** Determine the winter *R*-value and the *U*-factor of a masonry cavity wall that consists of 100-mm common bricks, a 90-mm air space, 100-mm concrete blocks made of lightweight aggregate, 20-mm air space, and 13-mm gypsum wallboard separated from the concrete block by 20-mm-thick (1-in.  $\times$  3-in. nominal) vertical furring whose center-to-center distance is 400 mm. Neither side of the two air spaces is coated with any reflective films. When determining the *R*-value of the air spaces, the temperature difference across them can be taken to be 16.7°C with a mean air temperature of 10°C. The air space constitutes 84 percent of the heat transmission area, while the vertical furring and similar structures constitute 16 percent.

*Answers:*  $1.02 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ ,  $0.978 \text{ W/m}^2 \cdot ^\circ\text{C}$

FIGURE P16-63

**16-64** Repeat Prob. 16-63 assuming one side of both air spaces is coated with a reflective film of  $\epsilon = 0.05$ .

**16-65** Determine the winter *R*-value and the *U*-factor of a masonry wall that consists of the following layers: 100-mm face bricks, 100-mm common bricks, 25-mm urethane rigid foam insulation, and 13-mm gypsum wallboard.

*Answers:*  $1.404 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$ ,  $0.712 \text{ W/m}^2 \cdot ^\circ\text{C}$

**16-66** The overall heat transfer coefficient (the *U*-value) of a wall under winter design conditions is  $U = 1.40 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Determine the *U*-value of the wall under summer design conditions.

**16-67** The overall heat transfer coefficient (the *U*-value) of a wall under winter design conditions is  $U = 2.25 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Now a layer of 100-mm face brick is added to the outside, leaving a 20-mm air space between the wall and the bricks. Determine the new *U*-value of the wall. Also, determine the rate of heat transfer through a 3-m-high, 7-m-long section of

the wall after modification when the indoor and outdoor temperatures are 22°C and -5°C, respectively.

**FIGURE P16-67**

**16-68** Determine the summer and winter  $R$ -values, in  $\text{m}^2 \cdot ^\circ\text{C}/\text{W}$ , of a masonry wall that consists of 100-mm face bricks, 13-mm of cement mortar, 100-mm lightweight concrete block, 40-mm air space and 20-mm plasterboard.

*Answers: 0.809 and 0.795  $\text{m}^2 \cdot ^\circ\text{C}/\text{W}$*

**16-69E** The overall heat transfer coefficient of a wall is determined to be  $U = 0.075 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$  under the conditions of still air inside and winds of 7.5 mph outside. What will the  $U$ -factor be when the wind velocity outside is doubled?

*Answer: 0.0754  $\text{Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$*

**16-70** Two homes are identical, except that the walls of one house consist of 200-mm lightweight concrete blocks, 20-mm air space, and 20-mm plasterboard, while the walls of the other house involve the standard  $R=2.4 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$  frame wall construction. Which house do you think is more energy efficient?

**16-71** Determine the  $R$ -value of a ceiling that consists of a layer of 19-mm acoustical tiles whose top surface is covered with a highly reflective aluminum foil for winter conditions. Assume still air below and above the tiles.

**FIGURE P16-71**

### Heat Loss from Basement Walls and Floors

**16-72C** What is the mechanism of heat transfer from the basement walls and floors to the ground? What is the effect of the composition and moisture content of the soil on this heat transfer?

**16-73C** Consider a basement wall that is completely below grade. Will heat loss through the upper half of the wall be greater or smaller than the heat loss through the lower half? Why?

**16-74C** Does a building lose more heat to the ground through the floor of a basement or through the below-grade section of the basement wall per unit surface area? Explain.

**16-75C** Is heat transfer from a floor on grade at ground level proportional to the surface area or perimeter of the floor?

**16-76C** Crawl spaces are often vented to prevent moisture accumulation and associated problems. How does venting the crawl space affect heat loss through the floor?

**16-77C** Consider a house with an unheated crawl space in winter. If the vents of the crawl space are tightly closed, do you think the cold water pipes should still be insulated to avoid the danger of freezing?

**16-78** Consider a basement in Anchorage, Alaska, where the mean winter temperature is  $-5.0^\circ\text{C}$ . The basement floor is 7 m wide and 10 m long, and the basement floor is 1.8 m below the ground level. The top 0.9-m section of the wall below the grade is insulated with  $R=2.20 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$  insulation. Assuming the interior temperature of the basement to be  $20^\circ\text{C}$ , determine the peak heat loss from the basement to the ground through its walls and floor.

**FIGURE P16-78**

**16-79** Consider a crawl space that is 10 m wide, 18 m long, and 0.80 m high whose vent is kept open. The interior of the house is maintained at  $21^\circ\text{C}$  and the ambient temperature is  $2.5^\circ\text{C}$ . Determine the rate of heat loss through the floor of the house to the crawl space for the cases of (a) insulated and (b) uninsulated floor. *Answers: (a) 1439 W, (b) 4729 W*

**16-80** The dimensions of a house with basement in Boise, Idaho, are  $18 \text{ m} \times 12 \text{ m}$ . The 1.8-m-high portion of the basement wall is below the ground level and is not insulated. If the basement is maintained at  $18^\circ\text{C}$ , determine the rate of design heat loss from the basement through its walls and floor.

**16-81E** The dimensions of a house with basement in Boise, Idaho, are  $60 \text{ ft} \times 32 \text{ ft}$ . The 6-ft-high portion of the basement wall is below the ground level and is not insulated. If the basement is maintained at  $68^\circ\text{F}$ , determine the rate of design heat loss from the basement through its walls and floor.

FIGURE P16-81E

**16-82** A house in Baltimore, Maryland, has a concrete slab floor that sits directly on the ground at grade level. The house is 18 m long and 15 m wide, and the weather in Baltimore can be considered to be moderate. The walls of the house are made of 20-cm block wall with brick and are insulated from the edge to the footer with  $R=0.95 \text{ m}^2 \cdot ^\circ\text{C}/\text{W}$  insulation. If the house is maintained at  $22^\circ\text{C}$ , determine the heat loss from the floor at winter design conditions. *Answer: 1873 W.*

**16-83** Repeat Prob. 16-82 assuming the below-grade section of the wall is not insulated.

**16-84** The crawl space of a house is 12 m wide, 20 m long, and 0.70 m high. The vents of the crawl space are kept closed, but air still infiltrates at a rate of 1.2 ACH. The indoor and outdoor design temperatures are  $22^\circ\text{C}$  and  $-5^\circ\text{C}$ , respectively, and the deep-down ground temperature is  $10^\circ\text{C}$ . Determine the heat loss from the house to the crawl space, and the crawl space temperature assuming the walls, floor, and ceiling of the crawl space are (a) insulated and (b) uninsulated.

*Answers: (a)  $1.3^\circ\text{C}$ , (b)  $11.7^\circ\text{C}$*

FIGURE P16-84

**16-85** Repeat Prob. 16-84 assuming the vents are tightly sealed for winter and thus air infiltrations is negligible.

### Heat Transfer through Windows

**16-86C** Why are the windows considered in three regions when analyzing heat transfer through them? Name those regions and explain how the overall  $U$ -value of the window is determined when the heat transfer coefficients for all three regions are known.

**16-87C** Consider three similar double-pane windows with air gap widths of 5, 10, and 20 mm. For which case will the heat transfer through the window will be a minimum?

**16-88C** In an ordinary double-pane window, about half of the heat transfer is by radiation. Describe a practical way of reducing the radiation component of heat transfer.

**16-89C** Consider a double-pane window whose air space width is 20 mm. Now a thin polyester film is used to divide the air space into two 10-mm-wide layers. How will the film affect (a) convection and (b) radiation heat transfer through the window?

**16-90C** Consider a double-pane window whose air space is flashed and filled with argon gas. How will replacing the air in the gap by argon affect (a) convection and (b) radiation heat transfer through the window?

**16-91C** Is the heat transfer rate through the glazing of a double-pane window higher at the center or edge section of the glass area? Explain.

**16-92C** How do the relative magnitudes of  $U$ -factors of windows with aluminum, wood, and vinyl frames compare? Assume the windows are identical except for the frames.

**16-93** Determine the  $U$ -factor for the center-of-glass section of a double-pane window with a 13-mm air space for winter design conditions. The glazings are made of clear glass having an emissivity of 0.84. Take the average air space temperature at design conditions to be  $10^\circ\text{C}$  and the temperature difference across the air space to be  $15^\circ\text{C}$ .

**16-94** A double-door wood-framed window with glass glazing and metal spacers is being considered for an opening that is

FIGURE P16-94

1.2 m high and 1.8 m wide in the wall of a house maintained at 20°C. Determine the rate of heat loss through the window and the inner surface temperature of the window glass facing the room when the outdoor air temperature is -8°C if the window is selected to be (a) 3-mm single glazing, (b) double glazing with an air space of 13 mm, and (c) low-e-coated triple glazing with an air space of 13 mm.

**16-95** Determine the overall  $U$ -factor for a double-door-type, wood-framed, double-pane window with 13-mm air space and metal spacers, and compare your result to the value listed in Table 16-19. The overall dimensions of the window are 2.00 m  $\times$  2.40 m, and the dimensions of each glazing are 1.92 m  $\times$  1.14 m.

**16-96** Consider a house in Atlanta, Georgia, that is maintained at 22°C and has a total of 14 m<sup>2</sup> of window area. The windows are double-door-type with wood frames and metal spacers. The glazing consists of two layers of glass with 12.7 mm of air space with one of the inner surfaces coated with reflective film. The winter average temperature of Atlanta is 11.3°C. Determine the average rate of heat loss through the windows in winter. *Answer: 319 W*

**16-97E** Consider an ordinary house with  $R$ -13 walls (walls that have an  $R$ -value of 13 h  $\cdot$  ft<sup>2</sup>  $\cdot$  °F/Btu). Compare this to the  $R$ -value of the common double-door windows that are double pane with  $\frac{1}{4}$  in of air space and have aluminum frames. If the windows occupy only 20 percent of the wall area, determine if more heat is lost through the windows or through the remaining 80 percent of the wall area. Disregard infiltration losses.

**16-98** The overall  $U$ -factor of a fixed wood-framed window with double glazing is given by the manufacturer to be  $U = 2.76 \text{ W/m}^2 \cdot ^\circ\text{C}$  under the conditions of still air inside and winds of 12 km/h outside. What will the  $U$ -factor be when the wind velocity outside is doubled? *Answer: 2.88 \text{ W/m}^2 \cdot ^\circ\text{C}*

**16-99** The owner of an older house in Wichita, Kansas, is considering replacing the existing double-door type wood-framed, single-pane windows with vinyl-framed, double-pane windows with an air space of 6.4 mm. The new windows are of

FIGURE P16-99

double-door type with metal spacers. The house is maintained at 22°C at all times, but heating is needed only when the outdoor temperature drops below 18°C because of the internal heat gain from people, lights, appliances, and the sun. The average winter temperature of Wichita is 7.1°C, and the house is heated by electric resistance heaters. If the unit cost of electricity is \$0.085/kWh and the total window area of the house is 17 m<sup>2</sup>, determine how much money the new windows will save the home owner per month in winter.

### Solar Heat Gain through Windows

**16-100C** What fraction of the solar energy is in the visible range (a) outside the earth's atmosphere and (b) at sea level on earth? Answer the same question for infrared radiation.

**16-101C** Describe the solar radiation properties of a window that is ideally suited for minimizing the air-conditioning load.

**16-102C** Define the SHGC (solar heat gain coefficient), and explain how it differs from the SC (shading coefficient). What are the values of the SHGC and SC of a single-pane, clear-glass window?

**16-103C** What does the SC (shading coefficient) of a device represent? How do the SCs of clear glass and heat-absorbing glass compare?

**16-104C** What is a shading device? Is an internal or external shading device more effective in reducing the solar heat gain through a window? How does the color of the surface of a shading device facing outside affect the solar heat gain?

**16-105C** What is the effect of a low-e coating on the inner surface of a window glass on the (a) heat loss in winter and (b) heat gain in summer through the window?

**16-106C** What is the effect of a reflective coating on the outer surface of a window glass on the (a) heat loss in winter and (b) heat gain in summer through the window?

**16-107** A manufacturing facility located at 32°N latitude has a glazing area of 60 m<sup>2</sup> facing west that consists of double-pane windows made of clear glass (SHGC = 0.766). To reduce the solar heat gain in summer, a reflective film that will reduce the SHGC to 0.35 is considered. The cooling season consists of June, July, August, and September, and the heating season, October through April. The average daily solar heat fluxes incident on the west side at this latitude are 2.35, 3.03, 3.62, 4.00, 4.20, 4.24, 4.16, 3.93, 3.48, 2.94, 2.33, and 2.07 kWh/day  $\cdot$  m<sup>2</sup> for January through December, respectively. Also, the unit costs of electricity and natural gas are \$0.09/kWh and \$0.45/therm, respectively. If the coefficient of performance of the cooling system is 3.2 and the efficiency of the furnace is 0.90, determine the net annual cost savings due to installing reflective coating on the windows. Also, determine the simple payback period if the installation cost of reflective film is \$20/m<sup>2</sup>. *Answers: \$53, 23 years*

**16-108** A house located in Boulder, Colorado ( $40^{\circ}\text{N}$  latitude), has ordinary double-pane windows with 6-mm-thick glasses and the total window areas are 8, 6, 6, and 4  $\text{m}^2$  on the south, west, east, and north walls. Determine the total solar heat gain of the house at 9:00, 12:00, and 15:00 solar time in July. Also, determine the total amount of solar heat gain per day for an average day in January.

**16-109** Repeat Prob. 16-108 for double-pane windows that are gray-tinted.

**16-110** Consider a building in New York ( $40^{\circ}\text{N}$  latitude) that has 200  $\text{m}^2$  of window area on its south wall. The windows are double-pane, heat-absorbing type, and are equipped with light-colored venetian blinds with a shading coefficient of  $SC = 0.30$ . Determine the total solar heat gain of the building through the south windows at solar noon in April. What would your answer be if there were no blinds at the windows?

FIGURE P16-110

**16-111** A typical winter day in Reno, Nevada ( $39^{\circ}\text{N}$  latitude), is cold but sunny, and thus the solar heat gain through the windows can be more than the heat loss through them during daytime. Consider a house with double-door-type windows that are double paned with 3-mm-thick glasses and 6.4 mm of air space and have aluminum frames and spacers. The house is

FIGURE P16-111

maintained at  $22^{\circ}\text{C}$  at all times. Determine if the house is losing more or less heat than it is gaining from the sun through an east window on a typical day in January for a 24-h period if the average outdoor temperature is  $10^{\circ}\text{C}$ . *Answer: less*

**16-112** Repeat Prob. 16-111 for a south window.

**16-113E** Determine the rate of net heat gain (or loss) through a 9-ft-high, 15-ft-wide, fixed  $\frac{1}{8}$ -in single-glass window with aluminum frames on the west wall at 3 PM solar time during a typical day in January at a location near  $40^{\circ}\text{N}$  latitude when the indoor and outdoor temperatures are  $70^{\circ}\text{F}$  and  $20^{\circ}\text{F}$ , respectively. *Answer: 12,890 Btu/h gain*

**16-114** Consider a building located near  $40^{\circ}\text{N}$  latitude that has equal window areas on all four sides. The building owner is considering coating the south-facing windows with reflective film to reduce the solar heat gain and thus the cooling load. But someone suggests that the owner will reduce the cooling load even more if she coats the west-facing windows instead. What do you think?

### Infiltration Heat Load and Weatherizing

**16-115C** What is infiltration? How does it differ from ventilation? How does infiltration affect the heating load in winter and the cooling load in summer? Explain.

**16-116C** Describe briefly two ways of measuring the infiltration rate of a building. Also, explain how the design infiltration rate differs from the seasonal average infiltration rate, and which is used when sizing a heating system.

**16-117C** How is the infiltration unit ACH (air changes per hour) defined? Why should too low and too high values of ACH be avoided?

**16-118C** How can the energy of the air vented out from the kitchens and bathrooms be saved?

**16-119C** Is latent heat load of infiltration necessarily zero when the relative humidity of the hot outside air in summer is the same as that of inside air? Explain.

**16-120C** Is latent heat load of infiltration necessarily zero when the humidity ratio (absolute humidity) of the hot outside air in summer is the same as that of inside air? Explain.

**16-121C** What are some practical ways of preventing infiltration in homes?

**16-122C** It is claimed that the infiltration rate and infiltration losses can be reduced by using radiant panel heaters since the air temperature can be lowered without sacrificing comfort. It is also claimed that radiant panels will increase the heat losses through the wall and the roof by conduction as a result of increased surface temperature. What do you think of these claims?

**16-123E** The average atmospheric pressure in Spokane, Washington (elevation = 2350 ft), is 13.5 psia, and the average winter temperature is  $36.5^{\circ}\text{F}$ . The pressurization test of a 9-ft-high, 3000-ft<sup>2</sup> older home revealed that the seasonal

average infiltration rate of the house is 2.2 ACH. It is suggested that the infiltration rate of the house can be reduced by half to 1.1 ACH by winterizing the doors and the windows. If the house is heated by natural gas whose unit cost is \$1.20/therm and the heating season can be taken to be six months, determine how much the home owner will save from the heating costs per year by this winterization project. Assume the house is maintained at 72°F at all times, and the efficiency of the furnace is 0.65. Also, assume the latent heat load during the heating season to be negligible. *Answer: \$1480*

**FIGURE P16-123E**

**16-124** Consider two identical buildings, one in Los Angeles, California, where the atmospheric pressure is 101 kPa and the other in Denver, Colorado, where the atmospheric pressure is 83 kPa. Both buildings are maintained at 21°C, and the infiltration rate for both buildings is 1.2 ACH on a day when the outdoor temperature at both locations is 10°C. Disregarding latent heat, determine the ratio of the heat losses by infiltration at the two cities.

**16-125** Determine the rate of sensible heat loss from a building due to infiltration if outdoor air at  $-10^{\circ}\text{C}$  and 90 kPa enters the building at a rate of 35 L/s when the indoors is maintained at 22°C. *Answer: 1335 W*

**16-126** The ventilating fan of the bathroom of a building has a volume flow rate of 30 L/s and runs continuously. The building is located in San Francisco, California, where the average

**FIGURE P16-126**

winter temperature is  $12.2^{\circ}\text{C}$ , and is maintained at  $22^{\circ}\text{C}$  at all times. The building is heated by electricity whose unit cost is \$0.09/kWh. Determine the amount and cost of the heat “vented out” per month in winter. *Answers: 256 kWh, \$23.00*

**16-127** For an infiltration rate of 1.2 ACH, determine the sensible, latent, and total infiltration heat load, in kW, of a building at sea level, that is 20 m long, 13 m wide, and 3 m high when the outdoor air is at  $32^{\circ}\text{C}$  and 50 percent relative humidity. The building is maintained at  $24^{\circ}\text{C}$  and 50 percent relative humidity at all times.

### Annual Energy Consumption

**16-128C** Is it possible for a building in a city to have a higher peak heating load but a lower energy consumption for heating in winter than an identical building in another city? Explain.

**16-129C** Can we determine the annual energy consumption of a building for heating by simply multiplying the design heating load of the building by the number of hours in the heating season? Explain.

**16-130C** Considerable energy can be saved by lowering the thermostat setting in winter and raising it in summer by a few degrees. As the manager of a large commercial building, would you implement this measure to save energy and cut costs?

**16-131C** What is the number of heating degree-days for a winter day during which the average outdoor temperature was  $10^{\circ}\text{C}$ , and it never went above  $18^{\circ}\text{C}$ ?

**16-132C** What is the number of heating degree-days for a winter month during which the average outdoor temperature was  $12^{\circ}\text{C}$ , and it never went above  $18^{\circ}\text{C}$ ?

**16-133C** Someone claims that the  $^{\circ}\text{C}$ -days for a location can be converted to  $^{\circ}\text{F}$ -days by simply multiplying  $^{\circ}\text{C}$ -days by 1.8. But another person insists that 32 must be added to the result because of the formula  $T(^{\circ}\text{F}) = 1.8T(^{\circ}\text{C}) + 32$ . Which person do you think is right?

**16-134C** What is balance-point temperature? Why is the balance-point temperature used in the determination of degree-days instead of the actual thermostat setting of a building?

**16-135C** Under what conditions is it proper to use the degree-day method to determine the annual energy consumption of a building? What is the number of heating degree-days for a day during which the average outdoor temperature was  $10^{\circ}\text{C}$ , and it never went above  $18^{\circ}\text{C}$ ?

**16-136** Suppose you have moved to Syracuse, New York, in August, and your roommate, who is short of cash, offered to pay the heating bills during the upcoming year (starting January 1) if you pay the heating bills for the current calendar year until December 31. Is this a good offer for you?

**16-137E** Using indoor and outdoor winter design temperatures of  $70^{\circ}\text{F}$  and  $-10^{\circ}\text{F}$ , respectively, the design heat load of a  $2500\text{-ft}^2$  house in Billings, Montana, is determined to be

83,000 Btu/h. The house is to be heated by natural gas that will be burned in a 95 percent efficient, high-efficiency furnace. If the unit cost of natural gas is \$1.10/therm, estimate the annual gas consumption of this house and its cost.

*Answers: 1848 therms, \$2033*

**16-138** Consider a building whose annual air-conditioning load is estimated to be 120,000 kWh in an area where the unit cost of electricity is \$0.10/kWh. Two air conditioners are considered for the building. Air conditioner A has a seasonal average COP of 3.2 and costs \$5500 to purchase and install. Air conditioner B has a seasonal average COP of 5.0 and costs \$7000 to purchase and install. If all else are equal, determine which air conditioner is a better buy.

**FIGURE P16-138**

**16-139** The lighting requirements of an industrial facility are being met by 700 40-W standard fluorescent lamps. The lamps are close to completing their service life, and are to be replaced by their 34-W high-efficiency counterparts that operate on the existing standard ballasts. The standard and high-efficiency fluorescent lamps can be purchased at quantity at a cost of \$1.77 and \$2.26 each, respectively. The facility operates 2800 hours a year and all of the lamps are kept on during operating hours. Taking the unit cost of electricity to be \$0.08/kWh and the ballast factor to be 1.1, determine how much energy and money will be saved a year as a result of switching to the high-efficiency fluorescent lamps. Also, determine the simple payback period. *Answers: 12,936 kWh, \$1035, 4 months*

**16-140** The lighting needs of a storage room are being met by six fluorescent light fixtures, each fixture containing four

**FIGURE P16-140**

lamps rated at 60 W each. All the lamps are on during operating hours of the facility, which are 6 AM to 6 PM 365 days a year. The storage room is actually used for an average of three hours a day. If the price of the electricity is \$0.08/kWh, determine the amount of energy and money that will be saved as a result of installing a motion sensor. Also, determine the simple payback period if the purchase price of the sensor is \$32 and it takes 1 hour to install it at a cost of \$40.

**16-141** An office building in the Reno, Nevada area ( $3346^{\circ}\text{C-days}$ ) is maintained at a temperature of  $20^{\circ}\text{C}$  at all times during the heating season, which is taken to be November 1 through April 30. The work hours of the office are 8 AM to 6 PM Monday through Friday, and there is no air-conditioning. An examination of the heating bills of the facility for the previous year reveals that the facility used 3530 therms of natural gas at an average price of \$1.15/therm, and thus paid \$4060 for heating. There are five thermostats in the facility to control the temperatures of various sections. The existing manual thermostats are to be replaced by programmable ones to reduce the heating costs. The new thermostats are to lower the temperature setting shortly before closing hour and raise it shortly before the opening hour. The thermostats will be set to  $7.2^{\circ}\text{C}$  during the off-work hours and to  $20^{\circ}\text{C}$  during the work hours. Determine the annual energy and cost savings as a result of installing five programmable thermostats. Also, determine the simple payback period if the installed cost of each programmable thermostat is \$325.

**16-142** A 75-hp motor with an efficiency of 91.0 percent is worn out and is to be replaced with a high-efficiency motor having an efficiency of 95.4 percent. The machine operates 4368 hours a year at a load factor of 0.75. Taking the cost of electricity to be \$0.08/kWh, determine the amount of energy and money saved as a result of installing the high-efficiency motor instead of the standard one. Also, determine the simple payback period if the purchase prices of the standard and high-efficiency motors are \$5449 and \$5520, respectively.

*Answers: 9290 kWh, \$743, 1.1 months*

**16-143E** The steam requirements of a manufacturing facility are being met by a boiler of 3.8 million Btu/h input. The combustion efficiency of the boiler is measured to be 0.7 by a handheld flue gas analyzer. After tuning up the boiler, the combustion efficiency rises to 0.8. The boiler operates 1500 hours a year intermittently. Taking the unit cost of energy to be \$4.35 per million Btu, determine the annual energy and cost savings as a result of tuning up the boiler.

**16-144** The space heating of a facility is accomplished by natural gas heaters that are 80 percent efficient. The compressed air needs of the facility are met by a large liquid-cooled compressor. The coolant of the compressor is cooled by air in a liquid-to-air heat exchanger whose air flow section is 1.0 m high and 1.0 m wide. During typical operation, the air is heated from  $20^{\circ}\text{C}$  to  $52^{\circ}\text{C}$  as it flows through the heat exchanger. The average velocity of air on the inlet side is measured to be 3 m/s.

The compressor operates 20 hours a day and 5 days a week throughout the year. Taking the heating season to be 6 months (26 weeks) and the cost of the natural gas to be \$1.00/therm (1 therm = 105,500 kJ), determine how much money will be saved by diverting the compressor waste heat into the facility during the heating season.

**FIGURE P16-144**

**16-145** Consider a family in Atlanta, Georgia, whose average heating bill has been \$600 a year. The family now moves to an identical house in Denver, Colorado, where the fuel and electricity prices are also the same. How much do you expect the annual heating bill of this family to be in their new home?

**16-146E** The design heating load of a new house in Cleveland, Ohio, is calculated to be 65,000 Btu/h for an indoor temperature of 72°F. If the house is to be heated by a natural gas furnace that is 90 percent efficient, predict the annual natural gas consumption of this house, in therms. Assume the entire house is maintained at indoor design conditions at all times.

**16-147** For inside and outside design temperatures of 22°C and -12°C, respectively, a home located in Boise, Idaho, has a design heating load of 38 kW. The house is heated by electric resistance heaters, and the cost of electricity is \$0.06/kWh. Determine how much money the home owner will save if she lowers the thermostat from 22°C to 14°C from 11 PM to 7 AM every night in December.

### Review Problems

**16-148** Consider a home owner who is replacing his 20-year-old natural gas furnace that has an efficiency of 60 percent. The home owner is considering a conventional furnace that has an efficiency of 82 percent and costs \$1600, and a high-efficiency furnace that has an efficiency of 95 percent and costs \$2700. The home owner would like to buy the high-efficiency furnace

if the savings from the natural gas pay for the additional cost in less than eight years. If the home owner is presently paying \$1100 a year for heating, determine if he should buy the conventional or high-efficiency model.

**16-149** The convection heat transfer coefficient for a clothed person seated in air moving at a velocity of 0.2 to 4 m/s is given by  $h = 8.3V^{0.6}$  where  $V$  is in m/s and  $h$  is in  $\text{W/m}^2 \cdot ^\circ\text{C}$ . The convection coefficient at lower velocities is  $3.1 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Plot the convection coefficient against the air velocity, and compare the average convection coefficient to the average radiation coefficient of about  $5 \text{ W/m}^2 \cdot ^\circ\text{C}$ .

**16-150** Workers in a casting facility are surrounded with hot surfaces, with an average temperature of 40°C. The activity level of the workers corresponds to a heat generation rate of 300 W, half of which is latent. If the air temperature is 22°C, determine the velocity of air needed to provide comfort for the workers. Take the average exposed surface area and temperature of the workers to be  $1.8 \text{ m}^2$  and 30°C, respectively.

**16-151** Replacing incandescent lights by energy-efficient fluorescent lights can reduce the lighting energy consumption to one-fourth of what it was before. The energy consumed by the lamps is eventually converted to heat, and thus switching to energy-efficient lighting also reduces the cooling load in summer but increases the heating load in winter. Consider a building that is heated by a natural gas furnace having an efficiency of 80 percent and cooled by an air conditioner with a COP of 3.5. If electricity costs \$0.08/kWh and natural gas costs \$1.25/therm, and the annual heating load of the building is roughly equal to the annual cooling load, determine if efficient lighting will increase or decrease the total heating and cooling cost of the building. *Answer: Decrease*

**16-152** A wall of a farmhouse is made of 200-mm common brick. Determine the rate of heat transfer through a  $20-\text{m}^2$  section of the wall when the indoor and outdoor temperatures are 20°C and -5°C, respectively, and the wall is exposed to 24 km/h winds. *Answer: 1280 W*

**16-153E** Determine the  $R$ -value and the overall heat transfer coefficient (the  $U$ -factor) of a 45° pitched roof that is built around nominal 2-in  $\times$  4-in wood studs with a center-to-center distance of 24 in. The 3.5-in-wide air space between the studs has a reflective surface and its effective emissivity is 0.05. The lower part of the roof is finished with  $\frac{1}{2}$ -in gypsum wallboard and the upper part with  $\frac{5}{8}$ -in plywood, building

**FIGURE P16-153E**

paper, and asphalt shingle roofing. The air space constitutes 80 percent of the heat transmission area, while the studs and headers constitute 20 percent.

**16-154** The winter design heat load of a planned house is determined to be 32 kW. The original design involved aluminum-frame single-pane windows with a  $U$ -factor of  $7.16 \text{ W/m}^2 \cdot ^\circ\text{C}$ , and heat losses through the windows accounted for 26 percent of the total. Alarmed by the projected high cost of annual energy usage, the owner decided to switch to vinyl-frame double-pane windows whose  $U$ -factor is  $2.74 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Determine the reduction in the heat load of the house as a result of switching to double-pane windows.

**16-155** The attic of a  $150\text{-m}^2$  house in Thessaloniki, Greece ( $40^\circ\text{N}$  latitude), is not vented in summer. The  $R$ -values of the roof and the ceiling are  $1.4 \text{ m}^2 \cdot ^\circ\text{C/W}$  and  $0.50 \text{ m}^2 \cdot ^\circ\text{C/W}$ , respectively, and the ratio of the roof area to ceiling area is 1.30. The indoors are maintained at  $23^\circ\text{C}$  at all times. Determine the rate of heat gain through the roof in late July at 16:00 (4 PM) solar time if the outdoor temperature is  $32^\circ\text{C}$ , assuming the roof is (a) light colored and (b) dark colored.

Answers: (a) 1700 W, (b) 2900 W

FIGURE P16-155

**16-156** The dimensions of a house in Norfolk, Virginia, are  $19 \text{ m} \times 10 \text{ m}$ , and the house has a basement. The  $1.8\text{-m}$ -high portion of the basement wall is below the ground level, and the top  $0.6\text{-m}$  section of the wall below the grade is insulated with  $R=0.73 \text{ m}^2 \cdot ^\circ\text{C/W}$  insulation. If the basement is maintained at  $17^\circ\text{C}$ , determine the rate of design heat loss from the basement through its walls and floor.

**16-157** A house in Anchorage, Alaska, has a concrete slab floor that sits directly on the ground at grade level. The house is  $20 \text{ m}$  long and  $15 \text{ m}$  wide, and the weather in Alaska is very severe. The walls of the house are made of  $20\text{-cm}$  block wall with brick and are insulated from the edge to the footer with  $R=0.95 \text{ m}^2 \cdot ^\circ\text{C/W}$  insulation. If the house is maintained at

$22^\circ\text{C}$ , determine the heat loss from the floor at winter design conditions.

FIGURE P16-157

**16-158** Repeat Prob. 16-157 assuming the below-grade section of the wall is not insulated. Answer: 3931 W

**16-159** A university campus has 200 classrooms and 400 faculty offices. The classrooms are equipped with 12 fluorescent light bulbs, each consuming 110 W, including the electricity used by the ballasts. The faculty offices, on average, have half as many light bulbs. The campus is open 240 days a year. The classrooms and faculty offices are not occupied an average of 4 hours a day, but the lights are kept on. If the unit cost of electricity is \$ $0.075/\text{kWh}$ , determine how much energy and money the campus will save a year if the lights in the classrooms and faculty offices are turned off during unoccupied periods.

**16-160E** For an infiltration rate of  $0.8 \text{ ACH}$ , determine the sensible, latent, and total infiltration heat load, in  $\text{Btu/h}$ , of a building at sea level that is  $60 \text{ ft}$  long,  $50 \text{ ft}$  wide, and  $9 \text{ ft}$  high when the outdoor air is at  $82^\circ\text{F}$  and 40 percent relative humidity. The building is maintained at  $74^\circ\text{F}$  and 40 percent relative humidity at all times.

**16-161** It is believed that January is the coldest month in the Northern hemisphere. On the basis of Table 16-5, determine if this is true for all locations.

**16-162** The December space heating bill of a fully occupied house in Louisville, Kentucky, that was kept at  $22^\circ\text{C}$  at all times was \$110. How much do you think the December space heating bill of this house would be if it still were kept at  $22^\circ\text{C}$  but there were no people living in the house, no lights were on, no appliances were operating, and there was no solar heat gain?

**16-163** For an indoor temperature of  $22^\circ\text{C}$ , the design heating load of a residential building in Charlotte, North Carolina, is determined to be  $28 \text{ kW}$ . The house is to be heated by natural gas, which costs \$ $1.20/\text{therm}$ . The efficiency of the gas furnace is 80 percent. Determine (a) the heat loss coefficient of the building, in  $\text{kW}/^\circ\text{C}$ , and (b) the annual energy usage for heating and its cost. Answers: (a)  $1 \text{ kW}/^\circ\text{C}$ , (b) 1815 therms, \$2178

### Computer, Design, and Essay Problems

**16-164** On average, superinsulated homes use just 15 percent of the fuel required to heat the same size conventional home built before the energy crises in the 1970s. Write an essay on superinsulated homes, and identify the features that make them so energy efficient as well as the problems associated with them. Do you think superinsulated homes will be economically attractive in your area?

**16-165** Conduct the following experiment to determine the heat loss coefficient of your house or apartment in  $\text{W}/\text{C}$  or  $\text{Btu}/\text{h} \cdot ^\circ\text{F}$ . First make sure that the conditions in the house are steady and the house is at the set temperature of the thermostat. Use an outdoor thermometer to monitor outdoor temperature. One evening, using a watch or timer, determine how long the heater was on during a 3-h period and the average outdoor temperature during that period. Then using the heat output rating of your heater, determine the amount of heat supplied. Also, estimate the amount of heat generation in the house during that period by noting the number of people, the total wattage of lights that were on, and the heat generated by the appliances and equipment. Using that information, calculate the average rate of heat loss from the house and the heat loss coefficient.

**16-166** Numerous professional software packages are available in the market for performing heat transfer analysis of buildings, and they are advertised in professional magazines such as the *ASHRAE Journal* magazine published by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE). Your company decides to purchase such a software package and asks you to prepare a report on the available packages, their costs, capabilities, ease of use, compatibility with the available hardware and other software, as well as the reputation of the software company, their history, financial health, customer support, training, and future prospects, among other things. After a preliminary investigation, select the top three packages and prepare a full report on them. Also, find out if there are any free software packages available that can be used for the same purpose.

**16-167** A 1982 U.S. Department of Energy article (FS 204) states that a leak of one drip of hot water per second can cost \$1.00 per month. Making reasonable assumptions about the drop size and the unit cost of energy, determine if this claim is reasonable.

**16-168** Obtain the following weather data for the city in which you live: the elevation, the atmospheric pressure, the number of heating and cooling degree-days, the 97.5 percent

level winter and summer design temperatures, the average annual and winter temperatures, the record high and low temperatures and when they occurred, and the unit cost of natural gas and electricity for residential buildings.

**16-169** Your neighbor lives in a 2500-ft<sup>2</sup> (about 250-m<sup>2</sup>) older house heated by natural gas. The current gas heater was installed in the early 1970s and has an efficiency (called the annual fuel utilization efficiency, or AFUE), rating of 65 percent. It is time to replace the furnace, and the neighbor is trying to decide between a conventional furnace that has an efficiency of 80 percent and costs \$1500 and a high-efficiency furnace that has an efficiency of 95 percent and costs \$2500. Your neighbor offered to pay you \$100 if you help him make the right decision. Considering the weather data, typical heating loads, and the price of natural gas in your area, make a recommendation to your neighbor based on a convincing economic analysis.

**16-170** The decision of whether to invest in an energy-saving measure is made on the basis of the length of time for it to pay for itself in projected energy (and thus cost) savings. The easiest way to reach a decision is to calculate the simple payback period by simply dividing the installed cost of the measure by the annual cost savings and comparing it to the lifetime of the installation. This approach is adequate for short payback periods (less than five years) in stable economies with low interest rates (under 10 percent) since the error involved is no larger than the uncertainties. However, if the payback period is long, it may be necessary to consider the *interest rate* if the money is to be borrowed, or the *rate of return* if the money is invested elsewhere instead of the energy conservation measure. For example, a simple payback period of five years corresponds to 5.0, 6.12, 6.64, 7.27, 8.09, 9.919, 10.84, and 13.91 for an interest rate (or return on investment) of 0, 6, 8, 10, 12, 14, 16, and 18 percent, respectively. Finding out the proper relations from engineering economics books, determine the payback periods for the interest rates given above corresponding to simple payback periods of 1 through 10 years.

**16-171** A radiant heater mounted on the ceiling is to be designed to assist the heating of a 250-m<sup>2</sup> residence in Las Vegas, Nevada, whose walls are 4 m high. The indoor air is to be maintained at 15°C at all times, and the radiant heater is to provide thermal comfort for the sedentary occupants in light clothing. The system considered consists of hot water pipes buried in the ceiling and occupies the entire ceiling. Recommend a temperature for the ceiling, and estimate the energy consumption of the radiant heater. Does the radiant heater appear to save enough energy to justify its cost?

# REFRIGERATION AND FREEZING OF FOODS

Refrigeration and freezing of perishable food products is an important and fascinating application area of heat transfer and thermodynamics. Refrigeration slows down the chemical and biological processes in foods and the accompanying deterioration and the loss of quality. The *storage life* of fresh perishable foods such as meats, fish, fruits, and vegetables can be extended by several days by cooling, and by several weeks or months by freezing. There are many considerations in the design and selection of proper refrigeration and heat transfer mechanisms, and this chapter demonstrates the importance of having a broad base and a good understanding of the processes involved when designing heat transfer equipment. For example, fruits and vegetables continue to *respire* and generate heat during storage; most foods freeze over a range of temperatures instead of a single temperature; the quality of frozen foods is greatly affected by the rate of freezing; the velocity of refrigerated air affects the rate of moisture loss from the products addition to the rate of heat transfer, and so forth.

We start this chapter with an overview of *microorganisms* that are responsible for the spoilage of foods since the primary function of refrigeration is to retard the growth rate of microorganisms. Then we present the general considerations in the *refrigeration* and *freezing* of foods and describe the different methods of freezing. In the following sections we describe the distinctive features and refrigeration needs of *fresh fruits and vegetables*, *meats*, and *other food products*. Next we consider the heat transfer mechanisms in *refrigerated storage rooms*. Finally, we discuss the *transportation* of refrigerated foods since most refrigerated foods spend part of their life in transit in refrigerated trucks, railroad cars, ships, and even airplanes.

## 17-1 • CONTROL OF MICROORGANISMS IN FOODS

**Microorganisms** such as *bacteria*, *yeasts*, *molds*, and *viruses* are widely encountered in air, water, soil, living organisms, and unprocessed food items, and cause *off-flavors* and *odors*, *slime production*, *changes* in the texture and appearances, and the eventual *spoilage* of foods. Holding perishable foods at warm temperatures is the primary cause of spoilage, and the prevention of food spoilage and the premature degradation of quality due to microorganisms is the largest application area of refrigeration. The first step in controlling microorganisms is to understand what they are and the factors that affect their transmission, growth, and destruction.

Of the various kinds of microorganisms, *bacteria* are the prime cause for the spoilage of foods, especially moist foods. Dry and acidic foods create an undesirable environment for the growth of bacteria, but not for the growth of yeasts and molds. *Molds* are also encountered on moist surfaces, cheese, and spoiled foods. Specific *viruses* are encountered in certain animals and humans, and poor sanitation practices such as keeping processed foods in the same area as the uncooked ones and being careless about handwashing can cause the contamination of food products.

When *contamination* occurs, the microorganisms start to adapt to the new environmental conditions. This initial slow or no-growth period is called the **lag phase** and the shelf life of a food item is directly proportional to the length of this phase (Fig. 17-1). The adaptation period is followed by an *exponential growth* period during which the population of microorganisms can double two or more times every hour under favorable conditions unless drastic sanitation measures are taken. The depletion of nutrients and the accumulation of toxins slow down the growth and start the *death* period.

The *rate of growth* of microorganisms in a food item depends on the characteristics of the food itself such as the chemical structure, pH level, presence of inhibitors and competing microorganisms, and water activity as well as the environmental conditions such as the temperature and relative humidity of the environment and the air motion (Fig. 17-2)

Microorganisms need *food* to grow and multiply, and their nutritional needs are readily provided by the carbohydrates, proteins, minerals, and vitamins in a food. Different types of microorganisms have different nutritional needs, and the types of nutrients in a food determine the types of microorganisms that may dwell on them. The preservatives added to the food may also inhibit the growth of certain microorganisms. Different kinds of microorganisms that exist compete for the same food supply, and thus composition of microorganisms in a food at any time depends on the *initial make-up* of the microorganisms.

All living organisms need *water* to grow, and microorganisms cannot grow in foods that are not sufficiently moist. Microbiological growth in refrigerated foods such as fresh fruits, vegetables, and meats starts at the *exposed surfaces* where contamination is most likely to occur. A fresh meat package left in a room will spoil quickly, as you may have noticed. A meat carcass hung in a controlled environment, on the other hand, will age healthily as a result of *dehydration* on the outer surface, which inhibits microbiological growth there and protects the carcass.

Microorganism growth in a food item is governed by the combined effects of the *characteristics of the food* and the *environmental factors*.

**FIGURE 17-1**  
Typical growth curve of microorganisms.

**FIGURE 17-2**  
The factors that affect the rate of growth of microorganisms.

We cannot do much about the characteristics of the food, but we certainly can alter the environmental conditions to more desirable levels through *heating*, *cooling*, *ventilating*, *humidification*, *dehumidification*, and control of the *oxygen* levels. The growth rate of microorganisms in foods is a strong function of temperature, and temperature control is the single most effective mechanism for controlling the growth rate.

Microorganisms grow best at “warm” temperatures, usually between 20 and 60°C. The growth rate *declines* at high temperatures, and *death* occurs at still higher temperatures, usually above 70°C for most microorganisms. *Cooling* is an effective and practical way of reducing the growth rate of microorganisms and thus extending the *shelf life* of perishable foods. A temperature of 4°C or lower is considered to be a safe refrigeration temperature. Sometimes a small increase in refrigeration temperature may cause a large increase in the growth rate, and a considerable decrease in shelf-life of the food (Fig. 17–3). The growth rate of some microorganisms, for example, doubles for each 3°C rise in temperature.

Another factor that affects microbiological growth and transmission is the *relative humidity* of the environment, which is a measure of the water content of the air. High humidity in *cold rooms* should be avoided since condensation that forms on the walls and ceiling creates the proper environment for *mold growth* and buildups. The drip of contaminated condensate onto food products in the room poses a potential health hazard.

Different microorganisms react differently to the presence of oxygen in the environment. Some microorganisms such as molds require oxygen for growth, while some others cannot grow in the presence of oxygen. Some grow best in low-oxygen environments, while others grow in environments regardless of the amount of oxygen. Therefore, the growth of certain microorganisms can be controlled by controlling the *amount of oxygen* in the environment. For example, vacuum packaging inhibits the growth of micro-organisms that require oxygen. Also, the storage life of some fruits can be extended by reducing the oxygen level in the storage room.

Microorganisms in food products can be controlled by (1) *preventing contamination* by following strict sanitation practices, (2) *inhibiting* growth by altering the environmental conditions, and (3) *destroying* the organisms by heat treatment or chemicals. The best way to minimize contamination in food processing areas is to use fine air filters in ventilation systems to capture the *dust particles* that transport the bacteria in the air. Of course, the filters must remain dry since microorganisms can grow in wet filters. Also, the ventilation system must maintain a positive pressure in the food processing areas to prevent any airborne contaminants from entering inside by infiltration. The elimination of *condensation* on the walls and the ceiling of the facility and the diversion of *plumbing* condensation drip pans of refrigerators to the drain system are two other preventive measures against contamination. Drip systems must be cleaned regularly to prevent microbiological growth in them. Also, any *contact* between raw and cooked food products should be minimized, and cooked products must be stored in rooms with positive pressures. Frozen foods must be kept at –18°C or below, and utmost care should be exercised when food products are packaged after they are frozen to avoid contamination during packaging.

The growth of microorganisms is best controlled by keeping the *temperature* and *relative humidity* of the environment in the desirable range. Keeping

**FIGURE 17–3**

The rate of growth of microorganisms in a food product increases exponentially with increasing environmental temperature.

**FIGURE 17–4**

Freezing may stop the growth of microorganisms, but it may not necessarily kill them.

the relative humidity below 60 percent, for example, prevents the growth of all microorganisms on the surfaces. Microorganisms can be destroyed by *heating* the food product to high temperatures (usually above 70°C), by treating them with *chemicals*, or by exposing them to *ultraviolet* light or solar radiation.

Distinction should be made between *survival* and *growth* of microorganisms. A particular microorganism that may not grow at some low temperature may be able to survive at that temperature for a very long time (Fig. 17-4). Therefore, freezing is not an effective way of killing microorganisms. In fact, some microorganism cultures are preserved by freezing them at very low temperatures. The *rate of freezing* is also an important consideration in the refrigeration of foods since some microorganisms adapt to low temperatures and grow at those temperatures when the cooling rate is very low.

## 17-2 ■ REFRIGERATION AND FREEZING OF FOODS

The *storage life* of fresh perishable foods such as meats, fish, vegetables, and fruits can be extended by several days by storing them at temperatures just above freezing, usually between 1 and 4°C. The storage life of foods can be extended by several months by freezing and storing them at subfreezing temperatures, usually between –18 and –35°C, depending on the particular food (Fig. 17-5).

Refrigeration *slows down* the chemical and biological processes in foods, and the accompanying deterioration and loss of quality and nutrients. Sweet corn, for example, may lose half of its initial sugar content in one day at 21°C, but only 5 percent of it at 0°C. Fresh asparagus may lose 50 percent of its vitamin C content in one day at 20°C, but in 12 days at 0°C. Refrigeration also extends the shelf life of products. The first appearance of unsightly yellowing of broccoli, for example, may be delayed by three or more days by refrigeration.

Early attempts to freeze food items resulted in poor-quality products because of the large ice crystals that formed. It was determined that the *rate of freezing* has a major effect on the size of ice crystals and the quality, texture, and nutritional and sensory properties of many foods. During *slow freezing*, ice crystals can grow to a large size, whereas during *fast freezing* a large number of ice crystals start forming at once and are much smaller in size. Large ice crystals are not desirable since they can *puncture* the walls of the cells, causing a degradation of texture and a loss of natural juices during thawing. A *crust* forms rapidly on the outer layer of the product and seals in the juices, aromatics, and flavoring agents. The product quality is also affected adversely by temperature fluctuations of the storage room.

The ordinary refrigeration of foods involves *cooling* only without any phase change. The *freezing* of foods, on the other hand, involves three stages: *cooling* to the freezing point (removing the sensible heat), *freezing* (removing the latent heat), and *further cooling* to the desired subfreezing temperature (removing the sensible heat of frozen food), as shown in Figure 17-6.

Fresh fruits and vegetables are *live products*, and thus they continue giving off heat that adds to the refrigeration load of the cold storage room. The storage life of fruits and vegetables can be extended greatly by removing the field heat and cooling as soon after harvesting as possible. The optimum storage temperature of most fruits and vegetables is about 0.5 to 1°C above their freezing point. But this is not the case for some fruits and vegetables such

**FIGURE 17-5**

Recommended refrigeration and freezing temperature for most perishable foods.

**FIGURE 17-6**

Typical freezing curve of a food item.

as bananas and cucumbers that experience undesirable *physiological changes*, when exposed to low (but still above-freezing) temperatures, usually between 0 and 10°C. The resulting tissue damage is called the **chilling injury** and is characterized by internal discoloration, soft scald, skin blemishes, soggy breakdown, and failure to ripen. The severeness of the chilling injury depends on both the temperature and the length of storage at that temperature. The lower the temperature, the greater the damage in a given time. Therefore, products susceptible to chilling injury must be stored at higher temperatures. A list of vegetables susceptible to chilling injury and the lowest safe storage temperature are given in Table 17–1.

Chilling injury differs from **freezing injury**, which is caused by prolonged exposure of the fruits and vegetables to subfreezing temperatures and thus the actual *freezing* at the affected areas. The freezing injury is characterized by rubbery texture, browning, bruising, and drying due to rapid moisture loss. The freezing points of fruits and vegetables do not differ by much, but their susceptibility to freezing injury differs greatly. Some vegetables are frozen and thawed several times with no significant damage, but others such as tomatoes suffer severe tissue injury and are ruined after one freezing. Products near the refrigerator coils or at the bottom layers of refrigerator cars and trucks are most susceptible to freezing injury. To avoid freezing injury, the rail cars or trucks should be *heated* during transportation in sub-freezing weather, and adequate air circulation must be provided in cold storage rooms. Damage also occurs during *thawing* if it is done too fast. It is recommended that thawing be done at 4°C.

**Dehydration**, or *moisture loss*, causes a product to shrivel or wrinkle and lose quality. Therefore, proper measures must be taken during cold storage of food items to minimize moisture loss, which also represents a direct loss of the salable amount. A fruit or vegetable that loses 5 percent moisture, for example, will weigh 5 percent less and will probably be sold at a lower unit price because of loss of quality.

The loss of moisture from fresh fruits and vegetables is also called **transpiration**. The amount of moisture lost from a fruit or vegetable per unit mass of the fruit or vegetable per unit time is called the *transpiration rate*. The transpiration rate varies with the environmental conditions such as the temperature, relative humidity, and air motion. Also, the transpiration rate is different for different fruits and vegetables. The tendency of a fruit or vegetable to transpire is characterized by the *transpiration coefficient*, which is the rate of transpiration per unit environmental vapor pressure deficit. The transpiration coefficient of apples, for example, is 58 ng/s · Pa · kg, whereas it is 1648 ng/s · Pa · kg for carrots and 8750 ng/s · Pa · kg for lettuce. This explains why the lettuce dehydrates quickly while the apples in the same environment maintain their fresh appearance for days.

Moisture loss can be minimized by (1) keeping the *storage temperature* of food as low as possible, (2) keeping the *relative humidity* of the storage room as high as possible, and (3) avoiding *high air velocities* (Fig. 17–7). However, air must be circulated continuously throughout the refrigerated storage room to keep it at a uniform temperature. To maintain high quality and product consistency, *temperature swings* of more than 1°C above or below the desired temperature in the storage room must be avoided. Air motion also minimizes the growth of molds on the surfaces of the wrapped or unwrapped food items and on the walls and ceiling of the storage room.

**TABLE 17–1**

Some vegetables susceptible to chilling injury and the lowest safe storage temperature (from ASHRAE Handbook: Refrigeration, Chap. 17, Table 3)

| Vegetable             | Lowest safe temperature, °C |
|-----------------------|-----------------------------|
| Cucumbers             | 10                          |
| Eggplants             | 7                           |
| Casaba melons         | 7 to 10                     |
| Watermelons           | 4                           |
| Okra                  | 7                           |
| Sweet peppers         | 7                           |
| Potatoes              | 3 to 4                      |
| Pumpkins              | 10                          |
| Hard-shell squash     | 10                          |
| Sweet potatoes        | 13                          |
| Ripe tomatoes         | 7 to 10                     |
| Mature green tomatoes | 13                          |

**FIGURE 17–7**

The proper environment for food storage to minimize moisture loss.

**Waxing** reduces moisture loss and thus slows down shriveling and maintains crispness in some products such as cucumbers, mature green tomatoes, peppers, and turnips. Waxing also gives the products an attractive glossy appearance. But a wax coating that is too thick may actually increase decay, especially when no fungicides are used.

Refrigeration is not necessary for all food items. For example, *canned foods* that are heat processed can be stored at room temperature for a few months without any noticeable change in flavor, color, texture, and nutritional value. Refrigeration should be considered for the storage of canned foods longer than two or three months to preserve quality and to avoid corrosion of the cans. *Dry foods* can last a long time, often more than a year, without refrigeration if they are protected against high temperatures and humidities. Dry foods that have been vacuum packed in water vapor-proof containers can maintain high quality and nutritional value for a long time. *Honey* can be stored at room temperature for about a year before any noticeable darkening or loss of flavor occurs. Cold storage below 10°C will extend the life of honey for several years. Storage of honey between 10 and 18°C is highly undesirable as it causes granulation.

The use of refrigeration is not limited to food items. It is commonly used in chemical and process industries to separate gases and solutions, to remove the heat of reaction, and to control pressure by maintaining low temperature. It is also used commonly in the beverage industry, in medicine, and even in the storage of furs and garments. Furs and wool products are commonly stored at 1 to 4°C to protect them against insect damage.

During cooling or freezing, heat is removed from the food usually by the combined mechanisms of *convection*, *radiation*, and *evaporation*, and the *rate of heat transfer* between the food and the surrounding medium at any time can be expressed as (Fig. 17-8)

$$\dot{Q} = hA_s\Delta T = hA_s(T_{\text{surface}} - T_{\text{ambient}}) \quad (\text{W}) \quad (17-1)$$

where

$h$  = average heat transfer coefficient for combined convection, radiation, and evaporation,  $\text{W/m}^2 \cdot ^\circ\text{C}$

$A_s$  = exposed surface area of the food,  $\text{m}^2$

$T_{\text{surface}}$  = surface temperature of the food,  $^\circ\text{C}$

$T_{\text{ambient}}$  = temperature of the refrigerated fluid (air, brine, etc.) away from the food surface,  $^\circ\text{C}$

The heat transfer coefficient  $h$  is not a property of the food or refrigerated fluid. Its value depends on the *shape* of the food, the *surface roughness*, the type of cooling fluid, the *velocity* of the fluid, and the *flow regime*. The heat transfer coefficient is usually determined experimentally and is expressed in terms of the Reynolds and Prandtl numbers. Some experimentally determined values of the heat transfer coefficient are given in Table 17-2. The values of  $h$  include *convection* as well as other effects such as *radiation* and *evaporative cooling*.

## Methods of Freezing

The method of freezing is an important consideration in the freezing of foods. Common freezing methods include *air-blast freezing*, where high-velocity air at about  $-30^\circ\text{C}$  is blown over the food products; *contact freezing*, where

**FIGURE 17-8**

The cooling of food products by air involves heat transfer by convection, radiation, and evaporation.

<sup>a</sup>To convert to Btu/h · ft<sup>2</sup> · °F, multiply the given  $h$  values by 0.1761.

<sup>b</sup>The cooling medium is water instead of air.

<sup>c</sup>The  $L$  in this last column is the characteristic length given under the “size” column and  $\text{Re} = VL/\nu$  is the Reynolds number where  $V$  is the average air velocity and  $\nu$  is the kinematic viscosity of air at the average temperature. The thermal conductivity and kinematic viscosity of air at 0°C are  $k = 0.028 \text{ W/m} \cdot ^\circ\text{C}$  and  $\nu = 12.6 \times 10^{-6} \text{ m}^2/\text{s}$ .

<sup>d</sup>The cooling medium is refrigerated brine instead of air.

packaged or unpackaged food is placed on or between cold metal plates and cooled by conduction; *immersion freezing*, where food is immersed in low-temperature brine; *cryogenic freezing*, where food is placed in a medium cooled by a cryogenic fluid such as liquid nitrogen or liquid or solid carbon dioxide; and the combination of the methods above.

In **air-blast freezers**, refrigerated air serves as the heat transfer medium and the heat transfer is primarily by convection. Perhaps the easiest method of

**FIGURE 17-9**

Schematic of a stationary blast cell freezer.

**FIGURE 17-10**

Schematic of a horizontal airflow spiral freezer.

freezing that comes to mind is to place the food items into a well-insulated *cold storage room* maintained at subfreezing temperatures. Heat transfer in this case is by natural convection, which is a rather slow process. The resulting low rates of freezing cause the growth of large ice crystals in the food and allow plenty of time for the flavors of different foods to mix. This hurts the quality of the product, and thus this simple method of freezing is usually avoided.

The next step is to use some large fans in the cold storage rooms to increase the convection heat transfer coefficient and thus the rate of freezing. These batch-type freezers, called *stationary blast cells* (Fig. 17-9), are still being used for many food products but are being replaced by conveyor-type air-blast freezers as appropriate since they allow the automation of the prod-cut flow and reduce labor costs. A simple version of mechanized freezers, called a *straight-belt freezer*, is very suitable for cooling fruits, vegetables, and uniform-sized products such as french fries. For smaller uniform-sized products such as peas and diced carrots, *fluidized-bed freezers* suspend the food items by a stream of cold air, usually at  $-40^{\circ}\text{C}$ , as they travel on a conveyor belt. The high level of air motion and the large surface area result in high rates of heat transfer and rapid freezing of the food products. The floor space requirements for belt freezers can be minimized by using *multi-pass straight belt freezers or spiral belt freezers*, shown in Fig. 17-10, which now dominate the frozen food industry. In another type of air-blast freezer, called the *impingement-style freezer*, cold air impinges upon the food product vertically from both sides of the conveyor belt at a high velocity, causing high heat transfer rates and very fast freezing.

In **contact freezers**, food products are sandwiched between two cold metal plates and are cooled by conduction. The plates are cooled by circulating cold refrigerant through the channels in the plates. Contact freezers are fast and efficient, but their use is limited to flat foods no thicker than about 8 cm with good thermal conductivity, such as meat patties, fish fillets, and chopped leafy vegetables. In **immersion freezing**, food products are immersed in brine or another fluid with a low-freezing point.

At atmospheric pressure, *liquid nitrogen* boils at  $-195^{\circ}\text{C}$  and absorbs 198 kJ/kg of heat during vaporization. Carbon dioxide is a solid at atmospheric pressure (called *dry ice*) and sublimes at  $-79^{\circ}\text{C}$  while absorbing 572 kJ/kg of heat. The saturated nitrogen and carbon dioxide vapors can further be used to precool the incoming food products before the vapors are purged into the atmosphere. The low boiling points and safety of these cryogenic substances make them very suitable for **cryogenic freezing** of food products. A common type of nitrogen freezer involves a long tunnel with a moving belt in it. Food products are frozen by nitrogen as they pass through the channel. Nitrogen provides extremely fast freezing because of the large temperature difference. Cryogenic cooling is used in limited applications because of its high cost. Sometimes cryogenic cooling is used in combination with air-blast freezing for improved quality and reduced cost. The food product is first crust-frozen in a bath of nitrogen to seal moisture and flavor in, and then transferred into the air-blast freezing section, where the freezing process is completed at a lower cost. This practice also reduces to negligible levels the dehydration losses, which can be as high as 4 percent for poorly designed and maintained systems.

**EXAMPLE 17-1** Cooling of Apples while Avoiding Freezing

Red Delicious apples of 70 mm diameter and 85 percent water content initially at a uniform temperature of 30°C are to be cooled by refrigerated air at -5°C flowing at a velocity of 1.5 m/s (Fig. 17-11). The average heat transfer coefficient between the apples and the air is given in Table 17-2 to be 21 W/m<sup>2</sup> · °C. Determine how long it will take for the center temperature of the apples to drop to 6°C. Also, determine if any part of the apples will freeze during this process.

**SOLUTION** The center temperature of apples drops to 6°C during cooling. The cooling time and if any part of the apples will freeze are to be determined.

**Assumptions** 1 The apples are spherical in shape with a radius of  $r_o = 3.5$  cm.  
2 The thermal properties and the heat transfer coefficient are constant.

**Properties** The thermal conductivity and thermal diffusivity of apples are  $k = 0.418 \text{ W/m} \cdot \text{°C}$  and  $\alpha = 0.13 \times 10^{-6} \text{ m}^2/\text{s}$  (Table A-7).

**Analysis** Noting that the initial and the ambient temperatures are  $T_i = 30^\circ\text{C}$  and  $T_\infty = -5^\circ\text{C}$ , the time required to cool the midsection of the apples to  $T_o = 6^\circ\text{C}$  is determined from transient temperature charts for a sphere as follows:

$$\left. \begin{aligned} \frac{1}{Bi} &= \frac{k}{hr_o} = \frac{0.418 \text{ W/m} \cdot \text{°C}}{(21 \text{ W/m}^2 \cdot \text{°C})(0.035 \text{ m})} = 0.57 \\ \frac{T_o - T_\infty}{T_i - T_\infty} &= \frac{6 - (-5)}{30 - (-5)} = 0.314 \end{aligned} \right\} \tau = \frac{\alpha t}{r_o^2} = 0.46$$

Therefore,

$$t = \frac{\tau r_o^2}{\alpha} = \frac{(0.46)(0.035 \text{ m})^2}{0.13 \times 10^{-6} \text{ m}^2/\text{s}} = 4335 \text{ s} \approx 1.20 \text{ h}$$

The lowest temperature during cooling will occur on the surface ( $r/r_o = 1$ ) of the apples that is in direct contact with refrigerated air and is determined from

$$\left. \begin{aligned} \frac{1}{Bi} &= \frac{k}{hr_o} = 0.57 \\ \frac{r}{r_o} &= 1 \end{aligned} \right\} \frac{T(r) - T_\infty}{T_o - T_\infty} = 0.50$$

It gives

$$T_{\text{surface}} = T(r) = T_\infty + 0.50(T_o - T_\infty) = -5 + 0.5[6 - (-5)] = 0.5^\circ\text{C}$$

which is above -1.1°C, the highest freezing temperature of apples. Therefore, **no part of the apples will freeze** during this cooling process.

### 17-3 • THERMAL PROPERTIES OF FOOD

Refrigeration of foods offers considerable challenges to engineers since the structure and composition of foods and their thermal and physical properties vary considerably. Furthermore, the properties of foods also change with *time* and *temperature*. Fruits and vegetables offer an additional challenge since they *generate heat* during storage as they consume oxygen and give off carbon dioxide, water vapor, and other gases.

The thermal properties of foods are dominated by their *water content*. In fact, the specific heat and the latent heat of foods are calculated with reasonable accuracy on the basis of their water content alone. The *specific heats* of foods can be expressed by **Siebel's formula** as

$$c_{p,\text{fresh}} = 3.35a + 0.48 \quad (\text{kJ/kg} \cdot ^\circ\text{C}) \quad (17-2)$$

$$c_{p,\text{frozen}} = 1.26a + 0.84 \quad (\text{kJ/kg} \cdot ^\circ\text{C}) \quad (17-3)$$

Bananas

Water content = 75%

Freezing point =  $-0.8^\circ\text{C}$ 

$$c_{p,\text{fresh}} = 3.35 \times 0.75 + 0.84 = 3.35 \text{ kJ/kg} \cdot ^\circ\text{C}$$

$$c_{p,\text{frozen}} = 1.26 \times 0.75 + 0.84 = 1.79 \text{ kJ/kg} \cdot ^\circ\text{C}$$

$$h_{\text{latent}} = 334 \times 0.75 = 251 \text{ kJ/kg}$$

**FIGURE 17-12**

The specific and latent heats of foods depend on their water content alone.

**TABLE 17-3**

The drop in the freezing point of typical ice cream whose composition is 12.5 percent milkfat, 10.5 percent serum solids, 15 percent sugar, 0.3 percent stabilizer, and 61.7 percent water (from ASHRAE *Handbook: Refrigeration*, Chap. 14, Table 9)

| Percent water frozen | Freezing point of unfrozen part, °C |
|----------------------|-------------------------------------|
| 0                    | -2.47                               |
| 10                   | -2.75                               |
| 20                   | -3.11                               |
| 30                   | -3.50                               |
| 40                   | -4.22                               |
| 50                   | -5.21                               |
| 60                   | -6.78                               |
| 70                   | -9.45                               |
| 80                   | -14.92                              |
| 90                   | -30.36                              |
| 100                  | -55.0                               |

where  $c_{p,\text{fresh}}$  and  $c_{p,\text{frozen}}$  are the specific heats of the food before and after freezing, respectively;  $a$  is the fraction of water content of the food ( $a = 0.65$  if the water content is 65 percent); and the constant  $0.84 \text{ kJ/kg} \cdot ^\circ\text{C}$  represents the specific heat of the solid (nonwater) portion of the food. For example, the specific heats of fresh and frozen chicken whose water content is 74 percent are.

$$c_{p,\text{fresh}} = 3.35a + 0.84 = 3.35 \times 0.74 + 0.84 = 3.32 \text{ kJ/kg} \cdot ^\circ\text{C}$$

$$c_{p,\text{frozen}} = 1.26a + 0.84 = 1.26 \times 0.74 + 0.84 = 1.77 \text{ kJ/kg} \cdot ^\circ\text{C}$$

Siebel's formulas are based on the specific heats of *water* and *ice* at  $0^\circ\text{C}$  of  $4.19$  and  $2.10 \text{ kJ/kg} \cdot ^\circ\text{C}$ , respectively, and thus they result in the specific heat values of water and ice at  $0^\circ\text{C}$  for  $a = 100$  (i.e., pure water). Therefore, Siebel's formulas give the specific heat values at  $0^\circ\text{C}$ . However, they can be used over a wide temperature range with reasonable accuracy.

The *latent heat* of a food product during freezing or thawing (the heat of fusion) also depends on its water content and is determined from (Fig. 17-12)

$$h_{\text{latent}} = 334a \quad (\text{kJ/kg}) \quad (17-4)$$

where  $a$  is again the fraction of water content and  $334 \text{ kJ/kg}$  is the *latent heat of water* during freezing at  $0^\circ\text{C}$  at atmospheric pressure. For example, the latent heat of chicken whose water content is 74 percent is

$$h_{\text{latent, chicken}} = 334a = 334 \times 0.74 = 247 \text{ kJ/kg}$$

Perishable foods are mostly water in content that turns to ice during freezing. Therefore, we may expect the food items to freeze at  $0^\circ\text{C}$ , which is the freezing point of pure water at atmospheric pressure. But the water in foods is far from being pure, and thus the freezing temperature of foods will be somewhat below  $0^\circ\text{C}$ , depending on the composition of a particular food. In general, food products freeze over a *range of temperatures* instead of a single temperature since the composition of the liquid in the food changes (becomes more concentrated in sugar) and its freezing point drops when some of the liquid water freezes (Table 17-3). Therefore, we often speak of the *average* freezing the temperature, or, for foods like lettuce that are damaged by freezing, the temperature at which *freezing begins*. The freezing temperature of most foods is between  $-0.3$  and  $-2.8^\circ\text{C}$ . In the absence of the exact data the freezing temperature can be assumed to be  $-2.0^\circ\text{C}$  for meats and  $-1.0^\circ\text{C}$  for vegetables and fruits.

The freezing temperature and specific and latent heats of common food products are given in Tables A-7 and A-7E. The *freezing temperature* in this table represents the temperature at which freezing starts for fruits and vegetables, and the average freezing starts for fruits and vegetables, and the average freezing temperature for other foods. The *water content* values are typical for mature products and may exhibit some variation. The specific and latent heat values

given are valid only for the *listed water content*, but they can be reevaluated easily for different water contents using the formulas above.

The accurate determination of heat transfer from the food during freezing to a certain temperature requires a knowledge of the unfrozen amount of water at that temperature. Therefore, it is convenient to present the enthalpies of foods at various temperature in tabular or graphical form, as shown in Table 17-4 for sweet cherries and in Fig. 17-13 for beef. Once the enthalpies are available, the heat transfer  $Q$  from the food can be determined from

$$Q = m(h_{\text{initial}} - h_{\text{final}}) = m(h_1 - h_2) \quad (\text{kJ}) \quad (17-5)$$

where  $m$  is the mass of the food and  $h_{\text{initial}}$  and  $h_{\text{final}}$  are the initial and final enthalpies of the food, respectively.

Other properties of foods such as density, thermal conductivity, and thermal diffusivity are listed in Tables A-7 and A-7E. Again, the exact values of these properties for a particular food depend on the composition, structure, and temperature of the food and may deviate from the listed values. However, sufficiently accurate heat transfer calculations can be made using the representative values in the tables.

The structures of some food products vary considerably in different directions, and thus the thermal conductivity and diffusivity of some food products can be somewhat different (usually about 10 percent) in directions parallel and perpendicular to the fiber structure. The lower values are listed in such cases to be conservative. Note that the thermal conductivity values for most foods are in the range of 0.2 to 1.0 W/m · °C, and the average thermal conductivity of foods is practically the same as the average thermal conductivity of water, which is 0.6 W/m · °C. In the absence of data, thermal diffusivity can be calculated from its definition,  $\alpha = k/\rho c_p$ .

**FIGURE 17-13**  
The enthalpy of beef.  
(From Riedel, 1957.)

**EXAMPLE 17-2** Freezing of Beef

A 50-kg box of beef at 8°C having a water content of 72 percent is to be frozen to a temperature of -30°C in 4 h. Using data from Fig. 17-13, determine (a) the total amount of heat that must be removed from the beef, (b) the amount of unfrozen water in beef at -30°C, and (c) the average rate of heat removal from the beef.

**SOLUTION** A box of beef is to be frozen. The amount of heat removed, the remaining amount of unfrozen water, and the average rate of heat removal are to be determined.

**Assumptions** The beef is at uniform temperatures at the beginning and at the end of the process.

**Properties** At a water content of 72 percent, the enthalpies of beef at 8 and -30°C are  $h_1 = 312 \text{ kJ/kg}$  and  $h_2 = 20 \text{ kJ/kg}$  (Fig. 17-13).

**Analysis** (a) The total heat transfer from the beef is determined from

$$Q = m(h_1 - h_2) = (50\text{kg})[(312 - 20)\text{kJ/kg}] = \mathbf{14,600 \text{ kJ}}$$

(b) The unfrozen water content at -30°C and 72 percent water content is determined from Figure 17-13 to be about 10 percent. Therefore, the total amount of unfrozen water in the beef at -30°C is

$$m_{\text{unfrozen}} = (m_{\text{total}})(\% \text{ unfrozen}) = (50\text{kg})(0.1) = \mathbf{5\text{kg}}$$

(c) Noting that 14,600 kJ of heat are removed from the beef in 4 h, the average rate of heat removal (or refrigeration) is

$$\dot{Q} = \frac{Q}{\Delta t} = \frac{14,600\text{kJ}}{(4 \times 3600\text{s})} = \mathbf{1.01 \text{ kW}}$$

Therefore, this facility must have a refrigeration capacity of at least 1.01 kW per box of beef.

This problem could also be solved by assuming the beef to be frozen completely at -2°C by releasing its latent heat of 240 kJ/kg and using specific heat values of 3.25 kJ/kg · °C above freezing and 1.75 kJ/kg · °C below freezing. The total heat removal from the box of beef in this case would be 16,075 kJ. Note that the difference between the two results is  $16,075 - 14,600 = 1475 \text{ kJ}$ , which is nearly equal to the latent heat released by 6 kg of water as it freezes.

**FIGURE 17-14**

Schematic for Example 17-3.

**EXAMPLE 17-3** Freezing of Sweet Cherries

A 40-kg box of sweet cherries at 10°C having a water content of 77 percent is to be frozen to a temperature of -30°C (Fig. 17-14). Using enthalpy data from Table 17-4, determine the total amount of heat that must be removed from the cherries.

**SOLUTION** A box of sweet cherries is to be frozen. The amount of heat that must be removed is to be determined.

**Assumptions** The cherries are at uniform temperatures at the beginning and at the end of the process.

**Properties** At a water content of 77 percent, the enthalpies of cherries at 0 and -30°C are  $h_1 = 324 \text{ kJ/kg}$  and  $h_2 = 26 \text{ kJ/kg}$  and the specific heat of fresh cherries is 3.43 kJ/kg · °C (Table 17-4).

**Analysis** The amount of heat removed as the cherries are cooled from 0°C to -30°C is

$$Q_{\text{freezing}} = m(h_1 - h_2) = (40 \text{ kg})[(324 - 26) \text{ kJ/kg}] = 11,920 \text{ kJ}$$

The amount of heat removed as the cherries are cooled from 10°C to 0°C is

$$Q_{\text{cooling}} = mc_p \Delta T_{\text{cooling}} = (40 \text{ kg})(3.43 \text{ kJ/kg} \cdot ^\circ\text{C})(10^\circ\text{C}) = 1372 \text{ kJ}$$

Then the total heat removed as the cherries are cooled from 10°C to -30°C becomes

$$Q_{\text{total}} = Q_{\text{cooling}} + Q_{\text{freezing}} = 1372 + 11,920 = 13,292 \text{ kJ}$$

Also, the cherries at -30°C will contain 3.6 kg of water since 9 percent of the water in the cherries will still be unfrozen at -30°C.

## 17-4 • REFRIGERATION OF FRUITS AND VEGETABLES

Fruits and vegetables are frequently *cooled* to preserve preharvest freshness and flavor, and to extend storage and shelf life. Cooling at the field before the product is shipped to the market or storage warehouse is referred to as **pre-cooling**. The cooling requirements of fruits and vegetables vary greatly, as do the cooling methods. Highly perishable products such as broccoli, ripe tomatoes, carrots, leafy vegetables, apricots, strawberries, peaches, and plums must be cooled as soon as possible after harvesting. Cooling is not necessary or as important for long-lasting fruits and vegetables such as potatoes, pumpkins, green tomatoes, and apples.

The refrigeration capacity of *precooling facilities* is usually much larger than that of cold storage facilities because of the requirement to cool the products to a specified temperature within a specified time. In applications where cooling is needed during daytime only, the size of the refrigeration equipment can be cut in half by utilizing cold storage facilities at night for activities such as ice making and during the day for precooling.

Fruits and vegetables are mostly water, and thus their properties are close in value to those of water. Initially, all of the heat removed from the product comes from the exterior of the products, causing a large temperature gradient within the product during fast cooling. But the *mass-average temperature*, which is the equivalent average temperature of the product at a given time, is used in calculations for simplicity.

The heat removed from the products accounts for the majority of the refrigeration load and is determined from

$$\dot{Q}_{\text{product}} = mc_p(T_{\text{initial}} - T_{\text{final}})/\Delta t \quad (\text{W}) \quad (17-6)$$

where  $\dot{Q}_{\text{product}}$  is the *average rate of heat removal* from the fruits and vegetables,  $m$  is the total mass,  $c_p$  is the average specific heat,  $T_{\text{initial}}$  and  $T_{\text{final}}$  are the mass-average temperatures of the products before and after cooling, respectively, and  $\Delta t$  is the cooling time (Fig. 17-15). The heat of respiration is negligible when the cooling time is less than a few hours.

Fresh fruits and vegetables are *live products*, and they continue to *respire* at varying rates for days and even weeks after harvesting. During respiration, a sugar like glucose combines with  $O_2$  to produce  $CO_2$  and  $H_2O$ . **Heat of**

TABLE 17-4

The variation of enthalpy and the unfrozen water content of sweet cherries (77 percent water content by mass, no stones) with temperature (from ASHRAE, *Handbook of Fundamentals*, Chap. 30, Table 5)\*

| Temperature,<br>°C | Percent<br>water<br>unfrozen | Enthalpy,<br>kJ/kg |
|--------------------|------------------------------|--------------------|

$T_{\text{avg}}$  = average temperature

$T_i$  = initial temperature

$T_\infty$  = water temperature

**FIGURE 17-16**

The cooling time of some fruits under ideal conditions during hydrocooling.

(From ASHRAE, *Handbook: Refrigeration*, Chap. 10, Fig. 2.)

**respiration** is released during this exothermic reaction, which adds to the refrigeration load during cooling of fruits and vegetables. The rate of respiration varies strongly with temperature. For example, the average heats of respiration of strawberries at 0, 10, and 20°C are 44, 213, and 442 mW/kg, respectively. The heat of respiration also varies greatly from one product to another. For example, at 20°C, it is 34 mW/kg for mature potatoes, 77 mW/kg for apples, 167 mW/kg for cabbage, and 913 mW/kg for broccoli. The heat of respiration of most vegetables decreases with time. The opposite is true for fruits that ripen in storage such as apples and peaches. For plums, for example, the heat of respiration increases from 12 mW/kg shortly after harvest to 21 mW/kg after 6 days and to 27 mW/kg after 18 days when stored at 5°C. Being infected with decay organisms also increases the respiration time.

The heat of respiration of some fruits and vegetables are given in Table 17-5. We should use the *initial rates* of respiration when calculating the cooling load of fruits and vegetables for the first day or two, and the *long-term equilibrium rates* when calculating the heat load for long-term cold storage. The *refrigeration load due to respiration* is determined from

$$\dot{Q}_{\text{respiration}} = \sum m_i \dot{q}_{\text{respiration},i} \quad (\text{W}) \quad (17-7)$$

which is the sum of the mass times the heat of respiration for all the food products stored in the refrigerated space. Fresh fruits and vegetables with the highest rates of respiration are the most perishable, and refrigeration is the most effective way to slow down respiration and decay.

The primary precooling methods for fruits and vegetables are *hydro-cooling*, where the products are cooled by immersing them into chilled water; *forced-air cooling*, where the products are cooled by forcing refrigerated air through them; *package icing*, where the products are cooled by placing crushed ice into the containers; and *vacuum cooling*, where the products are cooled by vaporizing some of the water content of the products under low pressure conditions.

**Hydrocooling** is a popular and effective method of precooling fruits and vegetables and is done by immersing or flooding products in chilled water or spraying chilled water over the products. Water is a good heat transfer medium compared to air, and the convection resistance at the product surface is usually negligible. This means the primary resistance to heat transfer is the internal resistance of the product, and internal heat is removed as soon as it arrives at the surface. The temperature difference between the product surface and the cooling water is normally less than 0.5°C. Under idealized conditions, the convection heat transfer coefficient and the cooling rate per unit surface area can be 680 W/m<sup>2</sup> · °C and 300 W/m<sup>2</sup>, respectively.

The variation of the mass-average product temperature with time is given in Fig. 17-16 for some fruits. Note that reducing the temperature difference between the fruit and the water to 10 percent of the initial value takes about 0.4 h for peaches but 0.7 h for citrus fruits. This is not much of a concern, however, since citrus fruits are often not cooled at all.

The water in a hydrocooling system is cooled by passing it through cooling coils in which a refrigerant flows at about -2°C. The water is normally recirculated to save water and energy. But recirculation also saves the microorganisms that come in with fruits and vegetables. Chemicals such as chlorine are commonly added (usually at a rate of 50 to 100 mg/kg water) to reduce bacteria build-up in water.

**Forced-air cooling** systems have the advantage that they are *simple* and easy to maintain and do not have leakage problems. But they are not as effective as hydrocooling systems. The heat transfer coefficients encountered in forced-air cooling are considerably lower than those encountered in hydrocooling, and thus the cooling of fruits and vegetables by forced air usually takes much longer. The refrigerated air usually approaches the cooling section at a velocity of 1.5 to 2 m/s, and the convection heat transfer coefficients range from about 30 to 60 W/m<sup>2</sup> · °C. The rate of airflow ranges from about 1 to 3 L/s per kg of product. The cooling time can be reduced by spacing the product containers and allowing for airflow throughout instead of stacking them closely and disturbing the airflow. Various air cooling methods, such as batch cooling in refrigerated rooms and impingement air cooling as products continuously pass through a cooling tunnel on conveyor belts, are in common use today. Cut flowers are commonly cooled by forced air.

**Vacuum cooling** is a batch process, and it is based on *reducing the pressure* of the sealed cooling chamber to the saturation pressure at the desired low temperature and evaporating some water from the products to be cooled. The heat of vaporization during evaporation is absorbed from the products, which lowers the product temperature. The saturation pressure of water at 0°C is 0.61 kPa, and the products can be cooled to 0°C by lowering the pressure to this level. The cooling rate can be increased by lowering the pressure below 0.61 kPa. But this is not desirable because of the danger of freezing and the added cost.

In vacuum cooling, there are two distinct stages. In the first stage, the products at ambient temperature, say at 25°C, are loaded into the flash chamber and the operation begins. The temperature in the chamber remains constant until the *saturation pressure* is reached, which is 3.17 kPa at 25°C. In the second stage that follows, saturation conditions are maintained inside at progressively *lower pressures* and the corresponding *lower temperatures* until the desired temperature, usually slightly above 0°C, is reached (Fig. 17-17).

The amount of heat removed from the product is proportional to the mass of water evaporated,  $m_v$ , and the heat of vaporization of water at the average temperature,  $h_{fg}$ , and is determined from

$$Q_{\text{vacuum}} = m_v h_{fg} \quad (\text{kJ}) \quad (17-8)$$

If the product is cooled from 30°C to 0°C, the average heat of vaporization can be taken to 2466 kJ/kg, which corresponds to the *average temperature* of 15°C. Noting that the specific heat of products is about 4 kJ/kg · °C the evaporation of 0.01 kg of water will lower the temperature of 1 kg of product by  $24.66/4 = 6^\circ\text{C}$ . That is, the vacuum-cooled products will lose 1 percent moisture for each 6°C drop in their temperature. This means the products will experience a *weight loss* of 4 percent for a temperature drop of about 24°C. To reduce the product moisture loss and enhance the effectiveness of vacuum cooling, the products are often *wetted* prior to cooling.

Vacuum cooling is usually more expensive than forced air or hydrocooling, and its use is limited to applications that result in much faster cooling. products with large surface area per unit mass and a high tendency to release moisture such as *lettuce* and *spinach* are well suited for vacuum cooling, products with low surface area to mass ratio are not suitable, especially those that have relatively impervious peel such as tomatoes and cucumbers. Some products such as mushrooms and green peas can be vacuum cooled successfully by wetting them first.

FIGURE 17-17

The variation in the temperature of the fruits and vegetables with pressure during vacuum cooling from 25°C to 0°C.

**FIGURE 17-18**

Ice is sometimes used to cool fruits and vegetables in the field and during short transit.

**Package icing** is used in small-scale applications to remove field heat and keep the product cool during transit, but its use is limited to products that are not harmed by contact with ice. Also, ice provides *moisture* as well as *refrigeration* (Fig. 17-18). Some shipping containers are cooled by pumping *slush ice* into them through a hose.

Fruits intended for long-term storage must be free of *mechanical injury* such as bruises and skin breaks since deterioration progresses rapidly in such areas. Also, the fruits must be harvested when *mature*. Undermature fruits will not ripen properly while overmature ones will deteriorate rapidly during storage. It is important that fruits be cooled as soon as possible after picking because at field temperatures some fruits deteriorate as much in one day as they do in one week in cold storage.

Fruits and vegetables are normally covered with *microorganisms* that cause decay and premature spoilage under favorable conditions. Refrigeration and the resulting low temperatures are the best protection against the damage caused by the growth of microorganisms. *High temperatures* increase the rate of ripening, decay, moisture loss, and loss of quality of food products during storage, transportation, and display. Precooling, cold storage, and refrigerated transportation have reduced these losses considerably and made it possible to move fruits and vegetables to distant markets at near-fresh conditions.

Fruits and vegetables require *oxygen* to respire, and studies have shown that the storage life of fruits and vegetables can be extended considerably by modifying the atmosphere in the cold storage rooms. This is usually done by reducing the oxygen level in the air to 1 to 5 percent and increasing the CO<sub>2</sub> level to retard the respiration rate and decay (Fig. 17-19). Therefore, many railcars and trucks that transport perishable products to distant cities are fitted with *modified atmosphere systems*. Lettuce is commonly shipped in a low oxygen atmosphere, but not all vegetables benefit from modified atmosphere. Certain vegetables benefit from a modified atmosphere for limited time only. Excess CO<sub>2</sub> accumulation can be prevented in the cargo space by utilizing hydrated lime to absorb CO<sub>2</sub>. Liquid nitrogen is often allowed to vaporize in the cargo room and force the regular air and thus oxygen out.

The modified atmosphere measure did not find much acceptance because of the complexities and the risks involved. For example, when the oxygen level is reduced too much, the products cannot respire and develop an alcoholic off-flavor. Also, very high levels of CO<sub>2</sub> harm the products. Modified atmosphere may *supplement* refrigeration, but it can never replace it. In fact, modified atmosphere may actually increase deterioration instead of decreasing it at temperatures above recommended values. An alternative way of extending the storage life is to *reduce* the oxygen level by reducing the atmospheric pressure below 0.2 atm in the storage room, accompanied by the removal of ethylene gas from the storage room to retard ripening.

Storage of fruits and vegetables in tightly sealed or tied *plastic bags* in order to keep the product moist is not recommended since the respiratory gases such as CO<sub>2</sub> and ethylene may reach harmful levels. Besides, the air packet inside acts as insulation that slows down the cooling of the product inside.

Most produce can be stored satisfactorily at 0°C and 90 to 95 percent relative humidity. An adequate refrigerator coil area should be provided to minimize the difference between the refrigerant and the air temperatures. A temperature difference of more than a few degrees will cause *excessive moisture removal* at

**FIGURE 17-19**

Reducing the oxygen level in storage rooms reduces respiration and extends storage life.

the coils, and thus will make it difficult to maintain the storage room at the desired high humidity.

Different fruits and vegetables have different storage requirements, and they respond differently to prolonged cold storage. Therefore, the characteristics of a particular product must be known before an effective cooling and storage mechanism can be devised for it.

The recommended storage temperature for most varieties of *apples* is  $-1^{\circ}\text{C}$ , which is  $1^{\circ}\text{C}$  above the highest freezing point of  $-2^{\circ}\text{C}$ . But some apple varieties need to be stored at  $2^{\circ}\text{C}$  since they develop physiological disorders at  $-1^{\circ}\text{C}$ . Some varieties susceptible to *chilling injury* are stored at about  $4^{\circ}\text{C}$ . *Pears* lose moisture faster than apples, and thus they should be maintained in humid environments. The recommended storage conditions for pears are  $-1^{\circ}\text{C}$  and 90 to 90 percent relative humidity. Pears ripen best following storage at temperatures 16 to  $21^{\circ}\text{C}$ . *Plums* are usually stored at  $-1$  to  $0^{\circ}\text{C}$  and 90 to 95 percent relative humidity. Most varieties of plums are not suitable for long-term storage, but some varieties can be stored for a few months with satisfactory results (Fig. 17–20).

*Grapes* are harvested after they are completely ripened but before being overripe since overripening may cause weakening of the stem attachment and increase the susceptibility to organisms causing decay. Grapes are normally precooled shortly after harvesting to minimize damage by the hot and dry field conditions. Care should be exercised during air cooling since the grapes have a large surface-to-volume ratio that makes them susceptible to moisture loss and drying. This is also the case for the stems of the grapes. Dry stems become brittle and break easily, causing a considerable loss of quality. Grafts are usually precooled by air supplied at  $1.5^{\circ}\text{C}$  or below a rate of at least 0.17 L/s per kg of grape and a minimum velocity of 0.5 m/s through the channels of the container. Sometimes the air is also humidified to minimize drying. It is also recommended that grapes be stored at  $-1^{\circ}\text{C}$  and 90 to 95 percent relative humidity. After precooling, the air velocity is lowered to below 0.1 m/s in the container channels. Also, some varieties of grapes are fumigated with sulfur dioxide prior to storage to minimize decay and prevent new infections.

*Peaches*, especially the early season varieties, are not suitable for long-term storage. However, some late season varieties can be stored for up to six weeks without any noticeable deterioration in texture and flavor. If left unattended, peaches begin to soften and decay in a few hours. Therefore, it is important to cool peaches to  $4^{\circ}\text{C}$  as soon as possible after harvesting, usually by hydrocooling or forced air. Peaches are stored at  $-0.5^{\circ}\text{C}$  and 90 to 95 percent relative humidity with low air velocities. *Nectarines* and apricots can be stored under similar storage conditions. *Sweet cherries* intended for storage must be picked with stems attached and precooled rapidly to  $-1^{\circ}\text{C}$  by hydrocooling or forced-air cooling. Cherries retain their quality during storage for two weeks. Controlled atmosphere with 20 to 25 percent  $\text{CO}_2$  or 0.5 to 2 percent  $\text{O}_2$  helps preserve firmness and full vivid color during storage.

Citrus fruits such as *oranges*, *grapefruit*, and *lemons* do not undergo much changes in their composition after they are picked, and thus the product quality depends mostly on the degree of ripeness when the fruit is harvested. After harvesting, the fruits are transported to packinghouses where they are sorted, washed, and disinfected. The fruits are then polished and waxed after they are dried by warm air. Most varieties of oranges can be stored for 2 to 3 months at

**FIGURE 17-20**

Recommended storage temperature for various fruits.

**FIGURE 17-21**

Recommended storage temperature for various vegetables.

0 to 1°C and 85 to 90 percent relative humidity. Maintaining high humidity in storage rooms is important since oranges tend to lose moisture rapidly. Storage temperatures up to 10°C can be used for shorter storage periods. Grapefruits and lemons can be stored at 10 to 15°C for more than a month.

*Bananas* are harvested when they are mature but unripe, as noticed by the green color of the peel. After they are washed and cut into retail-size clusters, they are boxed and transported from tropical climates to distant locations by refrigerated trucks or ships maintained at 14°C. The bananas are then moved to wholesale processing facilities by railcars or trucks again at 14°C. Product temperatures below 13°C can cause chilling injury, characterized by darkened areas of killed cells at the peel. Temperatures above about 16°C, on the other hand, may cause the bananas to ripen prematurely and must be avoided.

Unlike other produce storage facilities, bananas are ripened in carefully controlled wholesale processing facilities before they are shipped to retail stores. The ripening process takes four to eight days, depending on the temperatures used, which range between 14 and 18°C. The higher the storage temperature, the shorter the ripening time. The ripening process is initiated by the introduction of ethylene gas into the airtight storage air space at a mole fraction of 0.001 for one day. The refrigerant in the cooling system is maintained at a relatively high temperature (about 4.5°C) to avoid chilling injury.

The optimum temperatures and relative humidities for maximum storage at high quality of fruits and vegetables are well established and are available in handbooks (Fig. 17-21). The recommended storage temperatures and relative humidities are 0°C and 95 to 100 percent for artichokes, broccoli, brussels sprouts, leafy greens, lettuce, parsley, and radishes; 0°C and 98 to 100 percent for cabbage, carrots, celery, and parsnips; 0°C and 95 to 98 percent for sweet corn, green peas, and spinach; 0°C and 95 percent for cauliflower, mushrooms, and turnips; 0 to 2°C and 95 to 100 percent for asparagus; 0°C and 65 to 70 percent for dry garlic and onions; 2 to 3°C and 90 to 95 percent for cantaloupes; 3 to 13°C and 90 to 95 percent for potatoes, 4 to 7°C and 95 percent for green or snap beans; 7 to 10°C and 90 to 95 percent for okra and ripe tomatoes; 7 to 13°C and 90 to 95 percent for sweet peppers; 8 to 12°C and 90 to 95 percent for eggplants; 10 to 13°C and 95 percent for cucumbers; and 10 to 15°C and 90 to 95 percent for watermelons.

Sprouting of onions, potatoes, and carrots becomes a problem in storage facilities that are not adequately refrigerated. The problem can be controlled by using sprout inhibitors. Gamma radiation also suppresses sprouting.

*Heat treatment or radiation* can be used to control decay and kill the insects and microorganisms on or near the fruit surfaces. For example, immersing the peaches in 55°C water for 1.5 minutes (or in 49°C water for 3 minutes) reduces brown rot considerably. Also, ultraviolet lamps are successfully used to kill bacteria and fungi on the exposed surfaces of the cold storage rooms. Gamma radiation is effectively used to control decay in some products, but consumer resistance to irradiated foods remains a concern.

#### EXAMPLE 17-4 Cooling of Bananas by Refrigerated Air

A typical one-half-carlot-capacity banana room contains 18 pallets of bananas. Each pallet consists of 24 boxes, and thus the room stores 432 boxes of bananas. A box holds an average of 19 kg of bananas and is made of 2.3 kg of

fiberboard. The specific heats of banana and the fiberboard are  $3.55 \text{ kJ/kg} \cdot ^\circ\text{C}$  and  $1.7 \text{ kJ/kg} \cdot ^\circ\text{C}$ , respectively. The peak heat of respiration of bananas is  $0.3 \text{ W/kg}$ . The bananas are cooled at a rate of  $0.2^\circ\text{C/h}$ . If the temperature rise of refrigerated air is not to exceed  $1.5^\circ\text{C}$  as it flows through the room, determine the minimum flow rate of air needed. Take the density and specific heat of air to be  $1.2 \text{ kg/m}^3$  and  $1.0 \text{ kJ/kg} \cdot ^\circ\text{C}$ .

**SOLUTION** A banana cooling room is being analyzed. The minimum flow rate of air needed to cool bananas at a rate of  $0.2^\circ\text{C/h}$  is to be determined.

**Assumptions** 1 Heat transfer through the walls, floor, and ceiling of the banana room is negligible. 2 Thermal properties of air, bananas, and boxes are constant.

**Properties** The average of properties air, bananas, and boxes are as specified in the problem statement.

**Analysis** A sketch of the banana room is given in Fig. 17–22. Noting that the banana room holds 432 boxes, the total masses of the bananas and the boxes are determined to be

$$\begin{aligned}m_{\text{banana}} &= (\text{Mass per box})(\text{Number of boxes}) = (19 \text{ kg/box})(432 \text{ boxes}) \\&= 8208 \text{ kg} \\m_{\text{box}} &= (\text{Mass per box})(\text{Number of boxes}) = (2.3 \text{ kg/box})(432 \text{ box}) \\&= 993.6 \text{ kg}\end{aligned}$$

The total refrigeration load in this case is due to the heat of respiration and the cooling of the bananas and the boxes and is determined from

$$\dot{Q}_{\text{total}} = \dot{Q}_{\text{respiration}} + \dot{Q}_{\text{banana}} + \dot{Q}_{\text{box}}$$

where

$$\dot{Q}_{\text{respiration}} = m_{\text{banana}} \dot{q}_{\text{respiration}} = (8208 \text{ kg})(0.3 \text{ W/kg}) = 2462 \text{ W}$$

$$\begin{aligned}\dot{Q}_{\text{banana}} &= (mc_p \Delta T / \Delta t)_{\text{banana}} \\&= (8208 \text{ kg})(3.55 \text{ kJ/kg} \cdot ^\circ\text{C})(0.2^\circ\text{C/h}) = 5828 \text{ kJ/h} \\&= 1619 \text{ W} \quad (\text{since } 1 \text{ W} = 3.6 \text{ kJ/h})\end{aligned}$$

$$\begin{aligned}\dot{Q}_{\text{box}} &= (mc_p \Delta T / \Delta t)_{\text{box}} \\&= (993.6 \text{ kg})(1.7 \text{ kJ/kg} \cdot ^\circ\text{C})(0.2^\circ\text{C/h}) = 338 \text{ kJ/h} \\&= 94 \text{ W} \quad (\text{since } 1 \text{ W} = 3.6 \text{ kJ/h})\end{aligned}$$

and the quantity  $\Delta T / \Delta t$  is the rate of change of temperature of the products and is given to be  $0.2^\circ\text{C/h}$ . Then the total rate of cooling becomes

$$\dot{Q}_{\text{total}} = \dot{Q}_{\text{respiration}} + \dot{Q}_{\text{banana}} + \dot{Q}_{\text{box}} = 2462 + 1619 + 94 = 4175 \text{ W}$$

The temperature rise of air is limited to  $1.5^\circ\text{C}$  as it flows through the load. Noting that the air picks up heat at a rate of 4175 W, the minimum mass flow rate of air is determined to be

$$\dot{m}_{\text{air}} = \frac{\dot{Q}_{\text{air}}}{(c_p \Delta T)_{\text{air}}} = \frac{4175 \text{ W}}{(1000 \text{ J/kg} \cdot ^\circ\text{C})(1.5^\circ\text{C})} = 2.78 \text{ kg/s}$$

Banana cooling room

432 boxes  
19 kg banana/box  
2.3 kg fiberboard/box

Head of respiration =  $0.3 \text{ W/kg}$

Cooling rate =  $0.2^\circ\text{C/h}$

$\Delta T_{\text{air}} = 1.5^\circ\text{C}$

**FIGURE 17–22**

Schematic for Example 17–4.

Then the volume flow rate of air becomes

$$\dot{V}_{\text{air}} = \frac{\dot{m}_{\text{air}}}{\rho_{\text{air}}} = \frac{2.78 \text{ kg/s}}{1.2 \text{ kg/m}^3} = 2.32 \text{ m}^3/\text{s}$$

Therefore, the fan selected for the banana room must be large enough to circulate air at rate of  $2.32 \text{ m}^3/\text{s}$ .

## 17–5 ■ REFRIGERATION OF MEATS, POULTRY, AND FISH

Meat carcasses in slaughterhouses should be cooled *as fast as possible* to a uniform temperature of about  $1.7^\circ\text{C}$  to reduce the growth rate of microorganisms that may be present on carcass surfaces, and thus minimize spoilage. The right level of *temperature, humidity, and air motion* should be selected to prevent excessive shrinkage, toughening, and discoloration.

The deep body temperature of an animal is about  $39^\circ\text{C}$ , but this temperature tends to rise a couple of degrees in the midsections after slaughter as a result of the *heat generated* during the biological reactions that occur in the cells. The temperature of the exposed surfaces, on the other hand, tends to drop as a result of heat losses. The thickest part of the carcass is the *round*, and the center of the round is the last place to cool during chilling. Therefore, the cooling of the carcass can best be monitored by inserting a thermometer deep into the central part of the round.

About 70 percent of the beef carcass is water, and the carcass is cooled mostly by *evaporative cooling* as a result of moisture migration toward the surface where evaporation occurs. But this shrinking translates into a loss of salable mass that can amount to 2 percent of the total mass during an overnight chilling. To prevent *excessive* loss of mass, carcasses are usually washed or sprayed with water prior to cooling. With adequate care, spray chilling can eliminate carcass cooling shrinkage almost entirely.

The average total mass of dressed beef, which is normally split into two sides, is about 300 kg, and the average specific heat of the carcass is about  $3.14 \text{ kJ/kg} \cdot {}^\circ\text{C}$  (Table 17–6). The *chilling room* must have a capacity equal to the daily kill of the slaughterhouse, which may be several hundred. A beef carcass is washed before it enters the chilling room and absorbs a large amount of water (about 3.6 kg) at its surface during the washing process. This does not represent a net mass gain, however, since it is lost by dripping or evaporation in the chilling room during cooling. Ideally, the carcass does not lose or gain any net weight as it is cooled in the chilling room. However, it does lose about 0.5 percent of the total mass in the *holding room* as it continues to cool. The actual product loss is determined by first weighing the dry carcass before washing and then weighing it again after it is cooled.

The refrigerated air temperature in the chilling room of beef carcasses must be sufficiently high to avoid *freezing* and *discoloration* on the outer surfaces of the carcass. This means a long residence time for the massive beef carcasses in the chilling room to cool to the desired temperature. Beef carcasses are only partially cooled at the end of an overnight stay in the chilling room. The temperature of a

**TABLE 17–6**

**FIGURE 17-23**

Typical cooling curve of a beef carcass in the chilling and holding rooms at an average temperature of 0°C.

(From ASHRAE, Handbook: Refrigeration, Chap. 11, Fig. 2.)

beef carcass drops to 1.7 to 7°C at the surface and to about 15°C in mid parts of the round in 10 h. It takes another day or two in the *holding room* maintained at 1 to 2°C to complete *chilling* and *temperature equalization*. But hog carcasses are fully chilled during that period because of their smaller size. The *air circulation* in the holding room is kept at minimum levels to avoid excessive moisture loss and discoloration. The refrigeration load of the holding room is much smaller than that of the chilling room, and thus it requires a smaller refrigeration system.

Beef carcasses intended for distant markets are shipped the day after slaughter in refrigerated trucks, where the rest of the cooling is done. This practice makes it possible to deliver fresh meat long distances in a timely manner.

The variation in temperature of the beef carcass during cooling is given in Fig. 17-23. Initially, the cooling process is dominated by *sensible heat transfer*. Note that the average temperature of the carcass is reduced by about 28°C (from 36 to 8°C) in 20 h. The cooling rate of the carcass could be increased by *lowering* the refrigerated air temperature and *increasing* the air velocity, but such measures also increase the risk of *surface freezing*.

Most meats are judged on their **tenderness**, and the preservation of tenderness is an important consideration in the refrigeration and freezing of meats. Meat consists primarily of bundles of tiny *muscle fibers* bundled together inside long strings of *connective tissues* that hold it together. The tenderness of a certain cut of beef depends on the location of the cut, the age, and the activity level of the animal. Cuts from the relatively inactive mid-backbone section of the animal such as short loins, sirloin, and prime ribs are more tender than the cuts from the active parts such as the legs and the neck (Fig. 17-24). The more active the animal, the more the connective tissue, and the tougher the meat. The meat of an older animal is more flavorful, however, and is preferred for stewing since the toughness of the meat does not pose a problem for moist-heat cooking such as boiling. The protein *collagen*, which is the main component of the connective tissue, softens and dissolves in hot and moist environments and gradually transforms into *gelatin*, and tenderizes the meat.

The old saying “one should either cook an animal immediately after slaughter or wait at least two days” has a lot of truth in it. The biomechanical reactions in the muscle continue after the slaughter until the energy supplied to the muscle to do work diminishes. The muscle then stiffens and goes into *rigor mortis*. This process begins several hours after the animal is slaughtered and

The freezing time of meat can be reduced considerably by using low temperature air at high velocity.

**TABLE 17-7**

Storage life of frozen meat products at different storage temperatures (from ASHRAE Handbook: Refrigeration, Chap. 10, Table 7)

| Product      | Storage life, months |       |       |
|--------------|----------------------|-------|-------|
|              | Temperature          |       |       |
|              | -12°C                | -18°C | -23°C |
| Beef         | 4–12                 | 6–18  | 12–24 |
| Lamb         | 3–8                  | 6–16  | 12–18 |
| Veal         | 3–4                  | 4–14  | 8     |
| Pork         | 2–6                  | 4–12  | 8–15  |
| Chopped beef | 3–4                  | 4–6   | 8     |
| Cooked foods | 2–3                  | 2–4   |       |

continues for 12 to 36 h until an enzymatic action sets in and tenderizes the connective tissue, as shown in Fig. 17-25. It takes about seven days to complete tenderization naturally in storage facilities maintained at 2°C. Electrical stimulation also causes the meat to be tender. To avoid toughness, fresh meat should not be frozen before rigor mortis has passed.

You have probably noticed that steaks are tender and rather tasty when they are hot but toughen as they cool. This is because the gelatin that formed during cooking thickens as it cools, and meat loses its tenderness. So it is no surprise that first-class restaurants serve their steak on hot thick plates that keep the steaks warm for a long time. Also, cooking softens the connective tissue but toughens the tender muscle fibers. Therefore, barbecuing on *low heat* for a long time results in a tough steak.

Variety meats intended for long-term storage must be frozen rapidly to induce spoilage and preserve quality. Perhaps the first thought that comes to mind to freeze meat is to place the meat packages into the *freezer* and wait. But the freezing time is *too long* in this case, especially for large boxes. For example, the core temperature of a 13-cm-deep box containing 32 kg of variety meat can be as high as 16°C 24 h after it is placed into a -30°C freezer. The freezing time of large boxes can be shortened considerably by adding some *dry ice* into it.

A more effective method of freezing, called *quick chilling*, involves the use of lower air temperatures, -40 to -30°C, with higher velocities of 2.5 m/s to 5 m/s over the product (Fig. 17-26). The internal temperature should be lowered to -4°C for products to be transferred to a storage freezer and to -18°C for products to be shipped immediately. The *rate of freezing* depends on the *package material* and its insulating properties, the *thickness* of the largest box, the *type* of meat, and the *capacity* of the refrigeration system. Note that the air temperature will rise excessively during initial stages of freezing and increase the freezing time if the capacity of the system is inadequate. A smaller refrigeration system will be adequate if dry ice is to be used in packages. Shrinkage during freezing varies from about 0.5 to 1 percent.

Although the average freezing point of lean meat can be taken to be -2°C with a latent heat of 249 kJ/kg, it should be remembered that freezing occurs over a *temperature range*, with most freezing occurring between -1 and -4°C. Therefore, cooling the meat through this temperature range and removing the latent heat takes the most time during freezing.

Meat can be kept at an internal temperature of -2 to -1°C for local use and storage for *under a week*. Meat must be frozen and stored at much lower temperatures for *long-term storage*. The lower the storage temperature, the longer the storage life of meat products, as shown in Table 17-7.

The *internal temperature* of carcasses entering the cooling sections varies from 38 to 41°C for hogs and from 37 to 39°C for lambs and calves. It takes about 15 h to cool the hogs and calves to the recommended temperature of 3 to 4°C. The cooling-room temperature is maintained at -1 to 0°C and the temperature difference between the refrigerant and the cooling air is kept at about 6°C. Air is circulated at a rate of about 7 to 12 air changes per hour. *Lamb carcasses* are cooled to an internal temperature of 1 to 2°C, which takes about 12 to 14 h, and are held at that temperature with 85 to 90 percent relative humidity until shipped or processed. The recommended rate of *air circulation* is 50 to 60 air changes per hour during the first 4 to 6 h, which is reduced to 10 to 12 changes per hour afterward.

*Freezing* does not seem to affect the *flavor* of meat much, but it affects the *quality* in several ways. The *rate* and *temperature* of freezing may influence color, tenderness, and drip. Rapid freezing increases tenderness and reduces the tissue damage and the amount of drip after thawing. Storage at low freezing temperatures causes significant changes in *animal fat*. Frozen pork experiences more undesirable changes during storage because of its fat structure, and thus its acceptable storage period is shorter than that of beef, veal, or lamb.

Meat storage facilities usually have a *refrigerated shipping dock* where the orders are assembled and shipped out. Such docks save valuable storage space from being used for shipping purposes and provide a more acceptable working environment for the employees. Packing plants that ship whole or half carcasses in bulk quantities may not need a shipping dock; a load-out door is often adequate for such cases.

A refrigerated *shipping dock*, as shown in Fig. 17-27, reduces the *refrigeration load* of freezers or coolers and prevents *temperature fluctuations* in the storage area. It is often adequate to maintain the shipping docks at 4 to 7°C for the coolers and about 1.5°C for the freezers. The dew point of the dock air should be below the product temperature to avoid condensation on the surface of the products and loss of quality. The rate of *airflow* through the loading doors and other openings is proportional to the *square root* of the temperature difference, and thus reducing the temperature difference at the opening by half by keeping the shipping dock at the average temperature reduces the rate of airflow into the dock and thus into the freezer by  $1 - \sqrt{0.5} \approx 0.3$ , or 30 percent. Also, the air that flows into the freezer is already cooled to about 1.5°C by the refrigeration unit of the dock, which represents about 50 percent of the cooling load of the incoming air. Thus, the net effect of the refrigerated shipping dock is a reduction of the *infiltration load* of the freezer by about 65 percent since  $1 - 0.7 \times 0.5 = 0.65$ . The net gain is equal to the difference between the reduction of the infiltration load of the freezer and the refrigeration load of the shipping dock. Note that the dock refrigerators operate at much higher temperatures (1.5°C instead of about –23°C), and thus they consume much less power for the same amount of cooling.

## Poultry Products

Poultry products can be preserved by *ice-chilling* to 1 to 2°C or deep *chilling* to about –2°C for short-term storage, or by *freezing* them to –18°C or below for long-term storage. Poultry processing plants are completely *automated*, and the small size of the birds makes continuous conveyor line operation feasible.

The birds are first electrically stunned before cutting to prevent struggling, and to make the killing process more humane (!). Following a 90- to 120-s bleeding time, the birds are *scalded* by immersing them into a tank of warm water, usually at 51 to 55°C, for up to 120 s to loosen the feathers. Then the feathers are removed by feather-picking machines, and the eviscerated carcass is *washed* thoroughly before chilling. The internal temperature, of the birds ranges from 24 to 35°C after washing, depending on the temperatures of the ambient air and the washing water as well as the extent of washing.

To control the microbial growth, the USDA regulations require that poultry be chilled to 4°C or below in less than 4 h for carcasses of less than 1.8 kg, in less than 6 h for carcasses of 1.8 to 3.6 kg, and in less than 8 h for carcasses more than 3.6 kg. Meeting these requirements today is not difficult since the

**FIGURE 17-27**

A refrigerated truck dock for loading frozen items to a refrigerated truck.

**FIGURE 17-28**

Air chilling causes dehydration and thus weight loss for poultry, whereas immersion chilling causes a weight gain as a result of water absorption.

slow *air chilling* is largely replaced by the rapid *immersion chilling* in tanks of slush ice. Immersion chilling has the added benefit that it not only prevents dehydration, but it causes a *net absorption of water* and thus increases the mass of salable product. Cool air chilling of unpacked poultry can cause a moisture loss of 1 to 2 percent, while water immersion chilling can cause a moisture absorption of 4 to 15 percent (Fig. 17-28). Water spray chilling can cause a moisture absorption of up to 4 percent. Most water absorbed is held between the flesh and the skin and the connective tissues in the skin. In immersion chilling, some soluble solids are lost from the carcass to the water, but the loss has no significant effect on flavor.

Many slush ice tank chillers today are replaced by *continuous* flow-type immersion slush ice chillers. Continuous slush ice-chillers can reduce the internal temperature of poultry from 32 to 4°C in about 30 minutes at a rate up to 10,000 birds per hour. Ice requirements depend on the inlet and exit temperatures of the carcass and the water, but 0.25 kg of ice per kg of carcass is usually adequate. However, *bacterial contamination* such as salmonella remains a concern with this method, and it may be necessary to chlorinate the water to control contamination.

*Tenderness* is an important consideration for poultry products just as it is for red meat, and preserving tenderness is an important consideration in the cooling and freezing of poultry. Birds cooked or frozen before passing through rigor mortis remain very tough. Natural tenderization begins soon after slaughter and is completed within 24 h when birds are held at 4°C. Tenderization is rapid during the first three hours and slows down thereafter. Immersion in hot water and cutting into the muscle adversely affect tenderization. Increasing the *scalding temperature* or the scalding time has been observed to increase toughness, and decreasing the scalding time has been observed to increase tenderness. The *beating action* of mechanical feather-picking machines causes considerable toughening. Therefore, it is recommended that any cutting be done after tenderization. *Cutting up* the bird into pieces before natural tenderization is completed reduces tenderness considerably. Therefore, it is recommended that any cutting be done after tenderization. *Rapid chilling* of poultry can also have a toughening effect. It is found that the tenderization process can be speeded up considerably by a patented *electrical stunning* process.

Poultry products are *highly perishable*, and thus they should be kept at the *lowest* possible temperature to maximize their shelf life. Studies have shown that the populations of certain bacteria double every 36 h at -2°C, 14 h at 0°C, 7 h at 5°C, and less than 1 h at 25°C (Fig. 17-29). Studies also show that the total bacterial counts on birds held at 2°C for 14 days are equivalent to those held at 10°C for 5 days or 24°C for 1 day. It has also been found that birds held at -1°C had 8 days of additional shelf life over those held at 4°C.

The growth of microorganisms on the *surfaces* of the poultry causes the development of an *off-odor* and *bacterial slime*. The higher the initial amount of bacterial contamination, the faster the sliming occurs. Therefore, good sanitation practices during processing such as cleaning the equipment frequently and washing the carcasses are as important as the storage temperature in extending shelf life.

Poultry must be frozen *rapidly* to assure a light, pleasing appearance. Poultry that is frozen slowly appears dark and develops large ice crystals that damage the tissue. The ice crystals formed during rapid freezing are small.

**FIGURE 17-29**

The storage life of fresh poultry decreases exponentially with increasing storage temperature.

Delaying freezing of poultry causes the ice crystals to become larger. Rapid freezing can be accomplished by forced air at temperatures of  $-23$  to  $-40^{\circ}\text{C}$  and velocities of 1.5 to 5 m/s in *air-blast tunnel freezers*. Most poultry is frozen this way. Also, the packaged birds freeze much faster on open shelves than they do in boxes. If poultry packages must be frozen in boxes, then it is very desirable to leave the boxes open or to cut holes on the boxes in the direction of airflow during freezing. For best results, the blast tunnel should be fully loaded across its cross-section with even spacing between the products to assure uniform airflow around all sides of the packages. The freezing time of poultry as a function of refrigerated air temperature is given in Fig. 17-30. Thermal properties of poultry are given in Table 17-8.

Other freezing methods for poultry include sandwiching between *cold plates*, *immersion* into a refrigerated liquid such as glycol or calcium chloride brine, and *cryogenic cooling* with liquid nitrogen. Poultry can be frozen in several hours by cold plates. Very high freezing rates can be obtained by *immersing* the packaged birds into a low-temperature brine. The freezing time of birds in  $-29^{\circ}\text{C}$  brine can be as low as 20 min, depending on the size of the bird (Fig. 17-31). Also, immersion freezing produces a very appealing light appearance, and the high rates of heat transfer make continuous line operation feasible. It also has lower initial and maintenance costs than forced air, but *leaks* into the packages through some small holes or cracks remain a concern. The convection transfer coefficient is  $17 \text{ W/m}^2 \cdot ^{\circ}\text{C}$  for air at  $-29^{\circ}\text{C}$  and 2.5 m/s whereas it is  $170 \text{ W/m}^2 \cdot ^{\circ}\text{C}$  for sodium chloride brine at  $-18^{\circ}\text{C}$  and a velocity of 0.02 m/s. Sometimes liquid nitrogen is used to crust freeze the poultry products to  $-73^{\circ}\text{C}$ . The freezing is then completed with air in a holding room at  $-23^{\circ}\text{C}$ .

Properly packaged poultry products can be *stored* frozen for up to about a year at temperatures of  $-18^{\circ}\text{C}$  or lower. The storage life drops considerably at higher (but still below-freezing) temperatures. Significant changes occur in flavor and juiciness when poultry is frozen for too long, and a stale rancid odor develops. Frozen poultry may become dehydrated and experience **freezer burn**, which may reduce the eye appeal of the product and cause toughening of the affected area. Dehydration and thus freezer burn can be controlled by *humidification*, *lowering* the storage temperature, and packaging the product in essentially *impermeable* film. The storage life can be extended by packing the poultry in an *oxygen-free* environment. The bacterial counts in precooked frozen products must be kept at safe levels since bacteria may not be destroyed completely during the reheating process at home.

Frozen poultry can be *thawed* in ambient air, water, refrigerator, or oven without any significant difference in taste. Big birds like turkey should be thawed safely by holding it in a refrigerator at 2 to  $4^{\circ}\text{C}$  for two to four days, depending on the size of the bird. They can also be thawed by immersing them into cool water in a large container for 4 to 6 h, or holding them in a paper bag. Care must be exercised to keep the bird's surface *cool* to minimize *microbiological growth* when thawing in air or water.

## Fish

Fish is a *highly perishable* commodity, and the preservation of fish starts on the vessel as soon as it is caught. Fish deteriorates quickly because of bacterial and enzymatic activities, and *refrigeration* reduces these activities and

Note: Freezing time is the time required for temperature to fall from 0 to  $-4^{\circ}\text{C}$ . The values are for 2.3 to 3.6 kg chickens with initial temperature of 0 to  $2^{\circ}\text{C}$  and with air velocity of 2.3 to 2.8 m/s.

FIGURE 17-30

The variation of freezing time of poultry with air temperature.

(From van der Berg and Lenz, 1958.)

delays spoilage. Different species have different refrigeration requirements, and thus different practices exist for different species. *Large fish* are usually eviscerated, washed, and iced in the pens of the vessel's hold. *Smaller fish* such as ocean perch and flounder are iced directly without any processing. *Lobsters* and *crabs* are usually stored alive on the vessel without refrigeration. The fish caught in the arctic waters in winter are frozen by the cold weather and marketed as frozen fish. Salmon and halibut are usually stored in tanks of refrigerated sea water at -1°C. Fish raised in *aquaculture farms* are usually caught on demand and sold fresh in containers covered with ice. The ice used in the fishing industry can be a source of bacterial contamination itself, and thus ice should be made from chlorinated or potable water.

Fish are normally stored in chill rooms at 2°C as they await processing. They are packed in containers of 2- to 16-kg capacity in wet ice after processing and are transported to intended locations. It is desirable to keep fish *uniformly chilled* within 0 to 2°C during transit. At retail stores, fish should be displayed in special fish counters. Displaying in meat cases reduces the shelf life of fish considerably since the temperature of the meat case may be 4°C or higher.

The *maximum storage life* of fresh fish is 10 to 15 days, depending on the particular species, if it is properly iced and stored in refrigerated rooms at 0 to 2°C. Temperatures below 0°C should be avoided in storage rooms since they slow ice melting, which can result in high fish temperatures. Also, the humidity of the storage facility should be over 90 percent and the air velocity should be low to minimize dehydration. The shelf life of fresh fish can be doubled or tripled by treating the fish with *ionizing radiation*. Radiation has no adverse effect on quality, but consumer resistance has prevented its wide spread use. The shelf life can also be extended by inhibiting the growth of bacteria by storing the fish in a *modified atmosphere* with high levels of carbon dioxide and low levels of oxygen.

Fish are commonly frozen for *long-term storage*. Some fatty fish species such as *mackerel* turn rancid during storage and are not suitable for long-term storage. But others such as *cod* respond well to freezing and have a much

longer frozen storage life. The storage temperature of frozen fish should be as low as possible to maximize the storage life and to avoid oxidation of fish oils and the resulting off-flavor. Frozen fish should be stored at  $-26^{\circ}\text{C}$  or below (Fig. 17–32). Storage at  $-29^{\circ}\text{C}$  results in a shelf life of one year or more, but even occasional storage at  $-23^{\circ}\text{C}$  or above results in a rapid loss of quality and shortened storage life. Low temperatures retard bacterial activity but do not stop deterioration entirely. As a result, fish that is stored too long exhibits a marked loss of quality. Poorly stored fish become opaque, dull, and spongy when thawed, and the flesh may lose integrity and break up. The overall quality of frozen fish depends on the *condition* of the fish before freezing, the *freezing method*, and the *temperature and humidity* during storage and transportation.

The *packaging material* used should be thick enough to protect the product, but thin enough to allow rapid freezing while providing adequate protection against moisture loss during frozen storage. It is important to snug fit the product in the package to reduce the air space and its insulating effect and the resulting high freezing costs. Also, the freezing time of packaged fish fillets in plate freezers is proportional to the square of the package thickness. Therefore, packages that are too thick should be avoided to keep freezing time and cost at reasonable levels. Tightly fit packages also reduce moisture migration from the product to the inner surfaces of the package.

*Air-blast freezers* are commonly used to freeze fish with air velocities between 2.5 and 7.5 m/s. High velocities result in faster freezing but also higher unit freezing cost. They may also cause *freezer burn* and dehydration of unpacked fish. Typical freezing times of various fish packages are given in Fig. 17–33.

Fish products packaged in 2.5- and 5-kg boxes are often cooled by *plate freezers* rapidly and efficiently. The air spaces in packages must be minimized for effective plate freezing. Fish fillets are sometimes frozen by combined

**FIGURE 17–32**

Frozen fish must be stored at  $-26^{\circ}\text{C}$  or below to preserve high quality.

**FIGURE 17–33**

Freezing time of fish fillets and fish sticks in a tunnel-type blast freezer.

(From ASHRAE, Handbook: Refrigeration, Chap. 13, Fig. 2.)

conduction and convection by placing them on a slowly moving refrigerated stainless steel belt through an air-blast tunnel. Plate freezers are also used in large fishing vessels to freeze fish. *Immersion freezing* is not suitable for packaged products but is commonly used for freezing tuna at sea as well as shrimp and crab. Sodium chloride brine is commonly used for this purpose.

Frozen fish are *transported* in refrigerated trucks, railroad cars, or ships capable of maintaining  $-18^{\circ}\text{C}$  over long distances under various weather conditions. The vehicles are precooled to at least  $-12^{\circ}\text{C}$  before loading, and fish is stored at  $-18^{\circ}\text{C}$  or below in retail stores. Frozen fish must be thawed in a refrigerator to avoid rapid deterioration.

### EXAMPLE 17-5 Chilling of Beef Carcasses in a Meat Plant

The chilling room of a meat plant is  $18 \text{ m} \times 20 \text{ m} \times 5.5 \text{ m}$  in size and has a capacity of 450 beef carcasses. The power consumed by the fans and the lights of the chilling room are 26 and 3 kW, respectively, and the room gains heat through its envelope at a rate of 13 kW. The average mass of beef carcasses is 285 kg. The carcasses enter the chilling room at  $36^{\circ}\text{C}$  after they are washed to facilitate evaporative cooling and are cooled to  $15^{\circ}\text{C}$  in 10 h. The water is expected to evaporate at a rate of 0.080 kg/s. The air enters the evaporator section of the refrigeration system at  $0.7^{\circ}\text{C}$  and leaves at  $-2^{\circ}\text{C}$ . The air side of the evaporator is heavily finned, and the overall heat transfer coefficient of the evaporator based on the air side is  $20 \text{ W/m}^2 \cdot ^{\circ}\text{C}$ . Also, the average temperature difference between the air and the refrigerant in the evaporator is  $5.5^{\circ}\text{C}$ . Determine (a) the refrigeration load of the chilling room, (b) the volume flow rate of air, and (c) the heat transfer surface area of the evaporator on the air side, assuming all the vapor and the fog in the air freezes in the evaporator.

FIGURE 17-34

Schematic for Example 17-5.

**SOLUTION** The chilling room of a meat plant with a capacity of 450 beef carcasses is considered. The cooling load, the air-flow rate, and the heat transfer area of the evaporator are to be determined.

**Assumptions** 1 Water evaporates at a rate of 0.080 kg/s. 2 All the moisture in the air freezes in the evaporator.

**Properties** The heat of fusion and the heat of vaporization of water at  $0^{\circ}\text{C}$  are 333.7 kJ/kg and 2501 kJ/kg. The density and specific heat of air at  $0^{\circ}\text{C}$  are  $1.292 \text{ kg/m}^3$  and  $1.006 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ . Also, the specific heat of beef carcass is determined from the relation in Table A-7b to be

$$c_p = 1.68 + 2.51 \times (\text{water content}) = 1.68 + 2.51 \times 0.58 = 3.14 \text{ kJ/kg} \cdot ^{\circ}\text{C}$$

**Analysis** (a) A sketch of the chilling room is given in Fig. 17-34. The amount of beef mass that needs to be cooled per unit time is

$$\begin{aligned} \dot{m}_{\text{beef}} &= (\text{Total beef mass cooled}) / (\text{Cooling time}) \\ &= (450 \text{ carcasses})(285 \text{ kg/carcass}) / (10 \times 3600 \text{ s}) = 3.56 \text{ kg/s} \end{aligned}$$

The product refrigeration load can be viewed as the energy that needs to be removed from the beef carcass as it is cooled from  $36^{\circ}\text{C}$  to  $15^{\circ}\text{C}$  at a rate of 3.56 kg/s and is determined to be

$$\dot{Q}_{\text{beef}} = (\dot{m} c_p \Delta T)_{\text{beef}} = (3.56 \text{ kg/s})(3.14 \text{ kJ/kg} \cdot ^{\circ}\text{C})(36 - 15)^{\circ}\text{C} = 235 \text{ kW}$$

Then the total refrigeration load of the chilling room becomes

$$\dot{Q}_{\text{total, chill room}} = \dot{Q}_{\text{beef}} + \dot{Q}_{\text{fan}} + \dot{Q}_{\text{lights}} + \dot{Q}_{\text{heat gain}} = 235 + 26 + 3 + 13 = 277 \text{ kW}$$

The amount of carcass cooling due to evaporative cooling of water is

$$\dot{Q}_{\text{beef, evaporate}} = (\dot{m}h_{fg})_{\text{water}} = (0.080 \text{ kg/s})(2501 \text{ kJ/kg}) = 200 \text{ kW}$$

which is  $200/235 = 85$  percent of the total product cooling load. The remaining 15 percent of the heat is transferred by convection and radiation.

(b) Heat is transferred to air at the rate determined above, and the temperature of the air rises from  $-2^\circ\text{C}$  to  $0.7^\circ\text{C}$  as a result. Therefore, the mass flow rate of air is

$$\dot{m}_{\text{air}} = \frac{\dot{Q}_{\text{air}}}{(c_p \Delta T_{\text{air}})} = \frac{277 \text{ kW}}{(1.006 \text{ kJ/kg} \cdot ^\circ\text{C})(0.7 - (-2)^\circ\text{C})} = 102.0 \text{ kg/s}$$

Then the volume flow rate of air becomes

$$\dot{V}_{\text{air}} = \frac{\dot{m}_{\text{air}}}{r_{\text{air}}} = \frac{102.0 \text{ kg/s}}{1.292 \text{ kg/m}^3} = 78.9 \text{ m}^3/\text{s}$$

(c) Normally the heat transfer load of the evaporator is the same as the refrigeration load. But in this case the water that enters the evaporator as a liquid is frozen as the temperature drops to  $22^\circ\text{C}$ , and the evaporator must also remove the latent heat of freezing, which is determined from

$$\dot{Q}_{\text{freezing}} = (\dot{m}h_{\text{latent}})_{\text{water}} = (0.080 \text{ kg/s})(333.7 \text{ kJ/kg}) = 27 \text{ kW}$$

Therefore, the total rate of heat removal at the evaporator is

$$\dot{Q}_{\text{evaporator}} = \dot{Q}_{\text{total, chill room}} + \dot{Q}_{\text{freezing}} = 277 + 27 = 304 \text{ kW}$$

Then the heat transfer surface area of the evaporator on the air side is determined from  $\dot{Q}_{\text{evaporator}} = (UA)_{\text{air side}} \Delta T$ ,

$$A = \frac{\dot{Q}_{\text{evaporator}}}{U \Delta T} = \frac{304,000 \text{ W}}{(20 \text{ W/m}^2 \cdot ^\circ\text{C})(5.5^\circ\text{C})} = 2764 \text{ m}^2$$

Obviously, a finned surface must be used to provide such a large surface area on the air side.

## 17-6 • REFRIGERATION OF EGGS, MILK, AND BAKERY PRODUCTS

Eggs are important sources of nutrients, minerals, and vitamins, and they have a unique place in the diets of practically all cultures. Most eggs are consumed as *shell eggs*, while the rest are processed for use in other products such as mayonnaise and dehydrated egg products. The production and consumption of eggs remain fairly steady throughout the year, and thus the freezing of eggs

**TABLE 17-9**

Some properties of fresh chicken eggs

| Quantity        | Typical value          |
|-----------------|------------------------|
| Average mass    | 60 g                   |
| Average density | 1080 kg/m <sup>3</sup> |
| Specific heat   | 3.23 kJ/kg · °C        |
| Freezing point  | -2.2°C                 |
| Water content   | 66 percent             |
| Latent heat     | 220 kJ/Kg              |

for long-term storage is not practical. However, eggs are highly perishable and must be *refrigerated* to preserve quality and to assure a reasonable shelf life.

Various properties of eggs are listed in Table 17-9. The average density of fresh eggs is 1080 kg/m<sup>3</sup>, and thus fresh eggs settle at the bottom when they are put into a cup of water. The density decreases with time, however, as the egg loses moisture and the vacant space is filled with air. The egg shell contains about 17,000 pores through which air, water vapor, and microorganisms can pass. The *mass* of a chicken egg varies from about 35 to 80 g, with an average of 60 g. The white, the yolk, and the shell of an egg constitute 58, 31, and 11 percent of the egg mass, respectively.

In modern farms, eggs *laid* by the hens roll through the sloped floor onto a *conveyor* that transports the eggs to a *packing machine* that aligns the eggs into rows of 12 or 18. The dirt on eggs is a source of bacteria that may cause *m* decomposition and spoilage. Therefore, the eggs are routed to the *washing section* where they are washed with warm detergent water at a temperature of 43 to 52°C by a series of sprays and brushes and are *rinsed* with warm water and sanitized with chlorine or another chemical. The temperature, of eggs rises by about 3°C during washing. The eggs are then *dried* by air, *oiled*, and *checked* for internal and external defects under a high intensity light. The defective eggs are removed, and the remaining ones are *sized* automatically and are *packaged* into 12- or 18-egg cartons or flats.

*Egg cartons* are made of paper pulp or foam plastic, which are good insulating materials. Cartons that have *openings* on the top facilitate both viewing and cooling. Eggs in such stacks of cartons can be cooled by blasting cold air toward the openings. Cooling pallets of packed eggs by leaving them in cold storage may take two days or more since cold air will have difficulty reaching the mid section. Eggs are cooled most effectively on a *spiral belt cooler* after washing and before packaging, but incorporation of this cooling approach may require some costly modifications in most facilities. Cooling the eggs from about 32°C to about 7 to 13°C takes usually less than 1 h in this case. The eggs could also be cooled after they are packed provided that the boxing material does not prevent the air from flowing through the eggs, but the cooling time in this case would be considerably longer.

The most practical and effective way of preserving the quality of eggs and extending the storage life is *refrigeration*, which should start at the farm and continue through retail outlets. Shell eggs can be stored at 7 to 13°C and 75 to 80 percent relative humidity for *a few weeks*. Eggs lose about 1 percent of their mass per week as moisture. *Condensation* on the egg surfaces should be avoided since wet surfaces are conducive to bacterial and mold growth. Therefore, high moisture levels in storage rooms are undesirable. The chemical reactions that occur in eggs over time cause the yolk membrane to thin and the white to become watery. Absorption of *odors* from the environment also affects the flavor of eggs.

## Milk

Milk is one of the most essential foods for humans, but also one of the most suitable environments for the *growth* of microorganisms (Fig. 17-35). Therefore, the production and processing of milk are heavily regulated. A dairy farmer must meet stringent federal and state *regulations* to produce Grade A milk, such as having healthy cows and adequate and sanitary facilities and

**FIGURE 17-35**

A label on a milk carton by Model Dairy that emphasizes the importance of storage temperature.

equipment, and maintaining a bacteria count of less than 100,000 per mL. Also, the milk should not have objectionable flavors and odors.

The cows in a dairy farm are *mechanically milked*, and the milk flows into an insulated stainless steel *bulk tank* through sanitary tubes. The milk is *stirred* by an agitator and is *cooled* as milking continues. The raw milk is constantly agitated to maintain uniform milkfat distribution. The refrigeration capacity of the tank must be sufficient to cool 50 percent of its capacity from 32.2 to 10°C during the first hour, and from 10 to 4.4°C during the second hour. Milk is usually delivered to a dairy plant in a *stainless steel tank* on a truck. The tank is adequately *insulated* so that refrigeration is not required during transportation. The temperature rise of the tank filled with milk should not exceed 1.1°C in 18 h when the average temperature difference between the milk and the ambient air is 16.7°C. Horizontal storage tanks must also meet the same requirement.

A dairy plant receives, processes, and packages the milk. The minimum amounts of *milkfat* and *nonfat solids* in the milk are regulated. For example, the minimum legal milkfat requirements are 3.25 percent for whole milk, 0.5 percent for lowfat or skim milk (the milkfat contents of lowfat and skim milk in the market are about 2.0 and 0.5 percent, respectively), 18 percent for sour cream, and 36 percent for heavy cream (Fig. 17–36). The minimum legal requirement for nonfat solids in milk is 8.25 percent. The stored milk is first **standardized** to bring the milkfat content to desired levels using a *milk separator*. The separation of milkfat is easier and more efficient at higher temperatures. Therefore, milk is usually heated from the storage temperature of 4.4°C to about 20 to 33°C in warm milk separators. Only a portion of the milk needs to be separated. The remaining milk can be standardized by adding the required amount of skim milk or milkfat.

To kill the bacteria, milk is **pasteurized** in a batch or continuous flow type system by heating the milk to a *minimum temperature* of 62.8°C normally by hot water or steam and holding it at that temperature for at least 30 min. Milk can also be pasteurized *quickly* by heating it to 71.7°C or above and holding it at that temperature at least 15 s (Fig. 17–37). Fast pasteurization is very suitable for continuous-type systems.

The pasteurized milk is first *cooled* to the environment temperature by the plant's *cold water*, and then it is cooled to 4.4°C or less by *refrigerated water* usually in plate-type heat exchangers. The entire cooling process should be completed in less than 1 h for sanitary reasons. The continuous-type pasteurizers are equipped with a *regenerator*, which is a counterflow heat exchanger in which the incoming cold raw milk is heated by the hot pasteurized milk as it is cooled. The flow rates of both the pasteurized and the raw milk are the same, and thus the temperature drop of pasteurized milk will be practically equal to the temperature rise of the raw milk. The effectiveness of the regenerators are in the range of 80 to 90 percent.

The taste of milk depends on the feed of the cattle, and the milk is usually **vacuum processed** after pasteurization to reduce the *undesirable flavors* and *odors* in it. In this process, the temperature of pasteurized milk is raised to 82 to 93°C by injecting hot steam into it and then spraying the mixture into a vacuum chamber where it is cooled by evaporation to the pasteurizing temperatures. The vapor as well as the noncondensable gases responsible for the odors and off-flavor are removed by the vacuum pump. The unit is

FIGURE 17-36

Typical milkfat contents of whole, lowfat, and skim milk.

FIGURE 17-37

The pasteurizing time of milk can be minimized by raising the pasteurization temperature.

designed such that the amount of moisture removed is equal to the amount of steam added by the steam injector.

The milk is also **homogenized** before it is packaged to *break up* the large fat globules into smaller ones, usually under 2  $\mu\text{m}$  in size, to give it a “homogeneous” appearance. Homogenization distributes milkfat throughout the body of milk and prevents the milkfat from collecting at the top because of its lower density. This is done by pumping the warm milk at 56 to 82°C to a high pressure (usually 8 to 17 MPa) and shearing off the large globules by forcing the milk through homogenizing valves.

The homogenized milk is *refrigerated* again to about 4°C and is *packaged* in the familiar paperboard, plastic, or glass containers for distribution in refrigerated trucks. The paperboard carton is made of a 0.41-mm-thick paper layer with 0.025- and 0.019-mm polyethylene film laminated on the inside and outside, respectively. Plastic containers have a mass of about 60 g and are made from polyethylene resin by blow-molding. Other milk products such as yogurt, cheese, cream, and ice cream are produced by processing the milk further.

## Baked Products

Refrigeration plays an important part in all stages of modern bakery production from the preservation of raw materials such as flour and yeast to the cooling of finished dough. *Flour* is usually stored in bins in air-conditioned spaces at ambient temperatures. It is important to filter the *flour dust* in the air since it may settle on the heat transfer surfaces of the air-conditioning system and reduce heat transfer. *Yeast* is dormant at temperatures below 7°C, and thus it is stored in refrigerated spaces below 7°C but above its freezing point of -3.3°C since freezing kills most cells. Yeast is most active in the temperature range of 27 to 38°C, especially in the presence of nutrients such as *sugar* and *water*, but temperatures above 60°C must be avoided since yeast cells cannot survive at those temperatures. Ingredients such as *corn syrup* and *liquid sugar* are stored in heated tanks at about 52°C to prevent thickening and crystallization.

The first step in the preparation of baked products is the *mixing* of flour, yeast, water, and other ingredients, depending on the kind of product, into dough. The temperature of the dough tends to rise during mixing as a result of the *heat of hydration*, which is the heat released when dry flour absorbs water, and the *heat of friction*, which is the mechanical energy supplied to the mixer by the motor. Therefore, *cooling* is needed during kneading of the dough. The easiest way to maintain the dough at the desired temperature of 26 to 27°C is to cool the water to 2 to 4°C before mixing it with the other ingredients. Another method is to cool the mixing chamber externally with water jackets.

After mixing, the dough is allowed to *ferment* in a room maintained at about 27°C and 75 percent relative humidity for a period of 3.5 to 5 h. The dough temperature rises by about 5°C during fermentation. Some water as well as other *fermentation gases* such as alcohols and esters evaporate from the dough surface, and the rate of evaporation depends on the relative humidity of the environment and the air velocity.

The dough is formed into *loaves* and is kept in an enclosure at 35 to 49°C for about 1 h. The fully developed loaves are then *baked*, usually in gas-fired ovens at 200 to 230°C for 18 to 30 min, depending on the type of bread. The hot air in the oven is circulated to ensure uniform baking. The exposed

surfaces of the loaves are *sprayed with steam* to caramelize the sugars on the surface at early stages of baking to obtain a gold-colored crust. The temperature of the baked loaves is about 95°C inside and 230°C on the crust. The baked loaves are allowed to *cool* in racks to about 32 to 35°C, which takes about 1.5 to 3 h before they are bagged and shipped. The cooling time can be shortened by using forced airflow. The cooling rate is high initially because of the large temperature difference between the bread and the ambient air and the evaporative cooling due to the vaporization of the moisture in the bread (Fig. 17-38).

Bread starts losing its *freshness* shortly after baking as a result of the *starch crystallizing* and *losing moisture*, producing a crumbly texture. A tight wrap can slow the process by sealing the moisture in. Bread freezes at about  $-8^{\circ}\text{C}$ . To preserve quality and to keep the cellular structure intact, the bread must be cooled as fast as possible; Wrapped bread loaves can be cooled from an internal temperature of  $21^{\circ}\text{C}$  to  $-10^{\circ}\text{C}$  with cold air at  $-29^{\circ}\text{C}$  and  $3.5 \text{ m/s}$  in about 3 h. Unwrapped bread will freeze faster, but the moisture loss in this case will be excessive. *Frozen bread* can be defrosted at room temperature with satisfactory results. The thermal properties of baked products are given in Table 17-10.

FIGURE 17-38

The variation of temperature and moisture loss of a hot bread with time in a counterflow bread-cooling tunnel.

(From ASHRAE, Handbook: Refrigeration, Chap. 20 Fig. 1.)

### EXAMPLE 17-6 Retrofitting a Dairy Plant with a Regenerator

In a dairy plant, milk at  $40^{\circ}\text{F}$  is pasteurized continuously at  $162^{\circ}\text{F}$  at a rate of 2 gallons/s (Fig. 17-39). The milk is heated to pasteurizing temperature by hot water heated in a natural gas-fired boiler having an efficiency of 78 percent. The pasteurized milk is then cooled by cold water at  $60^{\circ}\text{F}$  before it is finally refrigerated back to  $40^{\circ}\text{F}$ . The plant is considering buying a regenerator with a certified effectiveness of 86 percent to save energy and water. The cost of the regenerator is \$150,000 installed, and the plant is not interested in any retrofitting project that has a payback period of more than three years. If the cost of natural gas is  $\$0.60/\text{therm}$  ( $1 \text{ therm} = 100,000 \text{ Btu}$ ), determine if the dairy plant can justify purchasing this regenerator.

**SOLUTION** A regenerator is considered to save heat during the cooling of milk in a dairy plant. It is to be determined if such a generator will pay for itself from the fuel it saves in less than three years.

**Assumptions** The density and specific heat of milk are constant.

**Properties** The average density and specific heat of milk can be taken to be  $\rho_{\text{milk}} \approx \rho_{\text{water}} = 62.4 \text{ lbm/ft}^3 = 8.35 \text{ lbm/gal}$  and  $c_{p,\text{milk}} = 0.928 \text{ Btu/lbm} \cdot ^{\circ}\text{F}$  (Table A-7Eb).

**Analysis** The mass flow rate of the milk is

$$\dot{m}_{\text{milk}} = \rho \dot{V}_{\text{milk}} = (8.35 \text{ lbm/gal})(2 \text{ gal/s}) = 16.7 \text{ lbm/s} = 60,120 \text{ lbm/h}$$

To heat the milk from  $40$  to  $162^{\circ}\text{F}$ , as is being done currently, heat must be transferred to the milk at a rate of

$$\begin{aligned} \dot{Q}_{\text{current}} &= [\dot{m}c_p(T_{\text{pasteurization}} - T_{\text{refrigeration}})]_{\text{milk}} \\ &= (60,120 \text{ lbm/h})(0.928 \text{ Btu/lbm} \cdot ^{\circ}\text{F})(162 - 40)^{\circ}\text{F} = 6,807,000 \text{ Btu/h} \end{aligned}$$

TABLE 17-10

Thermal properties of baked products and their ingredients (from ASHRAE Handbook: Refrigeration, Chap. 20, Table 2)

| Quantity                   | Typical value                               |
|----------------------------|---|
| <b>Specific heat</b>       |   |
| Dough                      | $2.51 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ |
| Flour                      | $1.76 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ |
| Milk                       | $3.98 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ |
| Ingredient mixture         | $1.68 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ |
| Baked bread:               |   |
| Above freezing             | $2.93 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ |
| Below freezing             | $1.42 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ |
| Freezing point             | $-9 \text{ to } -7^{\circ}\text{C}$         |
| Latent heat of baked bread | $109.3 \text{ kJ/kg}$                       |
| Head of hydration of dough | $1.51 \text{ kJ/kg}$                        |

FIGURE 17-39

Schematic for Example 17-6.

The proposed regenerator has an effectiveness of  $\varepsilon = 0.86$ , and thus it will save 86 percent of this energy. Therefore,

$$\dot{Q}_{\text{saved}} = \varepsilon \dot{Q}_{\text{current}} = (0.86) (6,807,000 \text{ Btu/h}) = 5,854,000 \text{ Btu/h}$$

The boiler has an efficiency of  $\eta_{\text{boiler}} = 0.78$ , and thus the energy savings above correspond to fuel savings of

$$\text{Fuel savings} = \dot{Q}_{\text{saved}} / \eta_{\text{boiler}}$$

$$= (5,854,000 \text{ Btu/h}) / 0.78 \left( \frac{1 \text{ therm}}{100,000 \text{ Btu}} \right) = 75.05 \text{ therm/h}$$

Nothing that  $1 \text{ year} = 365 \times 24 = 8760 \text{ h}$ , the annual savings from the fuel cost will be

$$\begin{aligned} \text{Cost savings} &= (\text{Fuel savings})(\text{Unit cost of fuel}) \\ &= (75.05 \text{ therm/h})(8760 \text{ h/yr})(\$0.60/\text{therm}) = \$394,500/\text{yr} \end{aligned}$$

This gives the simple payback period of

$$\text{Payback period} = \frac{\text{Cost of equipment}}{\text{Annual cost savings}} = \frac{\$150,000}{\$394,500/\text{yr}} = 0.38 \text{ yr} = \mathbf{4.6 \text{ months}}$$

Therefore, **the proposed regenerator will pay for itself in about 4.6 months** from the natural gas cost it saves. The purchase and installation of the regenerator are definitely indicated in this case.

## 17-7 • REFRIGERATION LOAD OF COLD STORAGE ROOMS

Refrigerated spaces are maintained *below* the temperature of their surroundings, and thus there is always a driving force for heat flow toward the refrigerated space from the surroundings. As a result of this heat flow, the *temperature* of the refrigerated space will *rise* to the surrounding temperature unless the heat gained is promptly *removed* from the refrigerated space. A refrigeration system should obviously be large enough the remove the entire heat gain in order to maintain the refrigerated space at the desired low temperature. Therefore, the *size* of a refrigeration system for a specified refrigerated space is determined on the basis of the *rate of heat gain* of the refrigerated space.

The *total rate of heat gain* of a refrigerated space through all mechanisms under peak (or times of highest demand) conditions is called the **refrigeration load**, and it consists of (1) *transmission load*, which is heat conducted into the refrigerated space through its walls, floor, and ceiling; (2) *infiltration load*, which is due to surrounding warm air entering the refrigerated space through the cracks and open doors; (3) *product load*, which is the heat removed from the food products as they are cooled to refrigeration temperature; (4) *internal load*, which is heat generated by the lights, electric motors, and people in the refrigerated space; and (5) *refrigeration equipment load*, which is the heat

generated by the refrigeration equipment as it performs certain tasks such as reheating and defrosting (Fig. 17–40).

The size of the refrigeration equipment must be based on *peak refrigeration load*, which usually occurs when the outside temperature is high and the maximum amount of products is brought into the cool storage room at field temperatures.

## 1 Transmission Load

The *transmission load* depends on the materials and construction of the walls, floor, and ceiling of the refrigerated space, the surface area, the air motion or wind conditions inside or outside, and the temperature difference between the refrigerated space and the ambient air. The *rate of heat transfer* through a particular wall, floor, or ceiling section can be determined from

$$\dot{Q}_{\text{transmission}} = UA_o \Delta T \quad (17-9)$$

where

$A_o$  = outside surface area of the section

$\Delta T$  = temperature difference between the outside air and the air inside the refrigerated space

$U$  = overall heat transfer coefficient

Noting that the *thickness-to-thermal-conductivity* ratio of a layer represents its unit thermal resistance, the **overall heat transfer coefficient** is determined from (Fig. 17–41)

$$U = \frac{1}{\frac{1}{h_i} + \sum \frac{L}{k} + \frac{1}{h_o}} \quad (\text{W/m}^2 \cdot ^\circ\text{C}) \quad (17-10)$$

where

$h_i$  = heat transfer coefficient at the inner surface of the refrigerated space

$h_o$  = heat transfer coefficient at the outer surface of the refrigerated space

$\sum L/k$  = sum of the thickness-to-thermal-conductivity ratios of the layers that make up the section under consideration

For still air, it is common practice to take  $10 \text{ W/m}^2 \cdot ^\circ\text{C}$  for  $h_i$  and  $h_o$ . A value of 20 or  $30 \text{ W/m}^2 \cdot ^\circ\text{C}$  can be used for  $h_0$  for low or moderate wind conditions outside, respectively.

The walls, floor, and ceiling of typical refrigerated rooms are well insulated, and the *unit thermal resistance*  $L/k$  of the *insulation layer* is usually much larger than the  $L/k$  of other layers such as the sheet metals and the convective resistance  $1/h_i$  and  $1/h_o$ . Therefore, the thermal resistances of sheet metal layers can always be ignored. Also, the *convection resistances*  $1/h_i$  and  $1/h_o$  are often negligible, and thus having very accurate values of  $h_i$  and  $h_o$  is usually not necessary.

When constructing refrigerated rooms, it is desirable to use *effective insulation materials* to *minimize* the refrigerated space for a fixed floor area. Minimum insulation thicknesses for expanded polyurethane ( $k = 0.023 \text{ W/m} \cdot ^\circ\text{C}$ ) recommended by the refrigeration industry are given in Table 17–11. Note that the *larger* the temperature difference between the refrigerated space and

FIGURE 17-40

Various mechanisms of heat gain that make up the total refrigeration load of a refrigerated space.

FIGURE 17-41

The determination of thermal resistance and the overall heat transfer coefficient for a two-layer wall section for the calculation of transmission losses.

**TABLE 17-11**

Minimum recommended expanded polyurethane insulation thicknesses for refrigerated rooms (from ASHRAE, *Handbook: Refrigeration*, Chap. 26, Table 2)

| Storage Temperature | Northern United States | Southern United States |
|---------------------|------------------------|------------------------|
| 10 to 16°C          | 25 mm                  | 50 mm                  |
| 4 to 10°C           | 50 mm                  | 75 mm                  |
| -4 to 4°C           | 50 mm                  | 75 mm                  |
| -9 to -4°C          | 75 mm                  | 100 mm                 |
| -18 to -9°C         | 75 mm                  | 100 mm                 |
| -26 to -18°C        | 100 mm                 | 100 mm                 |
| -40 to -26°C        | 125 mm                 | 125 mm                 |

**FIGURE 17-42**

Solar heating effect on the west or east wall can be compensated for by adding 4°C to the ambient temperature.

the ambient air, the *thicker* the insulation required to reduce the transmission heat gain to reasonable levels. *Equivalent thicknesses* for other insulating materials can be obtained by multiplying the values in this table by  $k_{ins}/k_{poly}$  where  $k_{ins}$  and  $k_{poly}$  are the thermal conductivities of the insulation material and the polyurethane, respectively.

Direct exposure to the *sun* increases the refrigeration load of a refrigerated room as a result of the solar energy absorbed by the outer surface being conducted into the refrigerated space. The effect of *solar heating* can conveniently be accounted for by adding a few degrees to the ambient temperature. For example, the solar heating effect can be compensated for by adding 4°C to the ambient temperature for the east and west walls, 3°C for the south walls, and 9°C for flat rooms with medium-colored surfaces such as unpainted wood, brick, and dark cement (Fig. 17-42). For dark- (or light-) colored surfaces, we should add (or subtract) to 1°C (or from) these values.

## 2 Infiltration Load

The heat gain due to the surrounding warm air entering the refrigerated space through the cracks and the open doors continues the *infiltration load* of the refrigeration system (Fig 17-43). The infiltration load changes with time. We should consider the *maximum value* to properly size the refrigeration system, and the *average value* to properly estimate the average energy consumption. In installations that require the doors to remain open for long periods of time, such as distribution warehouses, the infiltration load may amount to more than half of the total refrigeration load.

In the absence of any *winds*, the infiltration is due to the *density difference* between the cold air in the refrigerated space and the surrounding warmer air. When the average velocity of the air entering the refrigerated space under the influence of winds or pressure differentials is known, the rate of infiltration heat gain can be determined from ASHRAE, *Handbook: Refrigeration*, Chap. 26, p. 5:

$$\dot{Q}_{\text{infiltration windy air}} = 6V_{\text{air}}A_{\text{leak}}c_{p,\text{air}}(T_{\text{warm}} - T_{\text{cold}})\rho_{\text{cold}}D_{\text{time}} \quad (17-11)$$

where

- $V_{\text{air}}$  = average air velocity, usually between 0.3 and 1.5 m/s
- $A_{\text{leak}}$  = smaller of the inflow or outflow opening areas,  $\text{m}^2$
- $c_{p,\text{air}}$  = specific heat of air, 1.0 kJ/kg · °C
- $T_{\text{warm}}$  = temperature of the warm infiltration air, °C
- $T_{\text{cold}}$  = temperature of the cold infiltration air, °C
- $\rho_{\text{cold}}$  = temperature of the cold refrigerated air, kg/m<sup>3</sup>
- $D_{\text{time}}$  = density open-time factor

There is considerable uncertainty in the determination of the infiltration load, and field experience from similar installations can be a valuable aid in calculations. A practical way of determining the infiltration load is to estimate the rate of air infiltration in terms of **air changes per hour** (ACH), which is the number of times tire entire air content of a room is replaced by the infiltrating air per hour. Once the number of air changes per hour is estimated, the *mass flow rate* of air infiltrating into the room is determined from

$$\dot{m}_{\text{air}} = \frac{V_{\text{room}}}{V_{\text{air}}} \text{ACH} \quad (\text{kg/h}) \quad (17-12)$$

where  $V_{\text{room}}$  is the volume of the room and  $v_{\text{room}}$  is the specific volume of the dry air in the room. Once  $\dot{m}_{\text{air}}$  is available, the sensible and latent infiltration loads of the cold storage room can be determined from

$$\dot{Q}_{\text{infiltration, sensible}} = \dot{m}_{\text{air}}(h_{\text{ambient}} - h_{\text{room}}) \quad (\text{kJ/h}) \quad (17-13)$$

$$\dot{Q}_{\text{infiltration, latent}} = (\omega_{\text{ambient}} - \omega_{\text{room}})\dot{m}_{\text{air}}h_{fg} \quad (\text{kJ/h}) \quad (17-14)$$

where  $\omega$  is the humidity ratio of air (the mass of water vapor in 1 kg of dry air),  $h$  is the enthalpy of air, and  $h_{fg}$  is the heat of vaporization of water. The values of specific volume  $v$ , enthalpy  $h$ , and the humidity ratio  $\omega$  can be determined from the *psychrometric chart* when the temperature and relative humidity (or wet-bulb temperature) of air are specified. The total infiltration load is then the sum of the sensible and latent components.

The value of ACH should be determined under the most adverse operating conditions (such as during loading or unloading and high winds) to ensure satisfactory performance under those conditions.

### 3 Product Load

The *heat removed* from the food products as they are cooled to refrigeration temperature and the heat released as the fresh fruits and vegetables respire in storage constitute the **product load** of the refrigeration system (Fig. 17-44). As we mentioned earlier, the *refrigeration* of foods involves cooling only, but the *freezing* of foods involves cooling to the freezing point (removing the sensible heat), freezing (removing the latent heat), and further cooling to the desired subfreezing temperature (removing the sensible heat of frozen food). The three components of the product load can be determined from

$$\dot{Q}_{\text{cooling, fresh}} = mc_{p,\text{fresh}}(T_1 - T_{\text{freeze}}) \quad (\text{kJ}) \quad (17-15)$$

$$\dot{Q}_{\text{freezing}} = mh_{\text{latent}} \quad (\text{kJ}) \quad (17-16)$$

$$\dot{Q}_{\text{cooling, frozen}} = mc_{p,\text{frozen}}(T_{\text{freeze}} - T_2) \quad (\text{kJ}) \quad (17-17)$$

where

$m$  = mass of the food product

$c_{p,\text{fresh}}$  = specific heat of the food before freezing

$c_{p,\text{frozen}}$  = specific heat of the food after freezing

$h_{\text{latent}}$  = latent heat of fusion of the food

$T_{\text{freeze}}$  = freezing temperature of the food

$T_1$  = initial temperature of the food (before refrigeration)

$T_2$  = final temperature of the food (after freezing)

The *rate of refrigeration* needed to cool a product from  $T_1$  to  $T_2$  during a time interval  $\Delta t$  can be determined from

$$\dot{Q}_{\text{product}} = \frac{\dot{Q}_{\text{product, total}}}{\Delta t} = \frac{\dot{Q}_{\text{cooling, fresh}} + \dot{Q}_{\text{freezing}} + \dot{Q}_{\text{cooling, frozen}}}{\Delta t} \quad (17-18)$$

Note that it will take a relatively short time for a powerful refrigeration system to accomplish the desired cooling.

Food products are usually refrigerated in their *containers*, and the product load also includes cooling the containers. The amount of heat that needs to be

**FIGURE 17-43**

The warm air that enters a refrigerated space finds its way out after it is cooled, and the heat removed from the air constitutes the infiltration load.

**FIGURE 17-44**

The heat removed from the food products as they are cooled constitutes the product load of a refrigeration system.

removed from the container as it is cooled from  $T_1$  to  $T_2$  can be determined from

$$Q_{\text{container}} = mc_{p,\text{container}}(T_1 - T_2) \quad (\text{kJ}) \quad (17-19)$$

where  $m$  is the mass of the container and  $c_{p,\text{container}}$  is the specific heat of the container, which is  $0.50 \text{ kJ/kg} \cdot ^\circ\text{C}$  for stainless steel,  $1.7 \text{ kJ/kg} \cdot ^\circ\text{C}$  for nylon,  $1.9 \text{ kJ/kg} \cdot ^\circ\text{C}$  for polypropylene, and  $2.3 \text{ kJ/kg} \cdot ^\circ\text{C}$  for polyethylene containers. The contribution of  $Q_{\text{container}}$  to the refrigeration load is usually very small and can be neglected.

## 4 Internal Load

The heat generated by the *people, lights, electric motors, and other heat-dissipating equipment* in the refrigerated space constitutes the **internal load** of the refrigeration system (Fig. 17-45). The rate of heat dissipation by people depends on the size of the person, the temperature of the refrigerated space, the activity level, and the clothing, among other things. A person must generate more heat at lower temperatures to compensate for the increased rate of heat transfer at higher temperature differences. The *heat dissipated* by an *average person* in a refrigerated space maintained at temperature  $T$  in  $^\circ\text{C}$  is expressed as (ASHRAE, *Handbook: Refrigeration*, Chap. 26, p. 3)

$$\dot{Q}_{\text{people}} = 270 - 6T(\text{°C}) \quad (\text{W/person}) \quad (17-20)$$

Therefore, an average person will dissipate 210 W of heat in a space maintained at  $10^\circ\text{C}$  and 360 W in a space at  $-15^\circ\text{C}$ .

The rate of heat dissipation from *lights* is determined by simply adding the wattage of the light bulbs and the fluorescent tubes. For example, five 100-W incandescent light bulbs and eight 40-W fluorescent tubes contribute 820 W to the refrigeration load when they all are on.

The calculation of the heat dissipation from the *motors* is more complicated because of the uncertainties involved in the operation such as the *motor efficiency*, the *load factor* (the fraction of the rated load at which the motor normally operates), and the *utilization factor* (the fraction of the time during which the motor actually runs), and whether the motor running a device such as a fan is located inside the refrigerated space. Noting that the motors are usually oversized, the rated power of a motor listed on its tag tells us little about its contribution to the refrigeration load. When the body of a motor running a device is housed *outside* the refrigerated space, then the internal heat load of this motor is simply the power consumed by the device in the refrigerated space. But when the motor is housed *inside* the refrigerated space, then the heat dissipated by the motor also becomes part of the internal heat load since this heat now must be removed from the refrigeration system. Keeping the motors inside the refrigerated space may increase the internal load due to motors by 30 to 80 percent.

## 5 Refrigeration Equipment Load

The *refrigeration equipment load* refers to the heat generated by the refrigeration equipment itself as it performs certain tasks such as *circulating* the cold air with a fan, *electric reheating* to prevent condensation on the surfaces of the

**FIGURE 17-45**

The heat generated by the people lights, electric motors, and other heat-dissipating equipment in a refrigerated space constitutes the internal load.

refrigerator, and *defrosting* to prevent frost build-up and to evaporate moisture. Equipment load can be as little as 5 percent of the total refrigeration load for simple refrigeration systems or it may exceed 15 percent for systems maintained at very low temperatures. When the total refrigeration load is determined as described above, it is common practice to apply a safety factor of 10 percent to serve as a cushion to cover any unexpected situations.

### EXAMPLE 17-7 Freezing of Chicken

A supply of 50 kg of chicken at 6°C contained in a box is to be frozen to -18°C in a freezer (Fig. 17-46). Determine the amount of heat that needs to be removed. The container box is 1.5 kg, and the specific heat of the box material is 14 kJ/kg · °C.

**SOLUTION** A box of chicken is to be frozen in a freezer. The amount of heat removal is to be determined.

**Assumptions** 1 The thermal properties of fresh and frozen chicken are constant. 2 The entire water content of chicken freezes during the process.

**Properties** For chicken, the freezing temperature is -2.8°C, the latent heat of fusion is 247 kJ/kg, the specific heat is 3.32 kJ/kg · °C above freezing and 1.77 kJ/kg · °C below freezing (Table A-7a).

**Analysis** The total amount of heat that needs to be removed (the cooling load of the freezer) is the sum of the latent heat and the sensible heats of the chicken before and after freezing as well as the sensible heat of the box, and is determined as follows:

Cooling fresh chicken from 6°C to -2.8°C:

$$Q_{\text{cooling, fresh}} = (mc_p \Delta T)_{\text{fresh}} = (50 \text{ kg})(3.32 \text{ kJ/kg} \cdot ^\circ\text{C})[6 - (-2.8)]^\circ\text{C} = 1461 \text{ kJ}$$

Freezing chicken at -2.8°C:

$$Q_{\text{freezing}} = mh_{\text{latent}} = (50 \text{ kg})(247 \text{ kJ/kg}) = 12,350 \text{ kJ}$$

Cooling frozen chicken from -2.8°C to -18°C:

$$\begin{aligned} Q_{\text{cooling, frozen}} &= (mc_p \Delta T)_{\text{frozen}} \\ &= (50 \text{ kg})(1.77 \text{ kJ/kg} \cdot ^\circ\text{C})[-2.8 - (-18)]^\circ\text{C} = 1345 \text{ kJ} \end{aligned}$$

Cooling the box from 6°C to -18°C:

$$Q_{\text{box}} = (mc_p \Delta T)_{\text{box}} = (1.5 \text{ kg})(1.4 \text{ kJ/kg} \cdot ^\circ\text{C})[6 - (-18)]^\circ\text{C} = 50 \text{ kJ}$$

Therefore, the total amount of cooling that needs to be done is

$$\begin{aligned} Q_{\text{total}} &= Q_{\text{cooling, fresh}} + Q_{\text{freezing}} + Q_{\text{cooling, frozen}} + Q_{\text{box}} \\ &= 1461 + 12,350 + 1345 + 50 = \mathbf{15,206 \text{ kJ}} \end{aligned}$$

**DISCUSSION** Note that most of the cooling load (81 percent of it) is due to the removal of the latent heat during the phase change process. Also note that the cooling load due to the box is negligible (less than 1 percent), and can be ignored in calculations.

**FIGURE 17-46**

Schematic for Example 17-7.

**FIGURE 17-47**

Schematic for Example 17-8.

**EXAMPLE 17-8 Infiltration Load of Cold Storage Rooms**

A cold storage room whose internal dimensions are  $3 \text{ m} \times 6 \text{ m} \times 10 \text{ m}$  is maintained at  $1^\circ\text{C}$  and 95 percent relative humidity (Fig. 17-47). Under worst conditions, the amount of air infiltration is estimated to be 0.2 air changes per hour at the ambient conditions of  $30^\circ\text{C}$  and 90 percent relative humidity. Using the psychrometric chart, determine the total infiltration load of this room under these conditions.

**SOLUTION** The infiltration rate of a cold storage room is given to be 0.2 ACH. The total infiltration load of the room is to be determined.

**Assumptions** The entire infiltrating air is cooled to  $1^\circ\text{C}$  before it exfiltrates.

**Properties** The heat of vaporization of water at the average temperature  $15^\circ\text{C}$  is  $2466 \text{ kJ/kg}$  (Table A-9). The properties of the cold air in the room and the ambient air are determined from the psychrometric chart to be

$$\left. \begin{array}{l} T_{\text{ambient}} = 30^\circ\text{C} \\ \phi_{\text{ambient}} = 90\% \end{array} \right\} \quad \left. \begin{array}{l} \omega_{\text{ambient}} = 0.024 \text{ kg/kg dry air} \\ h_{\text{ambient}} = 93 \text{ kJ/kg dry air} \end{array} \right\}$$

$$\left. \begin{array}{l} T_{\text{room}} = 1^\circ\text{C} \\ \phi_{\text{room}} = 95\% \end{array} \right\} \quad \left. \begin{array}{l} \omega_{\text{room}} = 0.0038 \text{ kg/kg dry air} \\ h_{\text{room}} = 11 \text{ kJ/kg dry air} \\ v_{\text{room}} = 0.780 \text{ m}^3/\text{kg dry air} \end{array} \right\}$$

**Analysis** Noting that the infiltration of ambient air will cause the air in the cold storage room to be changed 0.2 times every hour, the air will enter the room at a mass flow rate of

$$\dot{m}_{\text{air}} = \frac{V_{\text{room}}}{v_{\text{room}}} \text{ ACH} = \frac{3 \times 6 \times 10 \text{ m}^3}{0.780 \text{ m}^3/\text{kg dry air}} (0.2 \text{ h}^{-1}) = 46.2 \text{ kg/h} = 0.0128 \text{ kg/s}$$

Then the sensible and latent infiltration heat gain of the room become

$$\begin{aligned} \dot{Q}_{\text{infiltration, sensible}} &= \dot{m}_{\text{air}}(h_{\text{ambient}} - h_{\text{room}}) \\ &= (0.0128 \text{ kg/s})(93 - 11) \text{ kJ/kg} = 1.05 \text{ kW} \end{aligned}$$

$$\begin{aligned} \dot{Q}_{\text{infiltration, latent}} &= (\omega_{\text{ambient}} - \omega_{\text{room}})\dot{m}_{\text{air}}h_{fg} \\ &= (0.024 - 0.0038)(0.0128 \text{ kg/s})(2466 \text{ kJ/kg}) = 0.64 \text{ kW} \end{aligned}$$

Therefore,

$$\dot{Q}_{\text{infiltration}} = \dot{Q}_{\text{infiltration, sensible}} + \dot{Q}_{\text{infiltration, latent}} = 1.05 + 0.64 = \mathbf{1.69 \text{ kW}}$$

That is, the refrigeration system of this cold storage room must be capable of removing heat at a rate of  $1.69 \text{ kJ/s}$  to meet the infiltration load. Of course, the total refrigeration capacity of the system will have to be larger to meet the transmission, product, and other loads as well.

## 17-8 • TRANSPORTATION OF REFRIGERATED FOODS

Perishable food products are transported by *trucks and trailers*, *railroad cars*, *ships*, *airplanes*, or a *combination* of them from production areas to distant markets. Transporting some farm products to a nearby market by a small truck may not require any special handling, but transporting large quantities over long distances usually requires strict climate control by refrigeration and adequate ventilation (Fig. 17-48).

Refrigerated *trucks* and *trailers* can be up to 17 m long, 2.6 m wide, and 4.3 m high, and they may have several compartments held at different temperatures. The body of the truck should be lightweight but stiff with good insulating characteristics. Using a *thick* insulation layer on walls reduces the rate *heat gain* into the refrigerated space, but it also reduces the available *cargo space* since the outer dimensions of the trucks and trailers are limited. Urethane foam is commonly used as an insulating material because of its low thermal conductivity ( $k = 0.026 \text{ W/m} \cdot \text{°C}$ ). The *thickness* of polyurethane insulation used is in the range of 7.5 to 10 cm for *freezer trucks* maintained at  $-18^\circ\text{C}$  or lower, and 2.5 to 6.5 cm for *refrigerated trucks* maintained above freezing temperatures (Fig. 17-49). The outer surface of the truck must be vapor proof to prevent water vapor from entering the insulation and condensing within the insulation.

Air entering inside the refrigerated space of the truck through cracks represents a significant heat gain since the *moisture* in the air will be cooled inside and condensed, releasing its latent heat. The *large temperature difference* between the ambient air and the interior of the refrigerated truck serves as a driving force for air infiltration. Air leakage is also caused by the *ram effect* of air during motion. It can be shown from Bernoulli's equation that a truck moving at a velocity of  $V$  will generate a ram air pressure of  $\Delta P = \rho V^2/2$  at the front section ( $\rho$  is the density of air). This corresponds to a *pressure rise* of about 300 Pa on the surface of the truck at a velocity of 80 km/h. Road tests have shown that air leakage rates for large trailers can reach 12.5 L/s at 80 km/h. Further, the water vapor in the air that condenses inside the refrigerated space may cause *corrosion*, *damage to insulation*, *rotting*, and *odors*.

Products with a *large heat capacity* such as milk and orange juice can be transported safely without refrigeration by subcooling them before loading into the truck. For example, orange juice shipped from Florida to New York (a distance of 2300 km) warmed up only  $5^\circ\text{C}$  without any refrigeration. *Liquid nitrogen*, *dry ice*, or *ordinary ice* can also be used for refrigeration in trucks. The cargo space must be maintained at  $-18^\circ\text{C}$  for most frozen products and  $-29^\circ\text{C}$  for other deep-frozen products such as ice cream.

The rate of heat gain by properly insulated trailers that are 11 to 16 m long ranges from 40 to 130  $\text{W}/^\circ\text{C}$  under steady conditions. But on a sunny day the *solar radiation* can increase this number by more than 20 percent. The rate of heat gain can also increase significantly as a result of the product cooling load, air infiltration, and opening of the door during loading and unloading.

The interior of refrigerated trucks should be *precooled* to the desired temperature before loading. The fruits and vegetables should also be cooled to the proper storage temperature before they are loaded into the refrigerated railcars or trucks. This is because the refrigerated cars or trucks do not have the additional refrigeration capacity to cool the products fast enough. Also, the

**FIGURE 17-48**  
Airflow patterns in a refrigerated trailer.

**FIGURE 17-49**  
Proper thickness polyurethane insulation for the walls of refrigerated and freezer trucks.

**FIGURE 17-50**

Typical rates of the heat gain by 15- and 18-m-long refrigerated railcars.

products must be protected from freezing in winter. Refrigerated cars or trucks provide *heating* in cold weather by electric heating or by operating the refrigeration system in reverse as a heat pump. Switching from cooling to heating is done automatically.

The heating and cooling processes in refrigerated cars and trucks are well automated, and all the operator needs to do is set the thermostat at the desired level. The system then provides the necessary refrigeration (or heating in cold weather) to maintain the interior at the set temperature. Thermostats must be calibrated regularly to ensure reliable operation since a deviation of a few degrees from the intended temperature setting may cause the products to be damaged by freezing or excessive decay.

Food products are normally loaded into cars or trucks in *containers* that can be handled by people or forklifts. The containers must allow for heat exchange while protecting the products. The containers must allow for air circulation through channels for uniform and effective cooling and ventilation.

The *railroad industry* also provides refrigerated car service for the transportation of perishable foods. The walls, floors, and ceiling of the cars are constructed with a minimum of 7.5-cm-thick insulation. Typical rates of heat gain are  $132 \text{ W}/^{\circ}\text{C}$  for 15-m-long cars and  $158 \text{ W}/^{\circ}\text{C}$  for 18-m-long cars (Fig. 17-50). Other aspects of transportation are similar to the trucks.

Perishable foods are also transported economically from one port to another by *refrigerated ships*. Some ships are designed specifically to transport fruits and vegetables, while others provide refrigerated sections for the transport of foods in various sizes of specially built containers that facilitate faster loading and unloading. Containers used to carry frozen food are insulated with at least 7.5-cm-thick urethane foam insulation. In fishing vessels, ice picked up from the port is commonly used to preserve fish and seafood for days with little or no additional refrigeration. Some fishing vessels cool the seawater to about  $2^{\circ}\text{C}$  and then use it to refrigerate the fish.

Perishable food products are also being transported by *air* in the cargo sections of passenger planes or in specifically designed cargo planes. As you would expect, air transport is more expensive, but the extra cost is justified for commodities that can command a high market price. Also, for some highly perishable products, the only means of transportation is air transportation. *Papaya* and *flowers*, for example, are transported from Hawaii to the mainland almost always by air. Likewise, *flowers* are transported to distant markets mostly by air. *Strawberries* are being transported anywhere in the world again by air at an increasing rate. *Fresh meats, seafood, and early season fruits and vegetables* are also commonly shipped by air. Many inland restaurants are able to serve high-quality fresh fish and seafood because of air transport. Air transportation may become economical for many perishable food items at times of short supply and thus higher prices (Fig. 17-51).

Air transport is completed in a matter of hours, and it is not practical to equip the airplanes with powerful but heavy refrigeration systems for such short periods. Airplane refrigeration is primarily based on *precooling* prior to loading, and the prevention of *temperature rise* during transit. This is achieved by precooling the products in a refrigerated storage facility; transporting them in refrigerated trucks; storing them in a refrigerated warehouse at the airport, if necessary; and transporting the products in well-insulated containers. Of course, quick loading and unloading are also important to minimize exposure

**FIGURE 17-51**

High-priced food products are commonly transported by air economically.

to adverse conditions. Sometimes dry ice is used to provide temporary refrigeration to the container.

Air transport also offers some *challenges* to refrigeration engineers. For example, the outer surface temperature of an airplane cruising at a Mach number of 0.9 increases by about  $28^{\circ}\text{C}$  over the ambient. Also, the relative humidity of the cabin of an airplane cruising at high altitudes is very low, typically under 10 percent. However, the humidity level can still be maintained at about 90 percent without adding any water, thanks to the moisture released during respiration from fruits and vegetables.

### EXAMPLE 17-9 Interstate Transport of Refrigerated Milk by Trucks

Milk is to be transported from Texas to California for a distance of 2100 km in a 7-m-long, 2-m-external-diameter cylindrical tank (Fig. 17-52). The walls of the tank are constructed of 5-cm-thick urethane insulation ( $k = 0.029 \text{ W/m} \cdot \text{ }^{\circ}\text{C}$ ) sandwiched between two metal sheets. The milk is precooled to  $3^{\circ}\text{C}$  before loading and its temperature is not to exceed  $7^{\circ}\text{C}$  on arrival. The average ambient temperature can be as high as  $30^{\circ}\text{C}$ , and the effect of solar radiation and the radiation from hot pavement surfaces can be taken to be equivalent to a  $4^{\circ}\text{C}$  rise in ambient temperature. If the average velocity during transportation is  $60 \text{ km/h}$ , determine if the milk can be transported without any refrigeration.

**SOLUTION** Milk is to be transported in a cylindrical tank by a truck. It is to be determined if the milk can be transported without any refrigeration.

**Assumptions** Thermal properties of milk and insulation are constant.

**Properties** The thermal conductivity of urethane is given to be  $k = 0.029 \text{ W/m} \cdot \text{ }^{\circ}\text{C}$ . The density and specific heat of refrigerated milk at temperatures near  $0^{\circ}\text{C}$  are  $\rho_{\text{milk}} = \rho_{\text{water}} = 1000 \text{ kg/m}^3$  and  $c_{p,\text{milk}} = 3.79 \text{ kJ/kg} \cdot \text{ }^{\circ}\text{C}$  (Table A-7).

**Analysis** Problems of this kind that involve “checking” are best solved by performing the calculations under the worst conditions, with the understanding that if the performance is satisfactory under those conditions, it will surely be satisfactory under any conditions.

We take the average ambient temperature to be  $30^{\circ}\text{C}$ , which is the highest possible, and raise it to  $34^{\circ}\text{C}$  to account for the radiation from the sun and the pavement. We also assume the metal sheets to offer no resistance to heat transfer and assume the convection resistances on the inner and outer sides of the tank wall to be negligible. Under these conditions, the inner and outer surface temperatures of the insulation will be equal to the milk and ambient temperatures, respectively. Further, we take the milk temperature to be  $3^{\circ}\text{C}$  during heat transfer calculations (to maximize the temperature difference) and the heat transfer area to be the outer surface area of the tank (instead of the smaller inner surface area), which is determined to be

$$\begin{aligned} A &= 2A_{\text{base}} + A_{\text{side}} = 2(\pi D_o^2/4) + (\pi D_o)L_o \\ &= 2\pi(2\text{ m})^2/4 + \pi(2\text{ m})(7\text{ m}) = 50.3 \text{ m}^2 \end{aligned}$$

**FIGURE 17-52**  
Schematic for Example 17-9.

Then the rate of heat transfer through the insulation into the milk becomes

$$\dot{Q} = k_{\text{ins}} A \frac{\Delta T_{\text{ins}}}{L_{\text{ins}}} = (0.029 \text{ W/m} \cdot ^\circ\text{C})(50.3 \text{ m}^2) \frac{(34 - 3)^\circ\text{C}}{0.05 \text{ m}} = 904.4 \text{ W}$$

This is the highest possible rate of heat transfer into the milk since it is determined under the most favorable conditions for heat transfer.

At an average velocity of 60 km/h, transporting the milk 2100 km will take

$$\Delta t = \frac{\text{Distance traveled}}{\text{Average velocity}} = \frac{2100 \text{ km}}{60 \text{ km/h}} = 35 \text{ h}$$

Then the total amount of heat transfer to the milk during this long trip becomes

$$Q = \dot{Q}\Delta t = (904.4 \text{ kJ/s})(35 \times 3600 \text{ s}) = 113,950,000 \text{ J} = 113,950 \text{ kJ}$$

The volume and mass of the milk in a full tank is determined to be

$$V_{\text{milk}} = (\pi D_i^2/4)L_i = [\pi(1.9 \text{ m})^2/4](6.9 \text{ m}) = 19.56 \text{ m}^3$$

$$m_{\text{milk}} = \rho V_{\text{milk}} = (1000 \text{ kg/m}^3)(19.56 \text{ m}^3) = 19,560 \text{ kg}$$

The transfer of 113,950 kJ of heat into the milk will raise its temperature to

$$Q = mc_p(T_2 - T_1) \rightarrow T_2 = T_1 + \frac{Q}{mc_p}$$

$$= 3^\circ\text{C} + \frac{113,950 \text{ kJ}}{(19,560 \text{ kg})(3.79 \text{ kJ/kg} \cdot ^\circ\text{C})} = 4.5^\circ\text{C}$$

That is, the temperature of the milk will rise from 3 to 4.5°C during this long trip under the most adverse conditions, which is well below the 7°C limit. Therefore, the milk can be transported even longer distances without any refrigeration.

**FIGURE 17-53**

Schematic for Example 17-10.

### EXAMPLE 17-10 Transport of Apples by Refrigerated Trucks

A large truck is to transport 40,000 kg of apples precooled to 3°C under average ambient conditions of 25°C and 90 percent relative humidity (Fig. 17-53). The structure of the walls of the truck is such that the rate of heat transmission is  $UA = 70 \text{ W per } ^\circ\text{C}$  temperature difference between the ambient and the apples. From past experience, ambient air is estimated to enter the cargo space of the truck through the cracks at a rate of 6 L/s, and the average heat of respiration of the apples at 3°C is 0.015 W/kg for this particular load. Determine the refrigeration load of this truck and the amount of ice needed to meet the entire refrigeration need of the truck for a 20-h-long trip.

**SOLUTION** A large truck is to transport 40,000 kg of apples. The refrigeration load of the truck and the amount of ice needed to meet this during a 20 h long trip is to be determined.

**Assumptions** 1 Infiltrating air exits the truck saturated at 3°C. 2 The moisture in the air is condensed out at the exit temperature of 3°C.

**Properties** The humidity ratio of air is 0.0180 kg water vapor/kg dry air at 25°C and 90 percent relative humidity, and 0.0047 at 3°C and 100 percent relative humidity. The latent heat of vaporization of water at 3°C is 2494 kJ/kg (Table A-9). The density of air at the ambient temperature of 25°C and 1 atm is 1.184 kg/m<sup>3</sup>, and its specific heat is  $c_p = 1.007 \text{ kJ/kg} \cdot ^\circ\text{C}$  (Table A-15). The latent heat of ice is 333.7 kJ/kg.

**Analysis** The total refrigeration load of the truck is due to the heat gain by transmission, infiltration, and respiration. Noting that  $UA$  is given to be 70 W/°C, the rate of heat gain by transmission is determined to be

$$\dot{Q}_{\text{transmission}} = UA\Delta T = (70 \text{ W}/^\circ\text{C})(25 - 3)^\circ\text{C} = 1540 \text{ W}$$

The rate of heat generation by the apples as a result of respiration is

$$\dot{Q}_{\text{respiration}} = mh_{\text{respiration}} = (40,000 \text{ kg})(0.015 \text{ W/kg}) = 600 \text{ W}$$

Ambient air enters the cargo space at a rate of 6 L/s, which corresponds to a mass flow rate of

$$\dot{m}_{\text{air}} = \rho \dot{V}_{\text{air}} = (1.184 \text{ kg/m}^3)(0.006 \text{ m}^3/\text{s}) = 0.00710 \text{ kg/s}$$

Noting that an equal amount of air at 3°C must leave the truck, the sensible heat gain due to infiltration is

$$\begin{aligned}\dot{Q}_{\text{infiltration, sensible}} &= (\dot{m}c_p\Delta T)_{\text{air}} = (0.00710 \text{ kg/s})(1.007 \text{ kJ/kg} \cdot ^\circ\text{C})(25 - 3)^\circ\text{C} \\ &= 0.157 \text{ kJ/s} = 157 \text{ W}\end{aligned}$$

Ambient air enters with a humidity ratio of 0.0180 kg H<sub>2</sub>O/kg air and leaves at 0.0047 kg H<sub>2</sub>O/kg air. The difference condenses in the truck and is drained out as a liquid, releasing  $h_{fg} = 2494 \text{ kJ/kg}$  of latent heat. Then the latent heat gain of the truck becomes

$$\begin{aligned}\dot{Q}_{\text{infiltration, latent}} &= \dot{m}_{\text{water}}h_{fg} \\ &= (0.0180 - 0.0047)(0.00710 \text{ kg/s})(2494 \text{ kJ/kg}) = 236 \text{ W}\end{aligned}$$

Then the refrigeration load, or the total rate of heat gain by the truck, becomes

$$\begin{aligned}Q_{\text{total}} &= \dot{Q}_{\text{transmission}} + \dot{Q}_{\text{respiration}} + \dot{Q}_{\text{infiltration}} \\ &= 1540 + 600 + (157 + 236) = \mathbf{2533 \text{ W}}$$

The total amount of heat gain during the 20-h-long trip is

$$Q_{\text{total}} = \dot{Q}_{\text{total}}\Delta t = (2533 \text{ J/s})(20 \times 3600 \text{ s}) = 182,376,000 \text{ J} = 182,376 \text{ kJ}$$

Then the amount of ice needed to meet this refrigeration load is determined from

$$m_{\text{ice}} = \frac{Q_{\text{total}}}{h_{\text{latent,ice}}} = \frac{182,376 \text{ kJ}}{333.7 \text{ kJ/kg}} = \mathbf{547 \text{ kg}}$$

**Discussion** Note that about half a ton of ice (1.5 percent of the mass of the load) is sufficient in this case to maintain the apples at 3°C.

## SUMMARY

Refrigeration and freezing of perishable food products are major application areas of heat transfer and thermodynamics. *Microorganisms* such as bacteria, yeasts, molds, and viruses cause off-flavors and odors, slime production, changes in the texture and appearance, and eventual spoilage of foods. The rate of growth of microorganisms in a food item depends on the characteristics of the food itself as well as the environmental conditions, such as the temperature and relative humidity of the environment and the air motion. Refrigeration slows down the chemical and biological processes in foods and the accompanying deterioration. The storage life of fresh perishable foods such as meats, fish, vegetables and fruits can be extended by several days by storing them at temperatures just above freezing, and by several months by storing them at sub-freezing temperatures.

Some fruits and vegetables experience undesirable physiological changes when exposed to low (but still above-freezing) temperatures, usually between 0 and 10°C. The resulting tissue damage is called the *chilling injury*. It differs from *freezing injury*, which is caused by prolonged exposure of the fruits and vegetables to subfreezing temperatures and thus the actual freezing at the affected areas. *Dehydration* or *moisture loss* causes a product to shrivel or wrinkle and lose quality. The loss of moisture from fresh fruits and vegetables is also called *transpiration*. Common freezing methods include *air-blast freezing*, where high-velocity air at about -30°C is blown over the food products; *contact freezing*, where packaged or unpackaged food is placed on or between cold metal plates and cooled by conduction; *immersion freezing*, where the food is immersed in low-temperature brine; and *cryogenic freezing*, where food is placed in a medium cooled by a cryogenic fluid such as liquid nitrogen or solid carbon dioxide.

The thermal properties of foods are dominated by their water content. The *specific heats* of foods can be expressed by *Siebel's formula* as

$$c_{p,\text{fresh}} = 3.35a + 0.84 \quad (\text{kJ/kg} \cdot ^\circ\text{C})$$

$$c_{p,\text{frozen}} = 1.26a + 0.84 \quad (\text{kJ/kg} \cdot ^\circ\text{C})$$

where  $c_{p,\text{fresh}}$  and  $c_{p,\text{frozen}}$  are the specific heats of the food before and after freezing, respectively, and  $a$  is the fraction of water content of the food. The *latent heat* of a food product during freezing or thawing (the heat of fusion) also depends on its water content and is determined from

$$h_{\text{latent}} = 334a \quad (\text{kJ/kg})$$

The heat removed from the food products accounts for the majority of the refrigeration load and is determined, from

$$\dot{Q}_{\text{product}} = mc_p(T_{\text{initial}} - T_{\text{final}})/\Delta t \quad (\text{W})$$

where  $\dot{Q}_{\text{product}}$  is the *average rate of heat removal* from the fruits and vegetables;  $m$  is the total mass;  $c_p$  is the average

specific heat;  $T_{\text{initial}}$  and  $T_{\text{final}}$  are the average temperatures of the products before and after cooling, respectively; and  $\Delta t$  is the cooling time. Fresh fruits and vegetables are live products, and they continue to respire after harvesting. *Heat of respiration* is released during this exothermic reaction. The refrigeration load due to respiration is determined from

$$\dot{Q}_{\text{respiration}} = \sum m_i \dot{q}_{\text{respiration},i} \quad (\text{W})$$

which is the sum of the mass times the heat of respiration for all the food products stored in the refrigerated space.

The primary precooling methods for fruits and vegetables are *hydro-cooling*, where the products are cooled by immersing them into chilled water; *forced-air cooling*, where the products are cooled by forcing refrigerated air through them; *package icing*, where the products are cooled by placing crushed ice into the containers; and *vacuum cooling*, where the products are cooled by vaporizing some of the water content of the products under low pressure conditions. Most produce can be stored satisfactorily at 0°C and 90 to 95 percent relative humidity.

Meat carcasses in slaughterhouses should be cooled as fast as possible to a uniform temperature of about 1.7°C to reduce the growth rate of microorganisms that may be present on carcass surfaces, and thus minimize spoilage. About 70 percent of the beef carcass is water, and the carcass is cooled mostly by *evaporative cooling* as a result of moisture migration toward the surface where evaporation occurs. Most meats are judged on their *tenderness*, and the preservation of tenderness is an important consideration in the refrigeration and freezing of meats. *Poultry products* can be preserved by *ice chilling* to 1 to 2°C or *deep chilling* to about -2°C for short-term storage, or by *freezing* them to -18°C or below for long-term storage. Poultry processing plants are completely automated, and several processes involve strict temperature control. *Fish* is a highly perishable commodity, and the preservation of fish starts on the vessel as soon as it is caught.

*Eggs* must be refrigerated to preserve quality and to assure a reasonable shelf life. Refrigeration should start at the farm and continue through retail outlets. Shell eggs can be stored at 7 to 13°C and 75 to 80 percent relative humidity for a few weeks. *Milk* is one of the most essential foods for humans, but also one of the most suitable environments for the growth of microorganisms. The stored milk is first *standardized* to bring the milkfat content to desired levels using a milk separator. To kill the bacteria, milk is *pasteurized* in a batch or continuous flow-type system by heating the milk to a minimum temperature of 62.8°C and holding it at that temperature for at least 30 min. The milk is usually *vacuum processed* after pasteurization to reduce the undesirable flavors and odors in it. The milk is also *homogenized* before it is packaged to break up the large fat globules into smaller ones to give it a "homogeneous" appearance. Refrigeration plays an important part in all stages of

modern *baker production* from the preservation of raw materials such as flour and yeast to the cooling of baked products.

The *total rate of heat gain* of a refrigerated space through all mechanisms under peak conditions is called the *refrigeration load*, and it consists of (1) *transmission load*, which is heat conducted into the refrigerated space through its walls, floor, and ceiling; (2) *infiltration load*, which is due to surrounding warm air entering the refrigerated space through the cracks and open doors; (3) *product load*, which is the heat removed from the food products as they are cooled to refrigeration temperature; (4) *internal load*, which is heat generated by the lights, electric motors, and people in the refrigerated space; and (5) *refrigeration equipment load*, which is the heat generated by the refrigeration equipment as it performs certain tasks such as reheating and defrosting.

The *rate of heat transfer* through a particular wall, floor, or ceiling section can be determined from

$$\dot{Q}_{\text{transmission}} = UA_o \Delta T \quad (\text{W})$$

where  $A_o$  = the outside surface area of the section,  $\Delta T$  = the temperature difference between the outside air and the air inside the refrigerated space, and  $U$  = the overall heat transfer coefficient. The infiltration load can be determined by estimating the rate of air infiltration in terms of *air changes per hour*

(ACH), which is the number of times the entire air content of a room is replaced by the infiltrating air per hour. Then the *mass flow rate* of infiltrating air is determined from

$$\dot{m}_{\text{air}} = \frac{V_{\text{room}}}{v_{\text{room}}} \text{ACH} \quad (\text{kg/h})$$

where  $V_{\text{room}}$  is the volume of the room and  $v_{\text{room}}$  is the specific volume of the dry air in the room. Once  $\dot{m}_{\text{air}}$  is available, the sensible and latent infiltration loads of the cold storage room can be determined from

$$\begin{aligned}\dot{Q}_{\text{infiltration, sensible}} &= \dot{m}_{\text{air}}(h_{\text{ambient}} - h_{\text{room}}) \quad (\text{kJ/h}) \\ \dot{Q}_{\text{infiltration, latent}} &= (\omega_{\text{ambient}} - \omega_{\text{room}})\dot{m}_{\text{air}} h_{fg} \quad (\text{kJ/h})\end{aligned}$$

where  $\omega$  is the humidity ratio of air (the mass of water vapor in 1 kg dry air),  $h$  is the enthalpy of air, and  $h_{fg}$  is the heat of vaporization of water. The total infiltration load is then the sum of the sensible and latent components.

Perishable food products are transported by *trucks and trailers, railroad cars, ships, airplanes*, or a combination of them from production areas to distant markets. Transporting large quantities over long distances usually requires strict climate control by refrigeration and adequate ventilation, and adequate insulation to keep the heat transfer rates at reasonable levels.

## PROBLEMS\*

### Control of Microorganisms in Foods

**17-1C** What are the common kinds of microorganisms? What undesirable changes do microorganisms cause in foods?

**17-2C** How does refrigeration prevent or delay the spoilage of foods? Why does freezing extend the storage life of foods for months?

**17-3C** What are the environmental factors that affect the growth rate of microorganisms in foods?

**17-4C** What is the effect of cooking on the microorganisms in foods? Why is it important that the internal temperature of a roast in an oven be raised above 70°C?

**17-5C** How can the contamination of foods with microorganisms be prevented or minimized? How can the growth of microorganisms in foods be retarded? How can the microorganisms in foods be destroyed?

**17-6C** How does (a) the air motion and (b) the relative humidity of the environment affect the growth of microorganisms in foods?

### Refrigeration and Freezing of Foods

**17-7C** What is the difference between the freezing injury and the chilling injury of fruits and vegetables?

**17-8C** How does the rate of freezing affect the size of the ice crystals that form during freezing and the quality of the frozen food products?

**17-9C** What is transpiration? Does lettuce or an apple have a higher coefficient of transpiration? Why?

**17-10C** What are the mechanisms of heat transfer involved during the cooling of fruits and vegetables by refrigerated air?

**17-11C** What are the four primary methods of freezing foods?

**17-12C** What is air-blast freezing? How does it differ from contact freezing of foods?

**17-13C** What is cryogenic freezing? How does it differ from immersion freezing of foods?

**17-14C** Which type of freezing is more likely to cause dehydration in foods: air-blast freezing or cryogenic freezing?

**17-15** White potatoes ( $k = 0.50 \text{ W/m} \cdot ^\circ\text{C}$  and  $\alpha = 0.13 \times 10^{-6} \text{ m}^2/\text{s}$ ) that are initially at a uniform temperature of 25°C and have an average diameter of 6 cm are to be cooled by refrigerated air at 2°C flowing at a velocity of 4 m/s. The average heat transfer coefficient between the potatoes and the air is experimentally determined to be 19 W/m<sup>2</sup> · °C. Determine how long it will take for the center temperature of the potatoes to

drop to 6°C. Also, determine if any part of the potatoes will experience chilling injury during this process.

FIGURE P17-15

**17-16E** Oranges of 2.5-in diameter ( $k = 0.26 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$  and  $\alpha = 1.4 \times 10^{-6} \text{ ft}^2/\text{s}$ ) initially at a uniform temperature of 78°F are to be cooled by refrigerated air at 25°F flowing at a velocity of 1 ft/s. The average heat transfer coefficient between the oranges and the air is experimentally determined to be 4.6 Btu/h · ft<sup>2</sup> · °F. Determine how long it will take for the center temperature of the oranges to drop to 40°F. Also, determine if any part of the oranges will freeze during this process.

**17-17** A 65-kg beef carcass ( $k = 0.47 \text{ W/m} \cdot ^\circ\text{C}$  and  $\alpha = 0.13 \times 10^{-6} \text{ m}^2/\text{s}$ ) initially at a uniform temperature of 37°C is to be cooled by refrigerated air at -6°C flowing at a velocity of 1.8 m/s. The average heat transfer coefficient between the carcass and the air is 22 W/m<sup>2</sup> · °C. Treating the carcass as a cylinder of diameter 24 cm and height 1.4 m and disregarding heat transfer from the base and top surfaces, determine how long it will take for the center temperature of the carcass to drop to 4°C. Also, determine if any part of the carcass will freeze during this process. *Answer: 14.0 h*

FIGURE P17-17

**17-18** Layers of 23-cm-thick meat slabs ( $k = 0.47 \text{ W/m} \cdot ^\circ\text{C}$  and  $\alpha = 0.13 \times 10^{-6} \text{ m}^2/\text{s}$ ) initially at a uniform temperature of 7°C are to be frozen by refrigerated air at -30°C flowing at a velocity of 1.4 m/s. The average heat transfer coefficient between the meat and the air is 20 W/m<sup>2</sup> · °C. Assuming the size of the meat slabs to be large relative to their thickness, determine how long it will take for the center temperature of the

\*Students are encouraged to answer *all* the concept "C" questions.

slabs to drop to  $-18^{\circ}\text{C}$ . Also, determine the surface temperature of the meat slab at that time.

**17-19E** Layers of 6-in-thick meat slabs ( $k = 0.26 \text{ Btu/h} \cdot \text{ft} \cdot ^{\circ}\text{F}$  and  $\alpha = 1.4 \times 10^{-6} \text{ ft}^2/\text{s}$ ) initially at a uniform temperature of  $50^{\circ}\text{F}$  are cooled by refrigerated air at  $23^{\circ}\text{F}$  to a temperature of  $36^{\circ}\text{F}$  at their center in 12 h. Estimate the average heat transfer coefficient during this cooling process.

*Answer:*  $1.5 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^{\circ}\text{F}$

**17-20** Chickens with an average mass of  $1.7 \text{ kg}$  ( $k = 0.45 \text{ W/m} \cdot ^{\circ}\text{C}$  and  $\alpha = 0.13 \times 10^{-6} \text{ m}^2/\text{s}$ ) initially at a uniform temperature of  $15^{\circ}\text{C}$  are to be chilled in agitated brine at  $-10^{\circ}\text{C}$ . The average heat transfer coefficient between the chicken and the brine is determined experimentally to be  $440 \text{ W/m}^2 \cdot ^{\circ}\text{C}$ . Taking the average density of the chicken to be  $0.95 \text{ g/cm}^3$  and treating the chicken as a spherical lump, determine the center and the surface temperatures of the chicken in 2 h and 30 min. Also, determine if any part of the chicken will freeze during this process.

FIGURE P17-20

### Thermal Properties of Foods

**17-21C** Explain how to determine the latent heat of fusion of food products whose water content is known.

**17-22C** Whose specific heat is greater: apricots with a water content of 70 percent or apples with a water content of 82 percent?

**17-23C** Do carrots freeze at a fixed temperature or over a range of temperatures? Explain.

**17-24C** Consider 1 kg of cherries with a water content of 75 percent and 1 kg of roast beef also with a water content of 75 percent, both at  $5^{\circ}\text{C}$ . Now both the cherries and the beef are completely frozen to  $-40^{\circ}\text{C}$ . The heat removed from the cherries will be (a) less than, (b) about equal to, or (c) greater than the heat removed from the beef.

**17-25C** Consider 1 kg of carrots with a water content of 65 percent and 1 kg of chicken also with a water content of 65 percent. Now both the carrots and the chicken are cooled from  $12^{\circ}\text{C}$  to  $3^{\circ}\text{C}$ . The heat removed from the carrots will be (a) less than, (b) about equal to, or (c) greater than the heat removed from the chicken.

**17-26** A 35-kg box of beef at  $6^{\circ}\text{C}$  having a water content of 60 percent is to be frozen to a temperature of  $-20^{\circ}\text{C}$  in 3 h. Using data from Figure 17-13, determine (a) the total amount of heat that must be removed from the beef, (b) the amount of unfrozen water in beef at  $-20^{\circ}\text{C}$ , and (c) the average rate of heat removal from the beef.

**17-27** A 50-kg box of sweet cherries at  $8^{\circ}\text{C}$  having a water content of 77 percent is to be frozen to a temperature of  $-20^{\circ}\text{C}$ . Using enthalpy data from Table 17-4, determine (a) the total amount of heat that must be removed from the cherries and (b) the amount of unfrozen water in cherries at  $-20^{\circ}\text{C}$ .

FIGURE P17-27

**17-28** A 2-kg box made of polypropylene ( $c_p = 1.9 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ ) contains 40 kg of cod fish with a water content of 80.3 percent (by mass) at  $18^{\circ}\text{C}$ . The fish is to be frozen to an average temperature of  $-18^{\circ}\text{C}$  in 2 h in its box. The enthalpy of the fish is given to be  $323 \text{ kJ/kg}$  at  $0^{\circ}\text{C}$  and  $47 \text{ kJ/kg}$  at  $-18^{\circ}\text{C}$ . It is also given that the unfrozen water content of the fish at  $-18^{\circ}\text{C}$  is 12 percent. Taking the average specific heat of the fish above freezing temperatures to be  $c_p = 3.69 \text{ kJ/kg} \cdot ^{\circ}\text{C}$ , determine (a) the total amount of heat that must be removed from the fish and its container, (b) the amount of unfrozen water in fish at  $-18^{\circ}\text{C}$ , and (c) the average rate of heat removal.

*Answers:* (a)  $13,830 \text{ kJ}$ , (b)  $4.8 \text{ kg}$ , (c)  $1.92 \text{ kW}$

**17-29E** A 5-lbm container made of stainless steel ( $c_p = 0.12 \text{ Btu/lbm} \cdot ^{\circ}\text{F}$ ) contains 90 lbm of applesauce with a water content of 82.8 percent (by mass) at  $77^{\circ}\text{F}$ . The applesauce is to be frozen to an average temperature of  $7^{\circ}\text{F}$  in its container. The enthalpy of the applesauce is given to be  $147.5 \text{ Btu/lbm}$  at  $32^{\circ}\text{F}$  and  $31.4 \text{ Btu/lbm}$  at  $7^{\circ}\text{F}$ . It is also given that the unfrozen water

FIGURE P17-29E

content of the applesauce at 7°F is 14 percent. Taking the average specific heat of the applesauce above freezing temperatures to be  $c_p = 0.89 \text{ Btu/lbm} \cdot ^\circ\text{F}$ , determine (a) the total amount of heat that must be removed from the applesauce and its container and (b) the amount of unfrozen water in applesauce at 7°F.

**17-30** Fresh strawberries with a water content of 89.3 percent (by mass) at 26°C are stored in 0.8-kg boxes made of polyethylene ( $c_p = 2.3 \text{ kJ/kg} \cdot ^\circ\text{C}$ ). Each box contains 25 kg of strawberries, and the strawberries are to be frozen to an average temperature of -16°C at a rate of 80 boxes per hour. The enthalpy of the strawberries is given to be 367 kJ/kg at 0°C and 54 kJ/kg at -16°C. Taking the average specific heat of the strawberries above freezing temperatures to be  $c_p = 3.94 \text{ kJ/kg} \cdot ^\circ\text{C}$ , determine the rate of heat removal from the strawberries and their boxes. *Answer: 232.5 kW*

**17-36C** What is modified atmosphere? How does modified atmosphere extend the storage life of some fruits and vegetables?

**17-37C** Why are apples, cucumbers, and tomatoes not suitable for vacuum cooling?

**17-38C** Why is it not recommended to store bananas below 13°C while it is highly recommended that apples be stored at -1°C?

**17-39** A typical full-carlot-capacity banana room contains 36 pallets of bananas. Each pallet consists of 24 boxes, and thus the

room stores 864 boxes of bananas. A box holds an average of 19 kg of bananas and is made of 2.3 kg of fiberboard. The specific heats of banana and the fiberboard are  $3.55 \text{ kJ/kg} \cdot ^\circ\text{C}$  and  $1.7 \text{ kJ/kg} \cdot ^\circ\text{C}$ , respectively. The peak heat of respiration of bananas is 0.3 W/kg. The bananas are cooled at a rate of  $0.4^\circ\text{C}/\text{h}$ . The rate of heat gain through the walls and other surfaces of the room is estimated to be 1800 kJ/h. If the temperature rise of refrigerated air is not to exceed  $2.0^\circ\text{C}$  as it flows through the room, determine the minimum flow rate of air needed. Take the density and specific heat of air to be  $1.2 \text{ kg/m}^3$  and  $1.0 \text{ kJ/kg} \cdot ^\circ\text{C}$ , respectively.

FIGURE P17-39

**17-40** It is claimed that fruits and vegetables are cooled by  $6^\circ\text{C}$  for each percentage point of weight loss as moisture during vacuum cooling. Using calculations, demonstrate if this claim is reasonable.

**17-41** Using Fig. 17-16, determine how long it will take to cool 6-cm-diameter peaches from 30°C to an average temperature of 5°C by chilled water at 2°C. Compare your result with that obtained from transient one-term solutions using a heat transfer coefficient of  $550 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Also, determine how many metric tons of peaches can be cooled per day during a 10-h work day by a hydrocooling unit with a refrigeration capacity of 120 tons (1 ton of refrigeration = 211 kJ/min).

**17-42** Using Fig. 17-16, determine how long it will take to cool 7-cm-diamameter apples from 28°C to an average temperature of 4°C by chilled water at 1.5°C. Compare your result with that obtained from transient one-term solutions using a heat transfer coefficient of  $540 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Also, determine how many metric tons of apples can be cooled per day during a 10-h work day by a hydrocooling unit with a refrigeration capacity of 80 tons (1 ton of refrigeration = 211 kJ/min)

*Answers: 0.39 h, 155.4 ton/day*

**17-43E** Apples ( $\rho = 52.4 \text{ lbm/ft}^3$ ,  $c_p = 0.91 \text{ Btu/lbm} \cdot ^\circ\text{F}$ ,  $k = 0.242 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ , and  $\alpha = 1.47 \times 10^{-6} \text{ ft}^2/\text{s}$ ) with a diameter of 2.5 in and an initial temperature of 80°F are to be cooled to an average temperature of 38°F with air at 28°F that approaches the cooling section at a velocity of 5 ft/s. The

average heat transfer coefficient between the apples and the air is estimated to be  $7.8 \text{ Btu/h} \cdot \text{ft}^2 \cdot ^\circ\text{F}$ , and it is recommended that air be supplied at a rate of  $0.07 \text{ ft}^3/\text{s}$  per kg of apples. The rectangular cooling section has a capacity of 10,000 lbm of apples with a porosity of 0.38 (i.e., the voids between the apples comprise 38 percent of the total volume). Disregarding the heat of respiration, determine (a) the volume of the cooling section where the apples are placed and its dimensions, (b) the amount of total heat transfer from a full load of apples to the cooling air, and (c) how long it will take for the center temperature of the apples to drop to  $40^\circ\text{F}$ .

**FIGURE P17-43E**

**17-44** Fresh strawberries with a water content of 88 percent (by mass) at  $30^\circ\text{C}$  are stored in 0.8-kg boxes made of nylon ( $c_p = 1.7 \text{ kJ/kg} \cdot ^\circ\text{C}$ ). Each box contains 23 kg of strawberries, and the strawberries are to be cooled to an average temperature of  $4^\circ\text{C}$  at a rate of 60 boxes per hour. Taking the average specific heat of the strawberries to be  $c_p = 3.89 \text{ kJ/kg} \cdot ^\circ\text{C}$  and the average rate of heat of respiration to be  $210 \text{ mW/kg}$ , determine the rate of heat removal from the strawberries and their boxes, in  $\text{kJ/h}$ . What would be the percent error involved if the strawberry boxes were ignored in calculations?

**17-45** Lettuce is to be vacuum cooled from the environment temperature of  $24^\circ\text{C}$  to a temperature of  $2^\circ\text{C}$  in 45 min in a 4-m outer diameter insulated spherical vacuum chamber whose walls consist of 3-cm-thick urethane insulation ( $k = 0.020 \text{ W/m} \cdot ^\circ\text{C}$ ) sandwiched between metal plates. The vacuum chamber contains

**FIGURE P17-45**

5000 kg of lettuce when loaded. Disregarding any heat transfer through the walls of the vacuum chamber, determine (a) the final pressure in the vacuum chamber and (b) the amount of moisture removed from the lettuce. It is claimed that the error involved in (b) due to neglecting heat transfer through the wall of the chamber is less than 2 percent. Is this a reasonable claim?

*Answers: (a) 0.714 kPa, (b) 179 kg*

**17-46** Spinach is to be vacuum cooled from the environment temperature of  $27^\circ\text{C}$  to a temperature of  $3^\circ\text{C}$  in 50 min in a 5-m outer diameter insulated spherical vacuum chamber whose walls consist of 2.5-cm-thick urethane insulation ( $k = 0.020 \text{ W/m} \cdot ^\circ\text{C}$ ) sandwiched between metal sheets. The vacuum chamber contains 6500 kg of spinach when loaded. Disregarding any heat transfer through the walls of the vacuum chamber, determine (a) the final pressure in the vacuum chamber and (b) the amount of moisture removed from the spinach in kg. It is claimed that the error involved in (b) due to neglecting heat transfer through the wall of the chamber is less than 2 percent. Is this a reasonable claim?

**FIGURE P17-46**

### Refrigeration of Meats, Poultry, and Fish

**17-47C** Why does a beef carcass lose up to 2 percent of its weight as it is cooled in the chilling room? How can this weight loss be minimized?

**17-48C** The cooling of a beef carcass from  $37^\circ\text{C}$  to  $5^\circ\text{C}$  with refrigerated air at  $0^\circ\text{C}$  in a chilling room takes about 48 h. To reduce the cooling time, it is proposed to cool the carcass with refrigerated air at  $-10^\circ\text{C}$ . How would you evaluate this proposal?

**17-49C** Consider the freezing of packaged meat in boxes with refrigerated air. How do (a) the temperature of air, (b) the velocity of air, (c) the capacity of the refrigeration system, and (d) the size of the meat boxes affect the freezing time?

**17-50C** How does the rate of freezing affect the tenderness, color, and the drip of meat during thawing?

**17-51C** It is claimed that beef can be stored for up to two years at  $-23^\circ\text{C}$  but no more than one year at  $-12^\circ\text{C}$ . Is this claim reasonable? Explain.

**17-52C** What is a refrigerated shipping dock? How does it reduce the refrigeration load of the cold storage rooms?

**17-53C** How does immersion chilling of poultry compare to forced-air chilling with respect to (a) cooling time, (b) moisture loss of poultry, and (c) microbial growth.

**17-54C** What is the proper storage temperature of frozen poultry? What are the primary methods of freezing for poultry?

**17-55C** What are the factors that affect the quality of frozen fish?

**17-56** The chilling room of a meat plant is  $15 \text{ m} \times 18 \text{ m} \times 5.5 \text{ m}$  in size and has a capacity of 350 beef carcasses. The power consumed by the fans and the lights in the chilling room are 22 and 2 kW, respectively, and the room gains heat through its envelope at a rate of 14 kW. The average mass of beef carcasses is 220 kg. The carcasses enter the chilling room at  $35^\circ\text{C}$ , after they are washed to facilitate evaporative cooling, and are cooled to  $16^\circ\text{C}$  in 12 h. The air enters the chilling room at  $-2.2^\circ\text{C}$  and leaves at  $0.5^\circ\text{C}$ . Determine (a) the refrigeration load of the chilling room and (b) the volume flow rate of air. The average specific heats of beef carcasses and air are 3.14 and  $1.0 \text{ kJ/kg} \cdot ^\circ\text{C}$ , respectively, and the density of air can be taken to be  $1.28 \text{ kg/m}^3$ .

**17-57** Turkeys with a water content of 64 percent that are initially at  $1^\circ\text{C}$  and have a mass of about 7 kg are to be frozen by submerging them into brine at  $-29^\circ\text{C}$ . Using Figure 17-31, determine how long it will take to reduce the temperature of the turkey breast at a depth of 3.8 cm to  $-18^\circ\text{C}$ . If the temperature at a depth of 3.8 cm in the breast represents the average temperature of the turkey, determine the amount of heat transfer per turkey assuming (a) the entire-water content of the turkey is frozen and (b) only 90 percent of the water content of the turkey is frozen at  $-18^\circ\text{C}$ . Take the specific heats of turkey to be 2.98 and  $1.65 \text{ kJ/kg} \cdot ^\circ\text{C}$  above and below the freezing point of  $-2.8^\circ\text{C}$ , respectively, and the latent heat of fusion of turkey to be 214 kJ/kg. *Answers: (a) 1753 kJ, (b) 1617 kJ*

FIGURE P17-57

**17-58E** Chickens with a water content of 74 percent, an initial temperature of  $32^\circ\text{F}$ , and a mass of about 7.5 lbm are to be frozen by refrigerated air at  $-40^\circ\text{F}$ . Using Fig. 17-30, determine how long it will take to reduce the inner surface temperature of chickens to  $25^\circ\text{F}$ . What would your answer be if the air temperature were  $-80^\circ\text{F}$ ?

**17-59** Chickens with an average mass of 2.2 kg and average specific heat of  $3.54 \text{ kJ/kg} \cdot ^\circ\text{C}$  are to be cooled by chilled water that enters a continuous flow-type immersion chiller at  $0.5^\circ\text{C}$ . Chickens are dropped into the chiller at a uniform temperature of  $15^\circ\text{C}$  at a rate of 500 chickens per hour and are cooled to an average temperature of  $3^\circ\text{C}$  before they are taken out. The chiller gains heat from the surroundings at a rate of 210 kJ/min. Determine (a) the rate of heat removal from the chicken, in kW, and (b) the mass flow rate of water, in kg/s, if the temperature rise of water is not to exceed  $2^\circ\text{C}$ .

**17-60** In a meat processing plant, 10-cm-thick beef slabs ( $\rho = 1090 \text{ kg/m}^3$ ,  $c_p = 3.54 \text{ kJ/kg} \cdot ^\circ\text{C}$ ,  $k = 0.47 \text{ W/m} \cdot ^\circ\text{C}$ , and  $\alpha = 0.13 \times 10^{-6} \text{ m}^2/\text{s}$ ) initially at  $15^\circ\text{C}$  are to be cooled in the racks of a large freezer that is maintained at  $-12^\circ\text{C}$ . The meat slabs are placed close to each other so that heat transfer from the 10-cm-thick edges is negligible. The entire slab is to be cooled below  $5^\circ\text{C}$ , but the temperature of the steak is not to drop below  $-1^\circ\text{C}$  anywhere during refrigeration to avoid "frost bite." The convection heat transfer coefficient and thus the rate of heat transfer from the steak can be controlled by varying the speed of a circulating fan inside. Using the transient temperature charts, determine the heat transfer coefficient  $h$  that will enable us to meet both temperature constraints while keeping the refrigeration time to a minimum. *Answer:  $9.9 \text{ W/m}^2 \cdot ^\circ\text{C}$*

FIGURE 17-60

### Refrigeration of Eggs, Milk, and Bakery Products

**17-61C** Why does a fresh egg settle at the bottom of a cup full of water while an old egg rises to the top?

**17-62C** What is standardization of milk? How is milk standardized?

**17-63C** Why and how is milk pasteurized? How can the pasteurization time be minimized? How does a regenerator reduce the energy cost of pasteurization?

**17-64C** What is the homogenization of milk? How is the milk homogenized?

**17-65C** Why is yeast usually stored between 1 and  $7^\circ\text{C}$ ? Why is the range of optimum dough temperature from 27 to  $38^\circ\text{C}$ ?

**17-66C** What is heat of hydration? How can the temperature rise of dough due to the heat of hydration be prevented during kneading?

**17-67** In a dairy plant, milk at  $4^\circ\text{C}$  is pasteurized continuously at  $72^\circ\text{C}$  at a rate of 12 L/s for 24 hours a day and 365 days a year. The milk is heated to the pasteurizing temperature

by hot water heated in a natural gas-fired boiler that has an efficiency of 82 percent. The pasteurized milk is then cooled by cold water at 18°C before it is finally refrigerated back to 4°C. To save energy and money, the plant installs a regenerator that has an effectiveness of 82 percent. If the cost of natural gas is \$1.05/therm (1 therm = 105,500 kJ), determine how much fuel and money the regenerator will save this company per year.

FIGURE P17-67

**17-68** A 1.5-kg box made of polypropylene ( $c_p = 1.9 \text{ kJ/kg} \cdot ^\circ\text{C}$ ) contains 30 loaves of white bread, each 0.45 kg, with a water content of 37.3 percent (by mass) at 20°C. The breads are to be frozen to an average temperature of  $-12^\circ\text{C}$  in 3 h in their box by refrigerated air. The enthalpy of bread is given to be 137 kJ/kg at 0°C and 56 kJ/kg at  $-12^\circ\text{C}$ . Taking the average specific heat of the bread above 0°C to be  $c_p = 2.60 \text{ kJ/kg} \cdot ^\circ\text{C}$ , determine (a) the total amount of heat that must be removed from a box of breads and (b) the average rate of heat removal from the breads and their box to the air per box.

**17-69** Eggs ( $\rho = 1.08 \text{ g/cm}^3$ ,  $k = 0.56 \text{ W/m} \cdot ^\circ\text{C}$ ,  $c_p = 3.34 \text{ kJ/kg} \cdot ^\circ\text{C}$ , and  $\alpha = 0.14 \times 10^{-6} \text{ m}^2/\text{s}$ ) with an average mass of 70 g and initially at a uniform temperature of  $32^\circ\text{C}$  are to be cooled by refrigerated air at  $2^\circ\text{C}$  flowing at a velocity of 3 m/s with an average heat transfer coefficient between the eggs and the air of  $45 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Determine how long it will take for the center temperature of the eggs to drop to  $12^\circ\text{C}$ . Also, determine the temperature difference between the center and the surface of the eggs and the amount of heat transfer per egg.

Answers: 26.7 min,  $5.6^\circ\text{C}$ , 5.50 kJ

FIGURE P17-69

**17-70E** A refrigeration system is being designed to cool eggs ( $\rho = 67.4 \text{ lbm/ft}^3$ ,  $k = 0.32 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ ,  $c_p = 0.80 \text{ Btu/lbm} \cdot ^\circ\text{F}$ , and  $\alpha = 1.5 \times 10^{-6} \text{ ft}^2/\text{s}$ ) with an average mass of 0.14 lbm from an initial temperature of  $90^\circ\text{F}$  to a final average temperature of  $50^\circ\text{F}$  by air at  $34^\circ\text{F}$  at a rate of 10,000 eggs per hour. Determine (a) the rate of heat removal from the eggs, in Btu/h, (b) the required volume flow rate of air, in  $\text{ft}^3/\text{h}$ ,

if the temperature rise of air is not to exceed  $10^\circ\text{F}$ , and (c) the size of the compressor of the refrigeration system, in kW, for a COP of 3.5 for the refrigeration system.

**17-71** The heat of hydration of dough,  $15 \text{ kJ/kg}$ , will raise the dough's temperature to undesirable levels unless some cooling mechanism is utilized. A practical way of absorbing the heat of hydration is to use refrigerated water when kneading the dough. If a recipe calls for mixing 2 kg of flour with 1 kg of water, and the temperature of the city water is  $15^\circ\text{C}$ , determine the temperature to which the city water must be cooled before mixing it with flour in order for the water to absorb the entire heat of absorption when the water temperature rises to  $15^\circ\text{C}$ . Take the specific heats of the flour and the water to be  $1.76$  and  $4.18 \text{ kJ/kg} \cdot ^\circ\text{C}$ , respectively. *Answer:  $4.2^\circ\text{C}$*

FIGURE P17-71

### Refrigeration Load of Cold Storage Rooms

**17-72C** What does the refrigeration load of a cold storage room represent? What does the refrigeration load consist of?

**17-73C** Define the transmission load of a cold storage room, and explain how it is determined. Discuss how the transmission load can be minimized.

**17-74C** What is infiltration heat gain for cold storage rooms? How can it be minimized?

**17-75C** Define the product load of a frozen food storage room, and explain how it is determined.

**17-76C** Define the internal load of a refrigeration room. Name the factors that constitute the internal load.

**17-77C** Consider the motors that power the fans of a refrigerated room. How does locating the motors inside the refrigeration room or outside of it affect the refrigeration load of the room?

**17-78** A supply of 40 kg of shrimp at  $8^\circ\text{C}$  contained in a box is to be frozen to  $-18^\circ\text{C}$  in a freezer. Determine the amount of heat that needs to be removed. The latent heat of the shrimp is 277 kJ/kg, and its specific heat is  $3.62 \text{ kJ/kg} \cdot ^\circ\text{C}$  above freezing and  $1.89 \text{ kJ/kg} \cdot ^\circ\text{C}$  below freezing. The container box is 1.2 kg and is made up of polyethylene, whose specific heat is  $2.3 \text{ kJ/kg} \cdot ^\circ\text{C}$ . Also, the freezing temperature of shrimp is  $-2.2^\circ\text{C}$ .

FIGURE P17-78

**17-79E** A cold storage room whose internal dimensions are  $12 \text{ ft} \times 15 \text{ ft} \times 30 \text{ ft}$  is maintained at  $35^\circ\text{F}$  and 95 percent relative humidity. Under worst conditions, the amount of air infiltration is estimated to be 0.4 air change per hour at the ambient conditions of  $90^\circ\text{F}$  and 90 percent relative humidity. Using the psychrometric chart, determine the total infiltration load of this room under these conditions. *Answer: 92,940 Btu/h*

**17-80** A holding freezer whose outer dimensions are  $80 \text{ m} \times 25 \text{ m} \times 7 \text{ m}$  is maintained at  $-25^\circ\text{C}$  at a location where the annual mean ambient temperature is  $15^\circ\text{C}$ . The construction of the walls is such that it has an  $R$ -value of  $3 \text{ m}^2 \cdot ^\circ\text{C/W}$  (equivalent to  $R-17$  in English units of  $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ ), which is well below the recommended value of  $R-6.5$ . The refrigeration system has a COP of 1.3, and the cost of electricity is  $\$0.10/\text{kWh}$ . Taking the heat transfer coefficients on the inner and outer surfaces of the walls to be 10 and  $20 \text{ W/m}^2 \cdot ^\circ\text{C}$ , respectively, determine the amount of electrical energy and money this facility will save per year by increasing the insulation value of the walls to the recommended level of  $R-6.5$ . Assume continuous operation for the entire year. What is the percent error involved in the total thermal resistance of the wall in neglecting the convection resistances on both sides?

**17-81** A chilling room whose outer dimensions are  $60 \text{ m} \times 30 \text{ m} \times 6 \text{ m}$  is maintained at  $-2^\circ\text{C}$  at a location where the annual mean ambient temperature is  $18^\circ\text{C}$ . The construction of the roof of the room is such that it has an  $R$ -value of  $2 \text{ m}^2 \cdot ^\circ\text{C/W}$  (equivalent to  $R-11.4$  in English units of  $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ ), which is well below the recommended value of  $R-7$ . The refrigeration system has a COP of 2.4, and the cost of electricity is  $\$0.09/\text{kWh}$ . Taking the heat transfer coefficients on the inner and outer surfaces of the walls to be 10 and  $25 \text{ W/m}^2 \cdot ^\circ\text{C}$ , respectively, determine the amount of electrical energy and money this facility will save per year by increasing the insulation value of the walls to the recommended level of  $R-7$ .

*Answers: 42,997 kWh/yr, \\$3870/yr*

**17-82** A cold storage room whose inner dimensions are  $50 \text{ m} \times 30 \text{ m} \times 7 \text{ m}$  is maintained at  $6^\circ\text{C}$ . At any given time, 15 people are working in the room, and lighting for the facility

FIGURE P17-81

is provided by 150 light bulbs, each consuming 100 W. There are also several electric motors in the facility that consume a total of 25 kW of electricity. It is estimated that the ambient air that enters the room through the cracks and openings is equivalent to 0.2 air change per hour. Taking the ambient air temperature to be  $20^\circ\text{C}$  and disregarding any condensation of moisture, determine (a) the internal load of this cold storage room and (b) the infiltration load, both in kW.

In order to save energy, it is proposed that the incandescent lights be replaced by 40 high-efficiency fluorescent tubes, each consuming 110 W. If the lights are on for an average of 15 h a day, every day, determine the amount of electrical energy and money this facility will save per year as a result of switching to fluorescent lighting. Assume the refrigeration system has a COP of 2.8, and the cost of electricity is  $\$0.09/\text{kWh}$ .

FIGURE P17-82

### Transportation of Refrigerated Foods

**17-83C** Why are the refrigerated trucks insulated? What are the advantages and disadvantages of having a very thick layer of insulation in the walls of a refrigerated truck?

**17-84C** Under what conditions is it worthwhile to transport food items by airplanes?

**17-85C** Why are the trucks precooled before they are loaded? Also, do refrigerated trucks need to be equipped with heating systems? Why? Explain.

**17-86C** A truck driver claims to have transported orange juice from Florida to New York in warm weather without any refrigeration, and that the temperature of the orange juice rose by only  $4^{\circ}\text{C}$  during this long trip. Is this claim reasonable?

**17-87E** Orange juice ( $\rho = 62.4 \text{ lbm/ft}^3$  and  $c_p = 0.90 \text{ Btu/lbm} \cdot ^{\circ}\text{F}$ ) is to be transported from Florida to New York for a distance of 1250 miles in a 27-ft-long, 6.3-ft-external-diameter cylindrical tank. The walls of the tank are constructed of 1-in-thick urethane insulation ( $k = 0.017 \text{ Btu/h} \cdot \text{ft} \cdot ^{\circ}\text{F}$ ) sandwiched between two metal sheets. The juice is precooled to  $35^{\circ}\text{F}$  before loading, and its temperature is not to exceed  $46^{\circ}\text{F}$  on arrival. The average ambient temperature can be as high as  $92^{\circ}\text{F}$ , and the effect of solar radiation and the radiation from hot pavement surfaces can be taken to be equivalent to a  $12^{\circ}\text{F}$  rise in ambient temperature. If the average velocity during transportation is 35 mph, determine if the orange juice can be transported without any refrigeration.

FIGURE P17-87E

**17-88** A large truck is to transport 30,000 kg of oranges precooled to  $4^{\circ}\text{C}$  under average ambient conditions of  $27^{\circ}\text{C}$  and 90 percent relative humidity, which corresponds to a humidity ratio of 0.0205 kg water vapor/kg dry air. The structure of the walls of the truck is such that the rate of heat transmission is  $UA = 80 \text{ W per } ^{\circ}\text{C}$  temperature difference between the ambient

FIGURE P17-88

and the oranges. From past experience, ambient air is estimated to enter the cargo space of the truck through the cracks at a rate of 4 L/s. The moisture in the air is condensed out at an average temperature of  $15^{\circ}\text{C}$ , at which the latent heat of vaporization of water is  $2466 \text{ kJ/kg}$ . Also, the average heat of respiration of the oranges at  $4^{\circ}\text{C}$  is  $0.017 \text{ W/kg}$  for this particular load. Taking the density of air to be  $1.15 \text{ kg/m}^3$ , determine the refrigeration load of this truck and the amount of ice needed to meet the entire refrigeration need of the truck for a 15-h-long trip.

**17-89** Consider a large freezer truck whose outer dimensions are  $14 \text{ m} \times 2.5 \text{ m} \times 4 \text{ m}$  that is maintained at  $-18^{\circ}\text{C}$  at a location where the ambient temperature is  $25^{\circ}\text{C}$ . The walls of the truck are constructed of 2.5-cm-thick urethane insulation ( $k = 0.026 \text{ W/m} \cdot ^{\circ}\text{C}$ ) sandwiched between thin metal plates. The recommended minimum thickness of insulation in this case is 8 cm. Taking the heat transfer coefficients on the inner and outer surfaces of the walls to be 8 and  $4 \text{ W/m}^2 \cdot ^{\circ}\text{C}$ , respectively, determine the reduction in the transmission part of the refrigeration load if the insulation thickness is upgraded to the recommended value. Also, taking the gross density of the load to be  $600 \text{ kg/m}^3$ , determine the reduction in the cargo load of the truck, in kg, as a result of increasing the thickness of insulation while holding the outer dimensions constant.

**17-90** The cargo space of a refrigerated truck whose inner dimensions are  $12 \text{ m} \times 2.3 \text{ m} \times 3.5 \text{ m}$  is to be precooled from  $25^{\circ}\text{C}$  to an average temperature of  $5^{\circ}\text{C}$ . The construction of the truck is such that a transmission heat gain occurs at a rate of  $80 \text{ W/}^{\circ}\text{C}$ . If the ambient temperature is  $25^{\circ}\text{C}$ , determine how long it will take for a system with a refrigeration capacity of 8 kW to precool this truck. Take the density of air to be  $1.20 \text{ kg/m}^3$ . *Answer: 5.4 min*

FIGURE P17-90

### Review Problems

**17-91** Wet broccoli is to be vacuum cooled from the environment temperature of  $25^{\circ}\text{C}$  to a temperature of  $4^{\circ}\text{C}$  in 1 h in a 4-m outer diameter insulated spherical vacuum chamber whose walls consist of 3-cm-thick fiberglass insulation ( $k = 0.026 \text{ W/m} \cdot ^{\circ}\text{C}$ ) sandwiched between metal plates. The vacuum chamber contains 6000 kg of broccoli when loaded, but 2 percent of this mass is due to water that sticks to the surface of the broccoli during wetting. Disregarding any heat transfer through the walls of the vacuum chamber, determine the final mass of the broccoli after cooling. It is claimed that the error involved in the predicted final mass of broccoli due to

neglecting heat transfer through the wall of the chamber is less than 5 percent. Is this a reasonable claim?

**Answer:** 5801 kg

FIGURE P17-91

**17-92** Red Delicious apples of 65-mm diameter and 85 percent water content ( $k = 0.42 \text{ W/m} \cdot ^\circ\text{C}$  and  $\alpha = 0.14 \times 10^{-6} \text{ m}^2/\text{s}$ ) initially at a uniform temperature of 22°C are to be cooled by (a) refrigerated air at 1°C flowing at a velocity of 1.5 m/s with an average heat transfer coefficient of 45 W/m<sup>2</sup> · °C between the apples and the air and (b) chilled water at 1°C flowing at a velocity of 0.3 m/s with an average heat transfer coefficient of 80 W/m<sup>2</sup> · °C between the apples and the water. Determine how long it will take for the center temperature of the apples to drop to 8°C and the temperature difference between the center and the surface of the apples for each case.

**17-93E** A 3.5-lbm box made of polypropylene ( $c_p = 0.45 \text{ Btu/lbm} \cdot ^\circ\text{F}$ ) contains 70 lbm of haddock fish with a water content of 83.6 percent (by mass) at 60°F. The fish is to be frozen to an average temperature of -4°F in 4 h in its box. The enthalpy of the fish is given to be 145 Btu/lbm at 32°F and 18 Btu/lbm at -4°F. It is also given that the unfrozen water content of the fish at -4°F is 9 percent. Taking the average specific heat of the fish

FIGURE P17-93

above freezing temperatures to be  $c_p = 0.89 \text{ Btu/lbm} \cdot ^\circ\text{F}$ , determine (a) the total amount of heat that must be removed from the fish, (b) the amount of unfrozen water in fish at -4°F, and (c) the average rate of heat removal from the fish.

**17-94** Fresh carrots with a water content of 87.5 percent (by mass) at 22°C are stored in 1.4-kg boxes made of polyethylene ( $c_p = 2.3 \text{ kJ/kg} \cdot ^\circ\text{C}$ ). Each box contains 30 kg of carrots, and the carrots are to be frozen to an average temperature of -18°C at a rate of 50 boxes per hour. The enthalpy of the carrots is given to be 361 kJ/kg at 0°C and 51 kJ/kg at -18°C. It is also given that the unfrozen water content of the carrots at -18°C is 7 percent. Taking the average specific heat of the carrots above freezing temperatures to be  $c_p = 3.90 \text{ kJ/kg} \cdot ^\circ\text{C}$ , determine (a) the rate of heat removal from the carrots and their boxes, and (b) the rate at which the water in carrots freezes during this process. **Answers:** (a) 166.7 kW, (b) 0.336 kg/s

**17-95** The chilling room of a meat plant is 15 m × 18 m × 5.5 m in size and has a capacity of 350 beef carcasses. The power consumed by the fans and the lights of the chilling room are 22 and 2 kW, respectively, and the room gains heat through its envelope at a rate of 11 kW. The average mass of beef carcasses is 280 kg. The carcasses enter the chilling room at 35°C, after they are washed to facilitate evaporative cooling, and are cooled to 16°C in 10 h. The water is expected to evaporate at a rate of 0.080 kg/s. The air enters the evaporator section of the refrigeration system at 0.5°C and leaves at -2.2°C. The air side of the evaporator is heavily finned, and the overall heat transfer coefficient of the evaporator based on the air side is 22 W/m<sup>2</sup> · °C. Also, the average temperature difference between the air and the refrigerant in the evaporator is 5.5°C. Determine (a) the refrigeration load of the chilling room, (b) the volume flow rate of air, and (c) the heat transfer surface area of the evaporator on the air side, assuming all the vapor and the fog in the air freeze

FIGURE P17-95

in the evaporator. The average specific heats of beef carcasses and air are 3.14 and  $1.0 \text{ kJ/kg} \cdot ^\circ\text{C}$ , respectively. Also, the heat of fusion of water is  $334 \text{ kJ/kg}$  and the heat of vaporization of water and the density of air can be taken to be  $2490 \text{ kJ/kg}$  and  $1.28 \text{ kg/m}^3$ , respectively.

**17-96** Turkeys with an average mass of  $7.5 \text{ kg}$  and average specific heat of  $3.28 \text{ kJ/kg} \cdot ^\circ\text{C}$  are to be cooled by chilled water that enters a continuous flow-type immersion chiller at  $0.6^\circ\text{C}$ . Turkeys are dropped into the chiller at a uniform temperature of  $14^\circ\text{C}$  at a rate of 200 turkeys per hour and are cooled to an average temperature of  $4^\circ\text{C}$  before they are taken out. The chiller gains heat from the surroundings at a rate of  $120 \text{ kJ/h}$ . Determine (a) the rate of heat removal from the turkeys, in kW, and (b) the mass flow rate of water, in kg/s, if the temperature rise of water is not to exceed  $2.5^\circ\text{C}$ .

**17-97E** In a chicken processing plant, whole chickens ( $\rho = 65.5 \text{ lbm/ft}^3$ ,  $c_p = 0.85 \text{ Btu/lbm} \cdot ^\circ\text{F}$ ,  $k = 0.27 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ , and  $\alpha = 1.4 \times 10^{-6} \text{ ft}^2/\text{s}$ ) averaging five pounds each and initially at  $60^\circ\text{F}$  are to be cooled in the racks of a large refrigerator that is maintained at  $5^\circ\text{F}$ . The entire chicken is to be cooled below  $40^\circ\text{F}$ , but the temperature of the chicken is not to drop below  $33^\circ\text{F}$  anywhere during refrigeration. The convection heat transfer coefficient and thus the rate of heat transfer from the chicken can be controlled by varying the speed of a circulating fan inside. Treating the chicken as a homogeneous spherical object, determine the heat transfer coefficient that will enable us to meet both temperature constraints while keeping the refrigeration time to a minimum.

FIGURE P17-97E

**17-98** A person puts a few peaches ( $\rho = 960 \text{ kg/m}^3$ ,  $c_p = 3.9 \text{ kJ/kg} \cdot ^\circ\text{C}$ ,  $k = 0.53 \text{ W/m} \cdot ^\circ\text{C}$ , and  $\alpha = 0.14 \times 10^{-6} \text{ m}^2/\text{s}$ ) into the freezer at  $-18^\circ\text{C}$  to cool them quickly for the guests who are about to arrive. Initially, the peaches are at

a uniform temperature of  $20^\circ\text{C}$ , and the heat transfer coefficient on the surfaces is  $18 \text{ W/m}^2 \cdot ^\circ\text{C}$ . Treating the peaches as 8-cm-diameter spheres, determine the center and surface temperatures of the peaches in 45 minutes. Also, determine the amount of heat transfer from each peach.

Answers:  $7.2^\circ\text{C}$ ,  $-3.7^\circ\text{C}$ ,  $19.7 \text{ kJ}$

**17-99** A refrigeration system is to cool bread loaves with an average mass of  $450 \text{ g}$  from  $22^\circ\text{C}$  to  $-10^\circ\text{C}$  at a rate of 500 loaves per hour by refrigerated air at  $-30^\circ\text{C}$  and 1 atm. Taking the average specific and latent heats of bread to be  $2.93 \text{ kJ/kg} \cdot ^\circ\text{C}$  and  $109.3 \text{ kJ/kg}$ , respectively, determine (a) the rate of heat removal from the breads, in  $\text{kJ/h}$ , (b) the required volume flow rate of air, in  $\text{m}^3/\text{h}$ , if the temperature rise of air is not to exceed  $8^\circ\text{C}$ , and (c) the size of the compressor of the refrigeration system, in  $\text{kW}$ , for a COP of 1.2 for the refrigeration system.

FIGURE P17-99

**17-100** A holding freezer whose outer dimensions are  $70 \text{ m} \times 22 \text{ m} \times 6 \text{ m}$  is maintained at  $-23^\circ\text{C}$  at a location where the annual mean ambient temperature is  $14^\circ\text{C}$ . The construction of the roof is such that it has an  $R$ -value of  $4 \text{ m}^2 \cdot ^\circ\text{C/W}$  (equivalent to  $R-23$  in English units of  $\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F/Btu}$ ), which is well below the recommended value of  $R-8.5$ . The refrigeration system has a COP of 1.25, and the cost of electricity is  $\$0.07/\text{kWh}$ . Taking the heat transfer coefficients on the inner and outer surfaces of the walls to be  $12$  and  $30 \text{ W/m}^2 \cdot ^\circ\text{C}$ , respectively, determine the amount of electrical energy and money this facility will save per year by increasing the insulation value of the walls to the recommended level of  $R-8.5$ . What is the percent error involved in the total thermal resistance of the roof in neglecting the convection resistances on both sides? Answers:  $50,650 \text{ kWh/yr}$ ,  $\$3546/\text{yr}$ , 2.9 percent

**17-101** Milk is to be transported from Wyoming to Chicago for a distance of 1600 km in an 8-m-long, 2.2-m-external-diameter cylindrical tank. The walls of the tank are constructed of 3-cm-thick urethane insulation ( $k = 0.029 \text{ W/m} \cdot ^\circ\text{C}$ ) sandwiched between two metal sheets. The milk is precooled to  $2^\circ\text{C}$  before loading, and its temperature is not to exceed  $5^\circ\text{C}$  on arrival. The average ambient temperature can be as high as  $32^\circ\text{C}$ , and the effect of solar radiation and the radiation from hot pavement surfaces can be taken to be equivalent to a  $5^\circ\text{C}$  rise in ambient temperature. If the average velocity during

transportation is 60 km/h, determine if the milk can be transported without any refrigeration.

**FIGURE P17-101**

### Computer, Design, and Essay Problems

**17-102** Write an essay on the operating principle of thermoelectric refrigerators, and discuss their advantages and disadvantages.

**17-103** Using a thermometer, measure the temperature of the main food compartment of your refrigerator, and check if it is between 1 and 4°C. Also, measure the temperature of the freezer compartment, and check if it is at the recommended value of -18°C.

**17-104** Using a timer (or watch) and a thermometer, conduct the following experiment to determine the predictable heat load of your refrigerator. First, make sure that the door of the refrigerator is not opened for at least a few hours to make sure that steady operating conditions are established. Start the timer when the refrigerator stops running and measure the time  $\Delta t_1$  it stays off before it kicks in. Then measure the time  $\Delta t_2$  it stays on. Noting that the heat removed during  $\Delta t_2$  is equal to the heat gain of the refrigerator during  $\Delta t_1 + \Delta t_2$  and using the power consumed by the refrigerator when it is running, determine the average rate of heat gain for your refrigerator, in W. Take the COP (coefficient of performance) of your refrigerator to be 1.3 if it is not available.

Now, clean the condenser coils of the refrigerator and remove any obstacles on the way of airflow through the coils. By repeating the measurements above, determine the improvement in the COP of the refrigerator.

**17-105** Design a hydrocooling unit that can cool fruits and vegetables from 30°C to 5°C at a rate of 20,000 kg/h under the following conditions:

The unit will be of flood type that will cool the products as they are conveyed into the channel filled with water. The products will be dropped into the channel filled with water at one

end and picked up at the other end. The channel can be as wide as 3 m and as high as 90 cm. The water is to be circulated and cooled by the evaporator section of a refrigeration system. The refrigerant temperature inside the coils is to be -2°C, and the water temperature is not to drop below 1°C and not to exceed 6°C.

Assuming reasonable values for the average product density, specific heat, and porosity (the fraction of air volume in a box), recommend reasonable values for the quantities related to the thermal aspects of the hydro-cooler, including (a) how long the fruits and vegetables need to remain in the channel, (b) the length of the channel, (c) the water velocity through the channel, (d) the velocity of the conveyor and thus the fruits and vegetables through the channel, (e) the refrigeration capacity of the refrigeration system, and (f) the type of heat exchanger for the evaporator and the surface area on the water side.

**17-106** Design a scalding unit for slaughtered chicken to loosen their feathers before they are routed to feather-picking machines with a capacity of 1200 chickens per hour under the following conditions:

The unit will be of immersion type filled with hot water at an average temperature of 53°C at all times. Chicken with an average mass of 2.2 kg and an average temperature of 36°C will be dipped into the tank, held in the water for 1.5 min, and taken out by a slow-moving conveyor. The chicken is expected to leave the tank 15 percent heavier as a result of the water that sticks to its surface. The center-to-center distance between chickens in any direction will be at least 30 cm. The tank can be as wide as 3 m and as high as 60 cm. The water is to be circulated through and heated by a natural gas furnace, but the temperature rise of water will not exceed 5°C as it passes through the furnace. The water loss is to be made up by the city water at an average temperature of 16°C. The ambient air temperature can be taken to be 20°C. The walls and the floor of the tank are to be insulated with a 2.5-cm-thick urethane layer. The unit operates 24 h a day and 6 days a week.

Assuming reasonable values for the average properties, recommend reasonable values for the quantities related to the thermal aspects of the scalding tank, including (a) the mass flow rate of the make-up water that must be supplied to the tank, (b) the length of the tank, (c) the rate of heat transfer from the water to the chicken, in kW, (d) the velocity of the conveyor and thus the chickens through the tank, (e) the rate of heat loss from the exposed surfaces of the tank and if it is significant, (f) the size of the heating system in kJ/h, (g) the type of heat exchanger for heating the water with flue gases of the furnace and the surface area on the water side, and (h) the operating cost of the scalding unit per month for a unit cost of \$1.10 therm of natural gas (1 therm = 105,000 kJ).

**17-107** A company owns a refrigeration system whose refrigeration capacity is 200 tons (1 ton of refrigeration = 211 kJ/min), and you are to design a forced-air cooling system

for fruits whose diameters do not exceed 7 cm under the following conditions:

The fruits are to be cooled from 28°C to an average temperature of 8°C. The air temperature is to remain above –2°C and below 10°C at all times, and the velocity of air approaching the fruits must remain under 2 m/s. The cooling section can be as wide as 3.5 m and as high as 2 m.

Assuming reasonable values for the average fruit density, specific heat, and porosity (the fraction of air volume in a box),

recommend reasonable values for the quantities related to the thermal aspects of the forced-air cooling, including (a) how long the fruits need to remain in the cooling section, (b) the length of the cooling section, (c) the air velocity approaching the cooling section, (d) the product cooling capacity of the system, in kg · fruit/h, (e) the volume flow rate of air, and (f) the type of heat exchanger for the evaporator and the surface area on the air side.
